The expected signal and backgrounds, with the exception of the QCD component, are evaluated with simulated samples and rescaled using the most precise available cross section predictions. The $Z^{\prime}, G^{*}$ signal, and $Z / \gamma^{*}$ processes are generated with PYTHIA 6.421 [25] using MRST2007 LO* [26] parton distribution functions (PDFs). Interference between the $Z / \gamma^{*}$ processes and the heavy resonances is small and therefore neglected. The diboson processes are generated with HERWIG 6.510 [27] using MRST2007 LO* PDFs. The $W+$ jets background is generated with ALPGEN [28] using CTEQ6L1 [29] PDFs and the $t \bar{t}$ background with MC@NLO 3.41 [30] using CTEQ66 [31]

FIG. 1 (color online). Dielectron (top) and dimuon (bottom) invariant mass ( $m_{\ell \ell}$ ) distribution after final selection, compared to the stacked sum of all expected backgrounds, with three example $Z_{\text {SSM }}^{\prime}$ signals overlaid. The bin width is constant in $\log m_{\ell \ell}$.

TABLE I. Expected and observed number of events in the dielectron (top) and dimuon (bottom) channels. The first bin is used to normalize the total background to the data. The errors quoted include both statistical and systematic uncertainties, except the error on the total background in the normalization region which is given by the square root of the number of observed events. The systematic uncertainties are correlated across bins and are discussed in the text.

PDFs. For both, JIMMY 4.31 [32] is used to describe multiple parton interactions and HERWIG to describe the remaining underlying event and parton showers. Final-state photon radiation is handled with PHOTOS [33]. The samples are processed through a full ATLAS detector simulation [34] based on GEANT4 [35].

The $Z / \gamma^{*}$ cross section is calculated at next-to-next-toleading order (NNLO) using PHOZPR [36] with MSTW2008 PDFs [37]. The ratio of this cross section to the leadingorder cross section is used to determine a mass-dependent QCD $K$ factor which is applied to the results of the leadingorder simulations. The same QCD $K$ factor is applied to the $Z^{\prime}$ signal. No QCD $K$ factor is available for $G^{*}$ production at $7 \mathrm{TeV}[38,39]$. Higher-order weak corrections (beyond the photon radiation included in the simulation) are calculated using HORACE $[40,41]$, yielding a weak $K$ factor due to virtual heavy gauge boson loops. The weak $K$ factor is only applied to the Drell-Yan background. The diboson cross sections are calculated to next-to-leading order (NLO) using MCFM [42] with an uncertainty of $5 \%$. The $W+$ jets cross section is rescaled to the inclusive NNLO
calculation of FEWZ [43], resulting in 30\% uncertainty when at least one parton with $E_{T}>20 \mathrm{GeV}$ accompanies the $W$ boson. The $t \bar{t}$ cross section is predicted at approximate NNLO, with $10 \%$ uncertainty [44,45].

The QCD background in the $e^{+} e^{-}$sample is estimated with data using "reversed electron identification" and "isolation fit" techniques [14], and a third method that uses fake rates measured from inclusive jet samples. In the reversed electron identification technique, data with both electron candidates failing some identification criteria (chosen not to affect kinematic distributions) are used to determine the QCD background distribution versus $m_{e e}$. This method is used for the central estimate and the others which bracket it, to assign a systematic uncertainty. The QCD background in the $\mu^{+} \mu^{-}$sample is evaluated from data using the muon isolation variable $\Sigma p_{T}(\Delta R<0.3) / p_{T}$ [14]. The QCD and $W+$ jets backgrounds are small (negligible) for the electron (muon) channel. Backgrounds from cosmic rays are negligible.

The observed invariant mass distributions are compared to the SM expectation. For this purpose, the Drell-Yan, $t \bar{t}$,

TABLE II. Summary of the dominant systematic uncertainties on the expected signal and background yields at $m_{\ell^{+} \ell^{-}}=1.5 \mathrm{TeV}$ for the $Z^{\prime}\left(G^{*}\right)$ analysis.

| Source | Dielectrons |  | Dimuons |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Signal | Background | Signal | Background |
| Normalization | $5 \%$ | Not applicable | $5 \%$ | Not applicable |
| PDFs $/ \alpha_{S}$ | Not applicable | $10 \%$ | Not applicable | $10 \%$ |
| QCD $K$ factor | Not applicable | $3 \%$ | Not applicable | $3 \%$ |
| Weak $K$ factor | Not applicable | $4.5 \%$ | Not applicable | $4.5 \%$ |
| Trigger/reconstruction | Negligible | Negligible | $4.5 \%$ | $4.5 \%$ |
| Total | $5 \%$ | $11 \%$ | $7 \%$ | $12 \%$ |

diboson and $W+$ jets backgrounds from Monte Carlo simulation are scaled according to their respective cross sections and added to the QCD background. The simulated backgrounds are then rescaled so that the sum matches the observed number of data events in the $70-110 \mathrm{GeV}$ mass interval. The scaling factor is within $1 \%$ of unity. The advantage of this approach is that the uncertainty on the luminosity, and any mass independent uncertainties on efficiencies, cancel between the $Z^{\prime}\left(G^{*}\right)$ and the $Z$ boson.

Figure 1 presents the invariant mass ( $m_{\ell \ell}$ ) distribution for the dielectron (top) and dimuon (bottom) final states after final selection, while Table I shows the number of data events and the estimated backgrounds in bins of reconstructed $m_{\ell \ell}$. The dilepton invariant mass distributions are well described by the prediction from SM processes. Figure 1 also displays the expected $Z_{\text {SSM }}^{\prime}$ signal for three mass hypotheses.

The invariant mass distribution of the data is compared to the backgrounds and signal templates with pole masses in the $0.13-2.0 \mathrm{TeV}$ range $[14,46]$. A likelihood function is

FIG. 2 (color online). Expected and observed 95\% C.L. upper limits on $\sigma B$ as a function of mass for $Z^{\prime}$ (top) and $G^{*}$ (bottom) models. Both results show the combination of the electron and muon channels. The thickness of the $Z_{\text {SSM }}^{\prime}$ (top) and the $G^{*}$ for $k / \bar{M}_{\mathrm{Pl}}=0.1$ (bottom) theory curves illustrate the theoretical uncertainties.
defined as the product of the Poisson probabilities over all mass bins in the search region. The Poisson probability in each bin is evaluated for the observed number of data events given the background and signal template expectation. The total signal acceptance as a function of mass is propagated into the expectation.

The significance of a signal is summarized by a $p$ value, the probability of observing an excess at least as signal-like as the one observed in data, in the absence of signal. The outcome of the search is ranked using a likelihood ratio, which is scanned as a function of $Z^{\prime}$ cross section and $m_{Z^{\prime}}$ over the full considered mass range. The data are consistent with the SM hypothesis, with $p$ values of $54 \%$ and $24 \%$ for the $e^{+} e^{-}$and $\mu^{+} \mu^{-}$channels, respectively.

Given the absence of a signal, an upper limit on the signal cross section is determined at the $95 \%$ C.L. using a Bayesian approach [47] with a flat, positive prior on the signal cross section.

Mass-dependent systematic uncertainties are incorporated as nuisance parameters which are integrated out [47]. They include normalization to the $Z$ peak, PDF, QCD, and weak $K$ factors, as well as trigger, reconstruction, and identification efficiencies. These uncertainties are correlated across all bins in the search region and they are correlated between signal and background.

Since the total background is normalized to the data in the region of the $Z \rightarrow \ell^{+} \ell^{-}$mass peak, the residual systematic uncertainties are small at the $Z$ pole and grow at higher mass. The dominant uncertainties are theoretical. The overall uncertainty due to PDF and $\alpha_{S}$ variations is estimated to be $10 \%$ at 1.5 TeV using the MSTW 2008 eigenvector PDF sets and other PDF sets corresponding to variations of $\alpha_{S}$. The difference with respect to CTEQ is included as an additional 3\% uncertainty. The uncertainty on the QCD $K$ factor is $3 \%$, evaluated from variations of the renormalization and factorization scales by factors of two around the nominal values. A systematic uncertainty of $4.5 \%$ is attributed to electroweak corrections [14]. The uncertainty on the $Z / \gamma^{*}$ cross section is $5 \%$, which is applied as a systematic uncertainty on the normalization.

Experimental systematic effects due to resolution and inefficiencies at high mass were studied. In the electron channel, the calorimeter energy resolution is dominated at large $E_{T}$ by a constant term which is $1.2 \%$ in the barrel and $1.8 \%$ in the end caps, with negligible uncertainty. The uncertainty on the resolution in the muon channel is due to residual misalignments and intrinsic position uncertainties in the muon spectrometer that propagate to a change in

TABLE III. Observed (expected) 95\% C.L. mass lower limits in TeV on $Z_{\mathrm{SSM}}^{\prime}$ resonance and $G^{*}$ graviton (with $k / \bar{M}_{\mathrm{PI}}=0.1$ ).

| Model | $e^{+} e^{-}$ | $\mu^{+} \mu^{-}$ | $\ell^{+} \ell^{-}$ |
| :--- | :---: | :---: | :---: |
| $Z_{\mathrm{SSM}}^{\prime}$ | $1.70(1.70)$ | $1.61(1.61)$ | $1.83(1.83)$ |
| $G^{*}$ | $1.51(1.50)$ | $1.45(1.44)$ | $1.63(1.63)$ |

TABLE IV. $\quad 95 \%$ C.L. lower limits on the masses of $E_{6}$-motivated $Z^{\prime}$ bosons and RS gravitons $G^{*}$ for various values of the coupling $k / \bar{M}_{\mathrm{Pl}}$. Both lepton channels are combined.

|  | $E_{6} Z^{\prime}$ models |  |  |  |  |  | RS graviton |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Model/coupling | $Z_{\psi}^{\prime}$ | $Z_{N}^{\prime}$ | $Z_{\eta}^{\prime}$ | $Z_{I}^{\prime}$ | $Z_{S}^{\prime}$ | $Z_{\chi}^{\prime}$ | 0.01 | 0.03 | 0.05 | 0.1 |
| Mass limit [TeV] | 1.49 | 1.52 | 1.54 | 1.56 | 1.60 | 1.64 | 0.71 | 1.03 | 1.33 | 1.63 |

the observed width of the $Z^{\prime}\left(G^{*}\right)$ line shape. The simulation was adjusted to reproduce the data at high muon momentum. The residual uncertainty translates into an event yield uncertainty of less than $1.5 \%$. The combined uncertainty on the muon trigger and reconstruction efficiency is estimated to be $4.5 \%$ at 1.5 TeV . This uncertainty is dominated by a conservative estimate of the impact of large energy loss from muon bremsstrahlung in the calorimeter on the muon reconstruction performance in the muon spectrometer. In the electron channel, a systematic uncertainty of $1.5 \%$ at 1.5 TeV is estimated for a possible identification inefficiency caused by the isolation requirement.

The dominant systematic uncertainties are summarized in Table II. Uncertainties below 3\% are neglected, and no theory uncertainties are applied to the $Z^{\prime}$ or $G^{*}$ signal in the limit setting procedure described below.

The limit on the number of produced $Z^{\prime}\left(G^{*}\right)$ events is converted into a limit on cross section times branching fraction $\sigma B$ by scaling with the observed number of $Z$ boson events and the theoretical value of $\sigma B(Z \rightarrow l l)$. The expected exclusion limits are determined using simulated pseudoexperiments containing only standard model processes, by evaluating the $95 \%$ C.L. upper limits for each pseudoexperiment for each fixed value of $m_{Z^{\prime}}\left(m_{G^{*}}\right)$. The median of the distribution of limits represents the expected limit. The ensemble of limits is used to find the $68 \%$ and $95 \%$ envelopes of the expected limits as a function of $m_{Z^{\prime}}$ $\left(m_{G^{*}}\right)$. Figure 2 (top) shows the combined dielectron and dimuon $95 \%$ C.L. observed and expected exclusion limits on $\sigma B\left(Z^{\prime} \rightarrow l l\right)$. It also shows the theoretical cross section times branching fraction for the $Z_{\mathrm{SSM}}^{\prime}$ and for $E_{6}$-motivated $Z^{\prime}$ models with the lowest and highest $\sigma B$. Figure 2 (bottom) shows the corresponding limits on the RS graviton. Mass limits obtained for the $Z_{\text {SSM }}^{\prime}$ and $G^{*}$ (with $k / \bar{M}_{\mathrm{Pl}}=0.1$ ) are displayed in Table III. The combined mass limits on the $E_{6}$-motivated models and the $G^{*}$ with various couplings are given in Table IV.

In conclusion, the ATLAS detector has been used to search for narrow, heavy resonances in the dilepton invariant mass spectrum above the $Z$ boson pole. Proton-proton collision data with $1.08(1.21) \mathrm{fb}^{-1}$ in the $e^{+} e^{-}\left(\mu^{+} \mu^{-}\right)$ channel have been used. The observed invariant mass spectra are consistent with the SM expectations. Limits are set on the cross section times branching fraction $\sigma B$. The resulting mass limits are 1.83 TeV for the sequential standard model $Z^{\prime}$ boson, $1.49-1.64 \mathrm{TeV}$ for various $E_{6}$-motivated $Z^{\prime}$ bosons, and $0.71-1.63 \mathrm{TeV}$ for a

Randall-Sundrum graviton with couplings $\left(k / \bar{M}_{\mathrm{PI}}\right)$ in the range $0.01-0.1$. The $Z^{\prime}$ boson limits are the most stringent to date, including indirect limits set by LEP2.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. [22] ATLAS uses a right-handed coordinate system with the $z$ axis along the beam pipe. The $x$ axis points to the center of the LHC ring, and the $y$ axis points upward. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$.

# Search for Magnetic Monopoles in $\sqrt{s}=7$ TeV $p p$ Collisions with the ATLAS Detector 

G. Aad et al.*<br>(ATLAS Collaboration)

(Received 26 July 2012; published 27 December 2012)

#### Abstract

This Letter presents a search for magnetic monopoles with the ATLAS detector at the CERN Large Hadron Collider using an integrated luminosity of $2.0 \mathrm{fb}^{-1}$ of $p p$ collisions recorded at a center-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$. No event is found in the signal region, leading to an upper limit on the production cross section at $95 \%$ confidence level of $1.6 / \epsilon \mathrm{fb}$ for Dirac magnetic monopoles with the minimum unit magnetic charge and with mass between 200 GeV and 1500 GeV , where $\epsilon$ is the monopole reconstruction efficiency. The efficiency $\epsilon$ is high and uniform in the fiducial region given by pseudorapidity $|\eta|<1.37$ and transverse kinetic energy $600-700<E^{\mathrm{kin}} \sin \theta<1400 \mathrm{GeV}$. The minimum value of 700 GeV is for monopoles of mass 200 GeV , whereas the minimum value of 600 GeV is applicable for higher mass monopoles. Therefore, the upper limit on the production cross section at $95 \%$ confidence level is 2 fb in this fiducial region. Assuming the kinematic distributions from Drell-Yan pair production of spin- $1 / 2$ Dirac magnetic monopoles, the efficiency is in the range $1 \%-10 \%$, leading to an upper limit on the cross section at $95 \%$ confidence level that varies from 145 fb to 16 fb for monopoles with mass between 200 GeV and 1200 GeV . This limit is weaker than the fiducial limit because most of these monopoles lie outside the fiducial region.

DOI: 10.1103/PhysRevLett.109.261803
Magnetic monopoles have long been the subject of dedicated search efforts for three main reasons: their introduction into the theory of electromagnetism would restore the symmetry between electricity and magnetism in Maxwell's equations; their existence would explain the quantization of electric charge [1]; and they appear in many grand unified theories [2]. However, to date no experimental evidence of a magnetically charged object exists.

Recent searches for magnetic monopoles from astrophysical sources [3-9] are complemented by searches at colliders [10-14]. This Letter describes a search for magnetic monopoles in proton-proton collisions recorded at a center-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ using the ATLAS detector at the CERN Large Hadron Collider (LHC).

The Dirac quantization condition [1], given in Gaussian units, leads to a prediction for the minimum unit magnetic charge $g$,

$$
\begin{equation*}
\frac{g e}{\hbar c}=\frac{1}{2} \Rightarrow \frac{g}{e}=\frac{1}{2 \alpha_{e}} \approx 68.5, \tag{1}
\end{equation*}
$$

where $e$ is the unit electric charge and $\alpha_{e}$ is the fine structure constant. With the introduction of a magnetic monopole, the duality of Maxwell's equations implies a magnetic coupling [15]

[^36]PACS numbers: 14.80.Hv, 13.85.Rm, 29.20.db, 29.40.Cs

$$
\begin{equation*}
\alpha_{m}=\frac{(g \beta)^{2}}{\hbar c}=\frac{1}{4 \alpha_{e}} \beta^{2}, \tag{2}
\end{equation*}
$$

where $\beta=v / c$ is the monopole velocity. For relativistic monopoles, $\alpha_{m}$ is very large, precluding any perturbative calculation of monopole production processes. Therefore, the main result of this analysis is a fiducial cross-section limit for Dirac monopoles of magnetic charge $g$ derived without assuming a particular production mechanism. A cross-section limit assuming the kinematic distributions from Drell-Yan monopole pair production is also provided.

Monopoles are highly ionizing particles, interacting with matter like an ion of electric charge $68.5 e$, according to Eq. (1). The high stopping power of the monopole ionization [16] results in the production of a large number of $\delta$ rays. These energetic "knock-on" electrons emitted from the material carry away energy from the monopole trajectory and further ionize the medium. In the mass and energy regime of this study, the $\delta$ rays have kinetic energies ranging from 1 MeV to a maximum of $\sim 100 \mathrm{MeV}$. The secondary ionization by these $\delta$ rays represents a significant fraction of the ionization energy loss of the magnetic monopole [16]. The dominant energy loss mechanism for magnetic monopoles in the mass and energy range considered herein is ionization [16-18]. Furthermore, the monopole ionization is independent of the monopole speed $\beta$ to first order, in contrast to the ionization of electrically charged particles.

In the ATLAS detector [19,20], the monopole signature can be easily distinguished using the transition radiation tracker (TRT) in the inner detector and the liquid argon (LAr) sampling electromagnetic (EM) calorimeter.

The TRT is a straw-tube tracker that comprises a barrel ( $|\eta|<1.0$ ) with 4 mm diameter straws oriented parallel to the beam line, and two end caps $(0.8<|\eta|<2.0)$ with straws orientated radially. A minimum ionizing particle deposits $\sim 2 \mathrm{keV}$ of energy in a TRT straw. Energy deposits in a TRT straw greater than 200 eV (called "low-threshold hits'") are used for tracking, while those that exceed 6 keV (called "high-threshold hits") typically occur due to the transition radiation emitted by highly relativistic electrons when they penetrate the radiator layers between the straws. As a result, an electron of energy 5 GeV or above has a $20 \%$ probability of producing a high-threshold hit in any straw it traverses. The high-threshold hits can also indicate the presence of a highly ionizing particle. A 2 T superconducting solenoid magnet surrounds the inner detector. The LAr barrel EM calorimeter lies outside the solenoid in the $|\eta|<1.5$ region. It is divided into three shower-depth layers and comprises accordion-shaped electrodes and lead absorbers. The cell granularity in the second layer is $\Delta \eta \times \Delta \phi=0.025 \times 0.025$. The characteristic signature of magnetic monopoles in ATLAS is a large localized energy deposit in the LAr EM calorimeter (EM cluster) in conjunction with a region of high ionization density in the TRT. A search for particles with large electric charge, which yield a similar signature, was performed previously [21] and production cross-section limits for such particles were set [22].
The trajectory of an electrically neutral magnetic monopole in the inner detector is straight in the $r-\phi$ plane and curved in $r-z$. The behavior of magnetic monopoles in the ATLAS detector is described by a GEANT4 [23] simulation [24], which includes the equations of motion, the ionization, the $\delta$-ray production and a modified Birks' law [25] to model recombination effects in LAr due to highly ionizing particles [26]. Equation 5.5 in Ref. [16] gives the $\delta$-ray production cross section and Eq. 5.7 describes the derivation of the magnetic monopole ionization; both equations are implemented in GEANT4.

Simulated Monte Carlo (MC) single-monopole samples are used to determine the efficiency as a function of the transverse kinetic energy $E_{\mathrm{T}}^{\text {kin }}=E^{\text {kin }} \sin \theta$ and pseudorapidity $\eta$ for various monopole masses. For the Drell-Yan process, it is assumed that spin- $1 / 2$ magnetic monopoles are produced in pairs from the initial $p p$ state via quarkantiquark annihilation into a virtual photon. MADGRAPH [27] is used to model this process by assuming leadingorder Drell-Yan heavy lepton pair production but making the replacement $e \rightarrow g \beta$ to reflect the magnetic coupling in Eq. (2). In the absence of a consistent theory describing the coupling of the monopole to the $Z$ boson, such a coupling is set to zero in the madgraph model. In the Drell-Yan samples, the CTEQ6L1 [28] parton distribution functions are used and PYTHIA version 6.425 [29] is used for the hadronization and the underlying event. Only DrellYan monopoles with transverse momentum $p_{\mathrm{T}}>200 \mathrm{GeV}$
are processed by the simulation since lower $p_{\mathrm{T}}$ monopoles fail to reach the calorimeter. For all the simulated samples, both the monopoles and the antimonopoles are assumed to be stable and all final-state particles are processed by the simulation of the ATLAS detector. Additional $p p$ collisions in each event are simulated according to the distribution of $p p$ interactions per bunch crossing in the selected data period.

A simple algorithm is used to preselect events with monopole candidates for further study. Monopoles with $E_{\mathrm{T}}^{\mathrm{kin}}$ above approximately 500 GeV traverse the inner detector and penetrate to the LAr calorimeter, depositing most of their energy there. Only one third of the deposited energy is recorded due to the recombination effects in LAr [26]. Lacking a dedicated monopole trigger, only events collected with a single-electron trigger with transverse energy threshold $E_{\mathrm{T}}>60 \mathrm{GeV}$ are considered. This trigger requires a track in the inner detector within $|\Delta \eta|<0.01$ and $|\Delta \phi|<0.02$ of the LAr energy deposit. Monopoles that fulfill the 60 GeV energy requirement travel fast enough to satisfy the tracking and timing requirements of the trigger. Very high-energy monopoles (i.e., those with $E_{\mathrm{T}}^{\text {kin }} \gtrsim 1400-1900 \mathrm{GeV}$, where the value of 1400 GeV is for monopoles of mass 1500 GeV and the value of 1900 GeV is for monopoles of mass 200 GeV ) exit the EM calorimeter and are rejected by a veto on hadronic energy that is intrinsic to the single-electron trigger. This trigger was operational during the first six months of 2011 data-taking and recorded an integrated luminosity of $2.0 \mathrm{fb}^{-1}$, defining the data set used for this search.

The reconstructed EM cluster is then required to have $E_{\mathrm{T}}>65 \mathrm{GeV}$ and $|\eta|<1.37$. The trigger efficiency is independent of $E_{T}$ for $E_{\mathrm{T}}>65 \mathrm{GeV}$, motivating the former requirement. The $\eta$ requirement ensures that the EM cluster is in the barrel region of the LAr calorimeter, where the two-dimensional spatial resolution is uniform. If two or more EM clusters in an event satisfy these criteria, only the cluster with the highest energy is considered as a monopole candidate.

In the barrel region, the monopole typically traverses 35 TRT straws and its high ionization ensures that most of these register high-threshold hits. Furthermore, as each $\delta$ ray produced by the monopole ionization deposits $\sim 2 \mathrm{keV}$ in a straw, the combined energy deposited by multiple $\delta$ rays crossing a single TRT straw gives rise to additional high-threshold hits. The large number of $\delta$ rays bend in the 2 T magnetic field in the $r$ - $\phi$ plane; therefore, the monopole trajectory appears as a $\sim 1$-cm-wide swath of highthreshold TRT hits. The fraction of TRT hits that exceed the high threshold in the vicinity of the path of an ionizing particle is therefore a powerful discriminator between the monopole signal and the background. The $\phi$ position of the EM cluster is used to define a road of width $\Delta \phi= \pm 0.05 \mathrm{rad}$ from the beam line to the cluster. At least 20 high-threshold TRT hits must be present in the
road. In addition, at least $20 \%$ of the TRT hits in the road must be high-threshold hits.

After the preselection, a more refined TRT hit counting algorithm is used to distinguish the signal from the backgrounds. A histogram with a bin width of 0.8 mrad is filled with the $\phi$ distribution of the high-threshold hits in the previously defined road. The location of the highest bin is used to calculate the center of a new road. In the TRT barrel, a rectangular road of $\pm 4 \mathrm{~mm}$ in the $r-\phi$ plane is used and the hits are counted. In the TRT end cap, a wedgeshaped road of width $\Delta \phi= \pm 0.006 \mathrm{rad}$ is used. These roads are wide enough to encompass two neighboring straws, taking into account the monopole trajectory and the associated $\delta$ rays, but sufficiently narrow to ensure that the fraction of hits that exceed the high threshold, $f_{\mathrm{HT}}$, is insensitive to the presence of neighboring tracks. In the barrel region, the number of hits in the road is required to be greater than 54 . An $\eta$-dependent requirement on the number of hits in the road is applied in the end cap and barrel-end-cap transition region to account for the TRT geometry.

Energy loss by bremsstrahlung and $e^{+} e^{-}$pair production is negligible for magnetic monopoles in the mass and energy range considered herein. Therefore, magnetic monopoles give rise to a narrow ionization energy deposit in the LAr calorimeter, the size of which provides another powerful discriminator of the monopole signal from backgrounds such as electrons and photons, which induce an EM shower via bremsstrahlung and $e^{+} e^{-}$pair production. The variable used is $\sigma_{\mathrm{R}}$, the energy-weighted two-dimensional $\eta-\phi$ cluster dispersion in the second layer of the EM calorimeter, which has the highest two-dimensional spatial resolution. The dispersion $\sigma_{\mathrm{R}}$ is calculated from the energies deposited in a $3 \times 7$ array of cells centered around the most energetic cell of the EM cluster: $\sigma_{\mathrm{R}}=\sqrt{\sigma_{\phi}^{2}+\sigma_{\eta}^{2}}$, where $\sigma_{\phi}^{2}=\Sigma\left(E_{i} \delta \phi_{i}^{2}\right) / \Sigma E_{i}-\left[\Sigma\left(E_{i} \delta \phi_{i}\right) / \Sigma E_{i}\right]^{2}, \delta \phi_{i}$ is the deviation in $\phi$ between cell $i$ and the most energetic cell, and $E_{i}$ is the energy of cell $i ; \sigma_{\eta}^{2}$ is defined similarly.

The high-threshold TRT hit fraction, $f_{\mathrm{HT}}$, and the cluster dispersion, $\sigma_{\mathrm{R}}$, are thus chosen as the distinguishing variables between the signal and background, and are shown in Fig. 1. The main physics background sources are highenergy electrons, photons, and jets, which exhibit no correlation between these variables in simulated processes. The background and monopole MC samples are used to define an approximate signal region. Then ( $\sigma_{\mathrm{R}}, f_{\mathrm{HT}}$ ) parameter pairs are generated by randomly sampling the onedimensional $\sigma_{\mathrm{R}}$ and $f_{\mathrm{HT}}$ distributions for data outside this approximate signal region. The borders of the signal region are tuned for maximal significance of observation of three signal events by replacing the background MC events with these parameter pairs. The final signal region $A$ is defined by $\sigma_{\mathrm{R}} \leq 0.017$ and $f_{\mathrm{HT}}>0.7$.

The efficiencies, which include trigger, reconstruction, and selection effects, in the two-dimensional $E_{\mathrm{T}}^{\text {kin }}$ versus $\eta$

FIG. 1 (color online). High-threshold TRT hit fraction, $f_{\mathrm{HT}}$, versus EM cluster dispersion, $\sigma_{\mathrm{R}}$. The circles represent 1000 simulated single monopoles with mass 800 GeV . The crosses represent ATLAS data. The regions marked $A, B, C$, and $D$ are discussed in the text.
plane are obtained from the simulated single-monopole samples. A fiducial region for each monopole mass is defined by the $E_{\mathrm{T}}^{\mathrm{kin}}$ range in which the efficiency is 0.80 or higher in the $|\eta|<1.37$ region. Figure 2 shows the efficiency versus $E_{T}^{\text {kin }}$, averaged over $|\eta|<1.37$. For monopoles with a mass of 200 GeV , the minimum transverse kinetic energy $\left(E_{\mathrm{T}}^{\mathrm{kin}}\right)_{\min }$ where the efficiency rises above 0.80 is 700 GeV . For monopoles with a mass between 500 GeV and $1500 \mathrm{GeV},\left(E_{\mathrm{T}}^{\mathrm{kin}}\right)_{\min }$ is 600 GeV . Monopoles with lower $E_{\mathrm{T}}^{\mathrm{kin}}$ fail to penetrate to the EM calorimeter and therefore do not satisfy the trigger requirements. Monopoles with very high $E_{\mathrm{T}}^{\text {kin }}$ exit the EM calorimeter and are rejected by the hadronic veto of the electron trigger. A common upper value of $E_{\mathrm{T}}^{\mathrm{kin}}=$ 1400 GeV is used for the fiducial region of all monopole masses. As the minimum efficiency is 0.80 in the fiducial

FIG. 2 (color online). Efficiency versus $E_{T}^{\text {kin }}$, averaged over $|\eta|<1.37$, for single monopoles of mass 200 GeV and mass 1500 GeV .
region, a common value of 0.80 is used in the determination of the upper cross-section limit.

The efficiencies can be under- or overestimated for several reasons. These effects are described below and the relative systematic uncertainties for each effect are given. (1) Cross talk in the second EM layer in the $\phi$ direction is not modeled in the simulation. The energy is reweighted assuming $1.8 \%$ cross talk [30] and the cluster dispersion, $\sigma_{\mathrm{R}}$, recomputed. The efficiency is reduced and the resulting relative shift of $-1.7 \%$ for single monopoles is taken as a one-sided uncertainty. (2) The simulation underestimates the TRT occupancy in the data by up to $20 \%$; therefore, the number of low-threshold hits (those unlikely to come from the monopole or related $\delta$ rays) is increased by $20 \%$. The resulting relative uncertainty is $-1.3 \%$. (3) The modification to Birks' law is varied between its upper and lower systematic uncertainties [26], yielding a relative uncertainty of $+1.8 \%$ and $+1.5 \%$, respectively. (4) The production of $\delta$ rays is varied by $3 \%$ [16] and the resulting uncertainty is negligible.
(5) The GEant4 "range cut" [23] controls the minimum kinetic energy threshold below which $\delta$ rays are not propagated explicitly. This parameter is reduced from $50 \mu \mathrm{~m}$ to $25 \mu \mathrm{~m}$ in the TRT simulation. The resulting relative uncertainty is $+0.14 \%$. (6) The material in the inner detector, in the barrel cryostat and in between the cryostat and the first layer of the EM calorimeter is increased by $5 \%, 10 \%$, and $5 \%$, respectively, in the simulation [31]. The resulting $-0.74 \%$ relative uncertainty is taken as symmetric. Including an uncertainty of $\sim 1.7 \%$ to account for the limited number of MC events, the total upper and lower relative uncertainties on the efficiency for single monopoles are $+2.6 \%$ and $-2.8 \%$, respectively.

The efficiencies to reconstruct at least one of the monopoles in the pairs produced with Drell-Yan kinematic distributions are given in Table I for each mass. Only masses up to 1200 GeV are considered, taking into account the phase space limitations for pair production. The total relative uncertainties, which reflect the same systematic variations described above, are also given. The efficiencies and their associated systematic uncertainties reflect large losses due to acceptance, since many Drell-Yan monopoles have insufficient energy to reach the calorimeter.

The background in the signal region is predicted directly from the data. The two-dimensional plane in Fig. 1 is divided into quadrants, one of which is dominated by

TABLE I. Efficiencies and their relative uncertainties in percent for Drell-Yan pair-produced monopoles of various masses.

| Mass $(\mathrm{GeV})$ | 200 | 500 | 800 | 1000 | 1200 |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Efficiency | 0.011 | 0.048 | 0.081 | 0.095 | 0.095 |
| Relative uncertainty |  |  |  |  |  |
| Upper (\%) | +32 | +24 | +22 | +23 | +20 |
| Lower (\%) | -36 | -23 | -22 | -25 | -25 |

signal (region $A$ ), and three others that are occupied mainly by background (regions $B, C$, and $D$ ). The ratio of background events in signal region $A$ to events in background region $B$ is expected to be the same as the ratio of background events in regions $C$ to $D$. This assumption is incorporated into a maximum likelihood fit to determine the estimated numbers of signal and background events in signal region $A$. The inputs to the fit include the observed event yields in quadrants $A$ through $D$, which are $0,5,16$, and 7001, respectively, the efficiencies and associated systematic uncertainties that have already been discussed, and the integrated luminosity and its $3.7 \%$ uncertainty [32]. For each monopole mass, the rate of appearance of signal events in quadrants $B$ and $C$, as predicted by the simulation, is also taken into account. According to the simulation, no signal event appears in quadrant $D$ for any monopole mass. The fit predicts $0.011 \pm 0.007$ background events in the signal region.

Using the results of the maximum likelihood fit, the upper limits on the production cross sections at $95 \%$ confidence level are calculated using the profile likelihood ratio as a test statistic [33]. The results are extracted using the $C L_{s}$ method [34]. The cross-section limits can be expressed as a function of the efficiency, $\boldsymbol{\epsilon}$, which is shown in Fig. 2 for single monopoles and given in Table I for Drell-Yan pair-produced monopoles. The upper limit on the production cross section at $95 \%$ confidence level is found to be $1.6 / \epsilon$ fb for Dirac magnetic monopoles with the minimum unit magnetic charge and with mass between 200 GeV and 1500 GeV . Assuming the kinematic distributions from Drell-Yan pair production of spin-1/2 Dirac magnetic monopoles, this translates to an upper limit on the cross section at $95 \%$ confidence level that varies from 145 fb to 16 fb for monopoles with mass between 200 GeV and 1200 GeV , as shown in Fig. 3. Since the number of expected background events is very small and no event is

FIG. 3 (color online). Upper limits on the monopole production cross sections at $95 \%$ confidence level. The solid line is the limit for single monopoles in the fiducial region and the dashed line is the limit assuming the kinematic distributions from Drell-Yan (DY) monopole pair production.
observed in the signal region, only the observed limits are shown. To compare with previous experiments that have provided lower mass limits on spin-1/2 Dirac magnetic monopoles by assuming Drell-Yan pair production, such an approach would yield a lower mass limit of 862 GeV in the present search [35].

The monopole reconstruction efficiency is high and uniform in the fiducial region given by pseudorapidity $|\eta|<1.37$ and transverse kinetic energy $\left(E_{\mathrm{T}}^{\mathrm{kin}}\right)_{\text {min }}<$ $E^{\text {kin }} \sin \theta<1400 \mathrm{GeV}$, where $\left(E_{\mathrm{T}}^{\mathrm{kin}}\right)_{\min }$ is 600 GeV for monopoles with a mass between 500 GeV and 1500 GeV . For monopoles with a mass of $200 \mathrm{GeV},\left(E_{\mathrm{T}}^{\mathrm{kin}}\right)_{\min }=$ 700 GeV . Therefore, the upper limit on the production cross section at $95 \%$ confidence level is 2 fb , as shown in Fig. 3, for Dirac magnetic monopoles with the minimum unit magnetic charge and with mass between 200 GeV and 1500 GeV in this fiducial region. The fluctuations of the observed limit in the fiducial region originate from variations of the nuisance parameters used in the profile likelihood ratio.

These results extend the upper limits on the production cross section for monopoles in this mass region established by preceding experiments. This is the first direct collider search that yields cross-section constraints on magnetic monopoles with masses greater than 900 GeV .

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We thank J. Apostolakis, V. Ivanchenko, M. Horbatsch, and V. Sanz for helpful discussions. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC, and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST, and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNRF, DNSRC, and Lundbeck Foundation, Denmark; EPLANET and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG, and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP, and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society, and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular, from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark,

Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (USA) and in the Tier-2 facilities worldwide.

[20] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the $z$ axis coinciding with the axis of the beam pipe. The $x$ axis points from the IP to the center of the LHC ring, and the $y$ axis points upward. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$.

[35] Over the range of monopole masses from 200 GeV to 1200 GeV , the leading-order Drell-Yan production cross section drops from $10^{5} \mathrm{fb}$ to 1 fb , but has large theoretical uncertainties, due to the nonperturbative nature of the magnetic coupling.

PLL

#### Abstract

We report R\&D results on two integrated circuit designs: a 5 Gbps $16: 1$ serializer and a 5 GHz LC phase-locked-loop (PLL). The prototypes were fabricated with a commercial thin-film silicon-on-sapphire $0.25 \mu \mathrm{~m}$ CMOS technology. Both the serializer and the PLL have been evaluated to meet design goals and tested against operation conditions in the environment of a particle physics detector front-end for the proposed HL-LHC upgrade.

## 1. Introduction

Serial data transmission over optical fibers is used in particle physics experiments. The transmitting data rate over a single fiber channel increased from a few megabits per second (Mbps) to 1.6 gigabits per second (Gbps. Example: the optical link that reads out the Liquid Argon Calorimeter [1], or LAr, in the ATLAS experiment at CERN). The operation environments require high system reliability due to lack of frequent access for maintenance or repair. In some cases the radiation in a particle physics detector front-end also puts special requirements on the electronics and optics that operate inside the detector volume [2]. In the upgrade program for the High Luminosity Large Hadron Collider (HL-LHC) at CERN, R\&D projects are carried out to meet the challenges of higher radiation tolerance and system reliability, and much higher data bandwidth with low power dissipation, compared with the optical link systems now operating in experiments on the LHC. This is because with the increase of radiation in the detector front-end, it is advantageous to simplify the front-end readout electronics by moving all level- 1 triggering circuits to the back-end data acquisition (DAQ) system where frequent access is possible and there is no or very little radiation in the operation environment. The price to pay in the data-streaming mode frontend electronics is on the data transmission bandwidth. Taking the ATLAS LAr optical link as an example, the data throughput will increase from 1.6 Gbps per front-end board (FEB) to over 100 Gbps per FEB. To meet this challenge, and to address the needs in many new detectors' readout R\&D, especially those designs to operate in radiation environment, we have been

[^39]working on designs of Application Specific Integrated Circuits (ASICs) for the transmitting side of an optical link. The final goal of data throughput in our R\&D program is 10 Gbps per fiber. As a step towards that goal, we prototyped a $16: 1$ serializer designed to operate at 5 Gbps , and an LC based phase-locked-loop (PLL) that runs up to 5 GHz . Both designs are based on a commercial thin-film silicon-on-sapphire (SOS) $0.25 \mu \mathrm{~m}$ CMOS technology. The design and measurement results of the serializer are reported in Section 2, while those for the LC-PLL in Section 3. In the conclusion we point out our roadmap to the final goal of ASICs and the link system of 10 Gbps per fiber, or an aggregated bandwidth of 120 Gbps per FEB.

## 2. Design and measurement results of the $\mathbf{5} \mathbf{G b p s}$ serializer ASIC

A functional block diagram of serial data transmission over fiber optics is shown in Fig. 1. The interface block prepares the upstream parallel data for serial transmission hence works at a clock rate that is close to the parallel data clock which is much lower (by about $8 \times$ in this case) than the serial data rate. The serializer and the optical interface blocks have circuits that work at the highest clock frequency of the system. For example, for a 5 Gbps serial data rate and circuits using both edges of the clock, one needs a 2.5 GHz PLL. The optical interface consists of a (current) laser driver (LD) circuit and a laser. The LD is the same as a CML line driver with matching modulation current and impedance of the laser in use. Because of these, we decided to first prototype a 16:1 serializer with a CML output to gain experience with this SOS technology. To increase the chances of success, this design is also based on a ring oscillator PLL as its clock unit, learned from a successful previous ASIC serializer, the

GOL chip, developed for particle physics [3]. This PLL limits the serial speed to be 5 Gbps . To probe the speed of the technology, we also implemented a standalone LC based PLL. The design and testing of this serializer are described in the following subsections while the LC-PLL is described in Section 3.

### 2.1. The design of the ASIC

The design of the serializer follows an inverted tree structure with a cascade of many $2: 1$ multiplexing units, as shown in Fig. 2. The advantage of this serializing structure are twofold: one, the multiplexers operate at lower speeds except the last stage which runs at the final serial data rate, offering the possibility of "trading power for speed" only in the last multiplexer which is specially designed; two, the power-of-2 structure simplifies the design of the clock unit, which in this particular design is shared with the PLL divider chain. A divide-by-two divider immediately after the VCO (voltage controlled oscillator) in the PLL also helps to maximize the clock speed. The disadvantage of this structure is a serializing ratio of the power of 2 , requiring a possible data reformatting at the interface stage in front of the serializer. Since in most applications such an interface ASIC will be needed to perform many functions such as data framing, scrambling, redundancy switch, and communication for control and monitoring, adding data bus reformatting to the interface to cope with a particular application is manageable. The high-speed clock is synthesized based a ring-oscillator-PLL, also illustrated in Fig. 2. The PLL can be selected to latch to either the rising or the falling

Fig. 1. Block diagram of a fiber optics based serial link system.
edge of the reference clock (the parallel input data clock), ensuring correctly clocking in the input data. A selection of PLL low pass filter bandwidth is implemented to cope with different input clock quality. A static D-Flip-Flop is used to improve the serializer's immunity to single event upset caused by ionizing particles. To achieve the needed speed with these static DFF, its internal clock and clock-bar are carefully adjusted to ensure the shortest D-to-Q time.

### 2.2. The evaluation of the prototype

Testing of the prototype chip was carried out by wire-bonding it to a PCB. Special caution was exercised for a few very fast signals both in the PCB design with impedance-matched traces and in placing the chip for wire-bonding with the shortest connecting wires. In general electric signal reflection is minimized by implementing impedance match for all differential signal traces. For CMOS signal traces, resistors are placed in series to reduce sharp rising (falling) edge. Shown in Fig. 3(a) is the eye diagram measurement with an eye mask. A bathtub curve is also traced with a Bit-Error-Rate-Tester (Anritsu MP1763C/1764C) and is shown in Fig. 3(b). From both measurements one can extract an eye opening of 0.69 UI (Unit Interval). Signal rise/fall time, amplitude of a $100 \Omega$ differential load, timing jitter in the serial bit stream, together with different jitter components are listed in Table 1. The measured power consumption of this ASIC is 463 mW , corresponding to $93 \mathrm{~mW} / \mathrm{Gbps}$. This measured power consumption in room temperature agrees with simulation within $5 \%$.

### 2.3. The next step in serializer design

Making use of the fact that in most particle physics detector front-end electronics, all readout channels are based on one system clock, we decided to design an array serializer, with two serializing units sharing one LC-PLL. The choice of this architecture is a balance of power saving and high-speed clock distribution. A block diagram of this design is shown in Fig. 4. The designed serial data rate is 8 Gbps , as shown in the post-layout simulation of the output eye diagram. The simulated power consumption of this ASIC is 1200 mW , or $75 \mathrm{~mW} / \mathrm{Gbps}$. This design reaches the highest achievable serial data rate with the particular process we choose in this SOS technology, with all the constraints we have, in particular the radiation tolerance requirement.

Table 1
Measurement results of the 5 Gbps serializer ASIC. Errors listed in the table are statistic only.

| Parameters (unit) | Value |
| :--- | :---: |
| Amplitude (V) | $1.16 \pm 0.03$ |
| Rise time (ps) | $52.0 \pm 0.9$ |
| Fall time (ps) | $51.9 \pm 1.0$ |
| Total jitter @ BER $10^{-12}(\mathrm{ps})$ | $61.6 \pm 6.9$ |
| Random jitter (ps) | $2.6 \pm 0.6$ |
| Total deterministic jitter (DJ) (ps) | $33.4 \pm 6.7$ |
| DJ: Periodic (ps) | $3.0 \pm 2.3$ |
| DJ: Inter-symbol interference | $3.0 \pm 2.3$ |
| (ps) |  |
| DJ: Duty cycle (ps) | $15.2 \pm 3.8$ |

## 3. Design and measurement results of the $\mathbf{5 G H z}$ LC-PLL

The chosen SOS technology offers high Q inductors. To take advantage of this, we designed an LC based PLL in the same prototype submission of the serializer, so one finds reusing many of the functional blocks from that serializer design. The challenge in the design is the varactor, the voltage controlled capacitor, of which the manufacturer does not provide a model for simulation. Due to schedule and budget constraints, we put a test bank of varactors together with the LC-PLL design in the same submission. Reported below are the results of the varactors and the LC-PLL.

### 3.1. The varactor results

Several varactors based on the RN and IN transistors are implemented in the prototype chip and are tested using LCR meters from Agilent (Model 4263B) and from Stanford Research System (SR720). The tests were carried out with frequencies from 100 Hz to 100 kHz , provided by the LCR meters. The tests were also carried out at room temperature and at liquid nitrogen temperature. Shown in Fig. 5 are the capacitance changes as a function of the bias voltage with the RN and IN transistor based varactors. Also shown are the simulation results. We use the RN transistors in our design. There is a systematic shift between simulated value and measured capacitance. Since the manufacturer does not provide a reliable simulation model for the varactors, we decide to take the measured value in our future designs.

Fig. 4. Block diagram of a 2-lane array serializer design.

### 3.2. The design of the ASIC and the measurement results

Block diagram of the LC-PLL is shown in Fig. 6. We reuse the phase-frequency-detector circuit (PFD), the charge-pump circuit (CP) and the low-pass-filter (LPF) from the ring-oscillator PLL inside the serializer. The first stage divider is a new design and works at 5 GHz . In order to test the design, and for lack of a 5 GHz output driver (we now know this is not possible with the chosen technology), we reuse the 2.5 GHz CML Driver for the signal output. We split the signal after the first divider stage, connecting one branch to the CML Driver. This is illustrated in Fig. 6. Based on

Fig. 5. Simulated and measured capacitance of RN (left) and IN (right) type of varactors.

Fig. 6. Block diagram of the LC-PLL with the CML output for testing purpose.

Table 2
Measurement results of the 5 GHz LC-PLL ASIC. Errors listed in the table are statistic only.

| Parameters (unit) | Value |
| :--- | :--- |
| Tuning frequency range (GHz) | $4.63 \pm 0.12$ to $4.98 \pm 0.02$ |
| Power consumption (mW) | $111 \pm 8$ |
| Output amplitude, pk-pk (V) | $1.23 \pm 0.09$ |
| Rise time (ps) | $44.9 \pm 2.4$ |
| Fall time (ps) | $44.4 \pm 2.2$ |
| Random jitter (ps) | $1.3 \pm 0.3$ |
| Deterministic jitter (ps) | $7.5 \pm 1.1$ |

simulated varactor tuning range, we thought that we should have a tuning range from 3.8 GHz to 5.0 GHz of the PLL. A mistake in the first divider design limited this range to be from 4.6 GHz to 5.0 GHz. This problem has been traced to a design mistake in the first stage divider and will be corrected in future designs. Listed in Table 2 are the results of this LC-PLL. The power consumption does not include those from the CML Driver and the LVDS receiver.

## 4. Conclusion

With one MPW run, we have 5 designs. Reported here are the results of a serializer, a LC-PLL and a testing block of varactors.

Built on these experiences, we are now designing LOCs2, and LOCld for the optical interface. Simulation results indicate that both LOCs2 and LOCld should work at 8 Gbps and this is really what this technology can offer. We will need either change the system design to work with the speed of 8 Gbps per fiber, or move to a newer SOS technology to reach higher speeds. The low speed (below 1 GHz ) and mostly digital circuits interface function block to complete the link transmitting side will be investigated at a later stage.

## Acknowledgments

This work is supported by the US-ATLAS R\&D program for the upgrade of the LHC and the US Department of Energy Grant DE-FG02-04ER41299. The authors would like to thank Peter Clarke, Jay Clementson, Yi Kang, Francis M. Rotella, John Sung, and Gary Wu from Peregrine Semiconductor Corporation for technical assistance; Justin Ross at Southern Methodist University for setting up and maintaining the software environment; Jasoslav Ban, Mauro Citterio, Christine Hu, Sachin Junnarkar, Valentino Liberali, Paulo Rodrigues Simoes Moreira, Mitch Newcomer, Quan Sun, Fukun Tang, and Carla Vacchi for technical assistance and reviewing of ASIC designs; Hucheng Chen, Francesco Lanni, and Sergio Rescia at Brookhaven National Laboratory for help on varactor measurements.

# Limits on the production of the standard model Higgs boson in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

The ATLAS Collaboration ${ }^{\star}$<br>CERN, 1211 Geneva 23, Switzerland

Received: 14 June 2011 / Revised: 16 July 2011 / Published online: 20 September 2011
© CERN for the benefit of the ATLAS collaboration 2011. This article is published with open access at Springerlink.com

#### Abstract

A search for the Standard Model Higgs boson at the Large Hadron Collider (LHC) running at a centre-ofmass energy of 7 TeV is reported, based on a total integrated luminosity of up to $40 \mathrm{pb}^{-1}$ collected by the ATLAS detector in 2010. Several Higgs boson decay channels: $H \rightarrow \gamma \gamma$, $H \rightarrow Z^{(*)} \rightarrow \ell \ell \ell \ell, H \rightarrow Z Z \rightarrow \ell \ell \nu \nu, H \rightarrow Z Z \rightarrow \ell \ell q q$, $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ and $H \rightarrow W W \rightarrow \ell \nu q q(\ell$ is e, $\mu)$ are combined in a mass range from 110 GeV to 600 GeV . The highest sensitivity is achieved in the mass range between 160 GeV and 170 GeV , where the expected $95 \%$ CL exclusion sensitivity is at Higgs boson production cross sections 2.3 times the Standard Model prediction. Upper limits on the cross section for its production are determined. Models with a fourth generation of heavy leptons and quarks with Standard Model-like couplings to the Higgs boson are also investigated and are excluded at $95 \%$ CL for a Higgs boson mass in the range from 140 GeV to 185 GeV .

## 1 Introduction

The search for the Standard Model Higgs boson [1-3] is one of the key aims of the Large Hadron Collider (LHC) at CERN. Prior to the LHC, the best direct information is a lower limit of 114.4 GeV , set using the combined results of the four LEP experiments [4], and an excluded band of 158 GeV to 173 GeV from the combined Tevatron experiments [5, 6]. First results from the ATLAS experiment are available in various Standard Model Higgs boson search channels [7-11]. There are also results from the CMS collaboration [12] in the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu^{1}$ channel which have a sensitivity similar to the equivalent search reported

[^40][^41]here. These results are based on proton-proton collision data collected in 2010 at a centre-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$. This paper combines the results from the different Higgs boson searches to obtain the overall sensitivity to a Standard Model Higgs boson with the 2010 ATLAS dataset.

All analyses use the most detailed calculations available for the cross sections, as discussed in Sect. 3. The searches in individual Higgs boson decay channels $H \rightarrow \gamma \gamma, H \rightarrow$ $W W^{(*)}$ and $H \rightarrow Z Z^{(*)}$ are outlined in Sects. 4, 5, and 6, respectively. The statistical interpretation uses the profilelikelihood ratio [13] as test-statistic. Thirty-one Higgs boson masses, in steps of 10 GeV from 110 GeV to 200 GeV (plus 115 GeV in addition) and 20 GeV from 200 GeV to 600 GeV , are tested. Exclusion limits are obtained using the power constrained $\mathrm{CL}_{\mathrm{s} b}$ limit [14], as discussed in Sect. 7. To allow for comparisons with the exclusion limits obtained by other experiments, the results are also determined using the $\mathrm{CL}_{s}$ method [15]. The limits are presented in terms of $\sigma / \sigma_{S M}$, the multiple of the expected Standard Model cross section at the Higgs boson mass considered. Results are also presented in terms of the corresponding ratio where the cross section in the denominator includes the effects of a fourth generation of heavy leptons and quarks with Standard Model-like couplings to the Higgs boson. Section 8 describes the treatment of the major sources of systematic uncertainty in the combined likelihood. The limits for individual channels and the combined results are detailed in Sect. 9 and the conclusions are drawn in Sect. 10.

## 2 The ATLAS detector

The ATLAS experiment [16] is a multipurpose particle physics apparatus with forward-backward symmetric cylindrical geometry covering $|\eta|<2.5$ for tracks and $\mid \eta<4.5$ for jets. ${ }^{2}$ The inner tracking detector (ID) consists of a sili-

[^42]con pixel detector, a silicon microstrip detector (SCT), and a transition radiation tracker (TRT). The ID is surrounded by a thin superconducting solenoid providing a 2 T magnetic field, and by high-granularity liquid-argon (LAr) sampling electromagnetic calorimeters. An iron-scintillator tile calorimeter provides hadronic coverage in the central rapidity range. The end-cap and forward regions are instrumented with LAr calorimetry for both electromagnetic and hadronic measurements. The muon spectrometer (MS) surrounds the calorimeters and consists of three large superconducting toroids, each with eight coils, a system of precision tracking chambers, and detectors for triggering.

The data used in this analysis were recorded in 2010 at the LHC at a centre-of-mass energy of 7 TeV . Application of beam, detector, and data-quality requirements results in a total integrated luminosity of 35 to $40 \mathrm{pb}^{-1}$ depending on the search channel, with an estimated uncertainty of $\pm 3.4 \%$ [17]. The events were triggered either by a single lepton or a pair of photon candidates with transverse momentum ( $p_{\mathrm{T}}$ ) thresholds which were significantly below the analysis offline requirements. The trigger introduces very little inefficiency except in one channel, $H \rightarrow$ $W W \rightarrow \ell \nu q q$, where there are efficiency losses in the muon channel of about $16 \%$.

Electron and photon candidates are reconstructed from energy clusters recorded in the liquid-argon electromagnetic calorimeter. The clusters must have shower profiles consistent with those expected from an electromagnetic shower. Electron candidates are matched to tracks reconstructed in the inner detector, while photon candidates require either no track or an identified conversion candidate. Muon candidates are reconstructed by matching tracks found in the inner detector with either tracks or hit segments in the muon spectrometer. Details of the quality criteria required on each of these objects differ amongst the analyses discussed here. There are in addition isolation criteria which again depend upon the specific backgrounds relevant to each analysis.

Jets are reconstructed from topological clusters [18] in the calorimeter using an anti- $\mathrm{k}_{\mathrm{t}}$ algorithm [19] with a radius parameter $R=0.4$. They are calibrated [18, 20] from the electromagnetic scale to the hadronic energy scale using $p_{\text {T }}$ and $\eta$ dependent correction factors based on Monte Carlo simulation and validated on data. They are required to have a $p_{\mathrm{T}}$ greater than 25 GeV unless otherwise stated. B tagging is performed using a secondary vertex algorithm based upon the decay length significance. A selection requirement is set to describe a jet as ' $b$-tagged' which has a $50 \%$ efficiency for true $b$-jets. The missing transverse energy is reconstructed

[^43]from topological energy clusters in the ATLAS calorimeters, with corrections for measured muons.

## 3 Cross sections, decays and simulation tools

### 3.1 Search for the standard model Higgs boson

At the LHC, the most important Standard Model Higgs boson production processes are the following four: gluon fusion $(g g \rightarrow H)$, which couples to the Higgs boson via a heavy-quark triangular loop; fusion of vector bosons radiated off quarks $(q q \rightarrow q q H)$; associated production with a vector boson $(q \bar{q} \rightarrow W H / Z H)$; associated production with a top-quark pair $(q \bar{q} / g g \rightarrow t \bar{t} H)$. The current calculations of the production cross sections have been gathered and summarised in Ref. [21].

Higher-order corrections have been calculated up to next-to-next-to-leading order (NNLO) in QCD for the gluon fusion [22-27], vector boson fusion [28] and associated $W H / Z H$ production processes [29], and to next-to-leading order (NLO) for the associated production with a $t \bar{t}$ pair [30, 31]. In addition, QCD soft-gluon resummations up to next-to-next-to-leading $\log$ (NNLL) are available for the gluon fusion process [32]. The NLO electroweak (EW) corrections are applied to the gluon fusion [33, 34], vector boson fusion [35, 36] and the associated $W H / Z H$ production [37] processes.

The Higgs boson decay branching ratios used take into account the recently calculated higher order QCD and EW corrections in each Higgs boson decay mode [21, 38]. The errors in these calculations for the states considered here are at most $2 \%$ and are neglected. For most four-fermion final states the predictions by Prophecy $4 \mathrm{f}[39,40]$ are used which include the complete NLO QCD+EW corrections with all interference and leading two-loop heavy Higgs boson corrections to the four-fermion width. The $H \rightarrow Z Z \rightarrow \ell \ell q q$ and $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ analyses use the less precise single $Z$ boson decay rates from Ref. [41].

The total signal production cross section in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$, multiplied by the branching ratio for the final states considered in this paper, is summarised in Fig. 1 as a function of the Higgs boson mass. Sources of uncertainties on these cross sections include missing higher-order corrections, imprecise knowledge of the parton distribution functions (PDFs) and the uncertainty on the strong force coupling constant, $\alpha_{s}$. These uncertainties are treated according to the recommendations given in Refs. [21, 42-45] and are $\pm(15-20) \%$ for the gluon fusion process, $\pm(3-9) \%$ for the vector boson fusion process and $\pm 5 \%$ for the associated $W H / Z H$ production process.

Fig. 1 The cross section multiplied by decay branching ratios for Standard Model Higgs boson production in $p p$ collisions at a 7 TeV cen-tre-of-mass energy as a function of mass [21]. All production modes are summed, and only final states considered in this paper are shown. Two bands are shown for each curve; the inner represents the QCD scale uncertainty and the outer also includes the $\alpha_{s}$ and PDF uncertainty

### 3.2 Higgs boson search in fourth generation models

Models with a fourth generation of heavy leptons and quarks with Standard Model-like couplings to the Higgs boson enhance its production cross section in gluon fusion by a factor of 4 to 10 compared to the predicted rate with three generations [46-49]. The model considered here [50] has very heavy fourth generation fermions, giving a minimum cross section but excluding the possibility that the Higgs boson decays to heavy neutrinos. These can weaken the exclusion for Higgs boson masses below the $W$ pair threshold [51]. It should be noted that the branching ratio into photons is suppressed by a factor around 8 in this model.

The Higgs boson production cross section in the gluon fusion process and its decay branching ratios have been calculated in the fourth generation model at NLO with HIGLU [52] and HDECAY [38]. The NNLO+NNLL QCD corrections are applied to the gluon fusion cross sections. The QCD corrections for the fourth generational model are assumed to be the same as in the Standard Model. The full two-loop Standard Model electroweak corrections [33, 34] are taken into account. The effect of a fourth generation in the Standard Model background processes, which includes contributions from loop diagrams, has been neglected.

### 3.3 Monte Carlo simulations

For the $H \rightarrow Z Z$ Monte Carlo samples, the Higgs signal is generated using PYTHIA [53] interfaced to PHOTOS [54] for final-state radiation. The $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ events produced by gluon fusion or vector boson fusion are modelled using the MC@NLO [55, 56] and SHERPA [57]

Monte Carlo generators, respectively. $H \rightarrow W W \rightarrow \ell v q q$ is modelled using PYTHIA for the gluon fusion and HERWIG [58] for vector boson fusion. The $\gamma \gamma$ signal is simulated with MC@NLO, HERWIG and PYTHIA for the gluon fusion, vector boson fusion and associated production processes respectively.

For background sample generation, the PYTHIA, ALPGEN [59], MC@NLO, MADGRAPH [60], SHERPA and HERWIG packages are employed.

All Monte Carlo samples are processed through a complete simulation of the ATLAS detector [61] using the GEANT programme [62].

## 4 Search for $H \rightarrow \gamma \gamma$

The search for the Higgs boson in the $\gamma \gamma$ decay mode is described below; further details can be found in Ref. [7]. The event selection requires the presence of at least two identified photons [63], including converted photons, isolated from any other activity in the calorimeter. The leading and the sub-leading photons are required to have transverse momenta above 40 GeV and 25 GeV , respectively. The directions of the photons are measured using the position determined in the first sampling of the electromagnetic calorimeter and that of the reconstructed primary vertex. The diphoton invariant mass spectrum is used to search for a peak above the background contributions.

The main background processes in the $H \rightarrow \gamma \gamma$ search arise from the production of two isolated prompt photons $(\gamma \gamma)$ and from fake photons in photon-jet ( $\gamma j$ ) and di-jet $(j j)$ events. Fake photons can originate from jets in which a leading $\pi^{0}$ or $\eta$ meson from the quark or gluon fragmentation is reconstructed as a single isolated photon. Each of these background contributions has been estimated from sideband control samples in the data. The backgroud from Drell-Yan events, $Z / \gamma^{*} \rightarrow e e$, where the electrons are mistakenly identified as photons, is estimated from studies of the $Z$ boson mass peak and extrapolated to the signal region. The total number of estimated background events is constrained to be the observed number. The di-photon invariant mass distribution for the events passing the full selection is shown in Fig. 2. The full-width at half maximum of a signal with $m_{h}=120 \mathrm{GeV}$ would be 4.2 GeV .

The expected signal yield, summing all production processes, and estimated background composition for a total integrated luminosity of $38 \mathrm{pb}^{-1}$ are summarised in Table 1. A total of 99 events passing all selection criteria are observed in data in the di-photon mass range from 100 GeV to 150 GeV . The background in this region is modelled by fitting an exponential function to the data. The signal peak is modelled by a Gaussian core portion and a power-law low-end tail [64]. Tails in the signal resolution are modelled

Fig. 2 Distribution of the di-photon invariant mass for the 99 events from data passing all event selection criteria in the $H \rightarrow \gamma \gamma$ search and for the Monte Carlo prediction. The overall uncertainty on the expected total yield is illustrated by the yellow band. The uncertainty due to the reducible background is also shown (dark yellow band). The predictions for the main components of the background (di-photon, pho-ton-jet, jet-jet and Drell-Yan) are also illustrated

Table 1 The number of expected and observed events in the $H \rightarrow \gamma \gamma$ search in the di-photon mass range from 100 GeV to 150 GeV for an integrated luminosity of $38 \mathrm{pb}^{-1}$. Also shown is the composition of the background expected from Monte Carlo simulation and the division of the observed data as discussed in the text as well as the expected number of $H \rightarrow \gamma \gamma$ signal events for a Higgs boson mass of $m_{H}=120 \mathrm{GeV}$. Total uncertainties are shown in the middle column while in the rightmost column the statistical and systematic uncertainties, respectively, are given

| Total | $\frac{\text { Expected }}{120 \pm 27}$ | $\frac{\text { Observed or Estimated }}{99}$ |
| :--- | :--- | :--- |
| $\gamma \gamma$ | $86 \pm 23$ | $75.0 \pm 13.3_{-3.6}^{+2.7}$ |
| $\gamma j$ | $31 \pm 15$ | $19.6 \pm 7.5 \pm 3.9$ |
| $j j$ | $1 \pm 1$ | $1.5 \pm 0.7_{-0.5}^{+1.8}$ |
| $Z / \gamma^{*}$ | $2.7 \pm 0.2$ | $2.9 \pm 0.1 \pm 0.6$ |
| $H \rightarrow \gamma \gamma$ | $0.45_{-0.10}^{+0.11}$ | $\left(m_{H}=120 \mathrm{GeV}\right)$ |

by a wide Gaussian component of small amplitude. No significant excess of events over the continuous background is found for any Higgs boson mass. The systematic uncertainty on the total signal acceptance is $\pm 15 \%$, where the dominant contributions come from photon identification $( \pm 11 \%)$ and photon isolation efficiencies $( \pm 10 \%)$.

## 5 Search for $\boldsymbol{H} \rightarrow \boldsymbol{W} \boldsymbol{W}$

The search for the Higgs boson in the decay channel $H \rightarrow W W$ benefits from the large branching ratio of the Higgs boson to decay into a pair of $W$ bosons for masses above $m_{H} \gtrsim 110 \mathrm{GeV}$, the sizable $W$ boson decay rates to leptons and the powerful identification of leptons with
the ATLAS detector. It offers the greatest sensitivity of any search channel when the Higgs boson mass is close to twice the $W$ boson mass, $m_{H} \sim 165 \mathrm{GeV}$. Two different decay modes of the $W$ bosons are considered: the $H \rightarrow W W^{*} \rightarrow \ell \nu \ell \nu$ channel is pursued for Higgs boson masses in the range from 120 GeV to 200 GeV , and the $H \rightarrow W W \rightarrow \ell \nu q q$ decay mode is used for Higgs boson masses in the range from 220 GeV to 600 GeV . The analyses are described below and further details can be found in Refs. [8, 9].

### 5.1 Search for $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$

The $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ analysis is performed using a dataset corresponding to an integrated luminosity of $35 \mathrm{pb}^{-1}$. Events are selected requiring exactly two isolated leptons with opposite charge. The leading lepton is required to have $p_{\mathrm{T}}>20 \mathrm{GeV}$ and the sub-leading lepton is required to have $p_{\mathrm{T}}>15 \mathrm{GeV}$. Events are classified into three channels depending on the lepton flavours: $e \mu$, $e e$ or $\mu \mu$. If the two leptons are of the same flavour, their invariant mass ( $m_{\ell \ell}$ ) is required to be above 15 GeV to suppress background from $\Upsilon$ production. To increase the sensitivity, the selections are then allowed to depend on the Higgs boson mass hypothesis. For all lepton combinations in the low (high) mass Higgs boson search, $m_{\ell \ell}$ is required to be below 50 (65) GeV for Higgs boson masses $m_{H} \leq 170 \mathrm{GeV}\left(m_{H}>170 \mathrm{GeV}\right)$ which suppress backgrounds from top-quark production and $Z$ boson production. The missing transverse energy in the event is required to be $E_{\mathrm{T}}^{\text {miss }}>30 \mathrm{GeV}$. An upper bound is imposed on the azimuthal angle between the two leptons, $\Delta \phi_{\ell \ell}<1.3$ (1.8) radians, taking advantage of the spin correlations [65] expected in the Higgs boson decay. The signal region is defined by the transverse mass $\left(m_{\mathrm{T}}\right)$ [66]:
$m_{\mathrm{T}}=\sqrt{\left(E_{\mathrm{T}}^{\ell \ell}+E_{\mathrm{T}}^{\mathrm{miss}}\right)^{2}-\left(\mathbf{P}_{\mathrm{T}}^{\ell \ell}+\mathbf{P}_{\mathrm{T}}^{\mathrm{miss}}\right)^{2}}$,
where $E_{\mathrm{T}}^{\ell \ell}=\sqrt{\left(\mathbf{P}_{\mathrm{T}}^{\ell \ell}\right)^{2}+m_{\ell \ell}^{2}},\left|\mathbf{P}_{\mathrm{T}}^{\mathrm{miss}}\right|=E_{\mathrm{T}}^{\mathrm{miss}}$ and $\mathbf{P}_{\mathrm{T}}^{\ell \ell}$ is the transverse momentum of the dilepton system. The transverse mass is required to be $0.75 \cdot m_{H}<m_{\mathrm{T}}<m_{H}$ for the event to be considered in a given $m_{H}$ range. Events are also treated separately depending on whether they have zero jets ( 0 -jet channel) or one jet (1-jet channel) reconstructed with $|\eta|<4.5$ due to the differences in background composition and expected signal-to-background ratio. To suppress background from top-quark production, events in the 1-jet channel are rejected if the jet is identified as coming from a $b$ quark. Events with two or more jets have been analysed as a separate channel. However, due to the marginal contribution to the overall sensitivity given the current total integrated luminosity and the additional systematic uncertainties, this channel is not included in this combination.

The expected background contributions from $W W$, topquark and $W+$ jets production are normalised using dedicated control regions in data as described in the next sections. Other smaller backgrounds are normalised according to their theoretical cross sections. The background from $Z / \gamma^{*}+$ jets production is normalised to the theoretical cross section with a correction factor determined from data.

### 5.1.1 The WW background

The di-boson $W W$ continuum can be distinguished from the Higgs boson signal through the kinematic selections. A control region is defined by changing the cut on $m_{\ell \ell}$ to require over 80 GeV (but not within 10 GeV of the $Z$ boson mass if the leptons are of the same flavour) and removing the selections on $m_{\mathrm{T}}$ and $\Delta \phi_{\ell \ell}$. The expected ratio of the background contribution in the control region and in the signal region is taken from Monte Carlo simulation. The three main sources of systematic uncertainty affecting this ratio are the theoretical uncertainty on the extrapolation, the jet energy scale uncertainty and the limited statistics in the simulated sample. Uncertainties due to these effects of $\pm 6 \%$ in the 0 -jet channel and $\pm 17 \%$ in the 1-jet channel have been determined.

### 5.1.2 The $t \bar{t}$ and single top-quark backgrounds

Top-quarks, whether from strong interaction $t \bar{t}$ production or weak interaction single top-quark production, are a copious source of final states with one or two $W$ bosons accompanied by one or more jets. Due to kinematic selection one or more of these jets may fail identification, thereby leading to a final state similar to that from the $H \rightarrow W W$ signal.

The background from top-quark production in the 0 -jet channel is estimated by first removing the jet veto. This gives a sample dominated by top-quarks, and the expected contamination from other processes in the control region is subtracted from the observed event yield. Then the probability that top events pass the jet veto is derived from the measured probability of not reconstructing a jet in data, using a sample of top candidates with two leptons, one b-jet and no other jet. The dominant systematic uncertainties originate from the limited statistics in data and the jet energy scale. A total uncertainty of $\pm 60 \%$ has been determined for the top-quark background estimate in the 0 -jet channel.

The top-quark background in the 1 -jet channel is normalised using a control region where the veto on jets coming from $b$-quarks is reversed and the $\Delta \phi_{\ell \ell}, m_{\ell \ell}$ and $m_{\mathrm{T}}$ selections are removed. An extrapolation factor from the control region to the signal region is estimated from Monte Carlo simulation. The dominant systematic uncertainties on the top-quark background estimate in the 1-jet channel are $\pm 23 \%$ from the theoretical uncertainties on the extrapolation factor and $\pm 22 \%$ from the uncertainty on the $b$-tagging efficiency.

### 5.1.3 The $W+$ jets background

The production of $W$ bosons accompanied by jets can mimic the $H \rightarrow W W$ signal if one of the jets is mis-identified as an isolated lepton. The $W+$ jets background is normalised using a control region defined by relaxing the identification and isolation criteria for one of the two leptons. The contribution to the signal region is estimated by multiplying the rate measured in the control region by the probability for fake leptons which pass the relaxed identification and isolation criteria to also pass the original lepton selection criteria. This misidentification probability is measured in a multi-jet data sample. The major sources of systematic uncertainty for the $W+$ jets background estimate come from the bias introduced by the jet trigger threshold used to select the multi-jet events and the residual difference in kinematics and flavour composition of the jets in multi-jet events and in events from $W+$ jets production. The total uncertainty on the estimated $W+$ jets background is $\pm 50 \%$.

### 5.1.4 The $Z / \gamma^{*}+$ jets background

The largest cross section for producing two isolated, high$p_{\mathrm{T}}$ leptons comes from the $Z / \gamma^{*} \rightarrow \ell \ell$ process. The background from $Z / \gamma^{*}+$ jets is significantly reduced by the upper bound on $m_{\ell \ell}$ and the requirement of high $E_{\mathrm{T}}^{\text {miss }}$ in the signal region. To correct for potential mis-modelling of the distribution of $E_{\mathrm{T}}^{\mathrm{miss}}$ at high values, a correction factor is derived from the observed difference between the fraction of events passing the $E_{\mathrm{T}}^{\text {miss }}>30 \mathrm{GeV}$ selection in data and Monte Carlo simulation for events with $m_{\ell \ell}$ within 10 GeV of the $Z$ boson mass [41]. As the discrepancy between data and Monte Carlo tends to be larger in events with jets, the correction factor is larger in the 1 -jet channel than in the 0 -jet channel. The flavours of the two leptons in the event also impact the magnitude of the correction factor, since any discrepancies between data and simulation have different sources. In the 1-jet channel, the correction factors are found to be $1.2 \pm 0.4 \pm 0.1^{3}$ in the $e e$ analysis and $2.4 \pm 0.5 \pm 0.2$ in the $\mu \mu$ analysis. Under the assumption that the same correction factors apply to events below the upper bound on $m_{\ell \ell}$, the expected $Z / \gamma^{*}+$ jets background is obtained from the Monte Carlo simulation normalised to the product of the theoretical cross section and the correction factors.

### 5.1.5 Results for the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ search

The expected and observed numbers of events in the $H \rightarrow$ $W W$ analysis for a Higgs boson mass of 170 GeV are shown in Table 2. Three events in total are observed in the 0 -jet

[^44]Table 2 Numbers of expected signal ( $m_{H}=170 \mathrm{GeV}$ ) and background events and the observed numbers of events in the data passing all selections in the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ search. The dataset used in this analysis corresponds to an integrated luminosity of $35 \mathrm{pb}^{-1}$. The uncertainties shown are the statistical and systematic uncertainties respectively

channel for the combined $e e, e \mu$ and $\mu \mu$ final states, compared to an expected number of events from background sources only of $1.70 \pm 0.12 \pm 0.17$. More events are expected in the $\mu \mu$ channel compared to the $e e$ channel due to different lepton identification efficiencies for electrons and muons. In the 1 -jet channel, one event is observed in the data compared to a total number of expected events from background sources of $1.26 \pm 0.13 \pm 0.23$. The observed $m_{\mathrm{T}}$ distributions in data after all selections except the transverse mass cut for the combined $e \mu, e e$ and $\mu \mu$ channels are compared to the expected distributions from simulated events in Fig. 3.

### 5.2 Search for $H \rightarrow W W \rightarrow \ell \nu q q$

The $H \rightarrow W W \rightarrow \ell \nu q q$ analysis uses a dataset corresponding to an integrated luminosity of $35 \mathrm{pb}^{-1}$. Events are selected requiring exactly one lepton with $p_{\mathrm{T}}>30 \mathrm{GeV}$. The missing transverse energy in the event is required to be $E_{\mathrm{T}}^{\mathrm{miss}}>30 \mathrm{GeV}$. Events with fewer than two jets are rejected. ${ }^{4}$ Events with $\geq 4$ jets are treated as a separate search channel, which is however not included in the current combination. The pair of jets with invariant mass closest to the $W$ boson mass is considered to be coming from the $W$ boson and the measured mass must be between 71 GeV and

[^45]91 GeV . The event is rejected if any of the jets in the event is identified as coming from a $b$-quark. The invariant mass of the Higgs boson candidate, $m_{\ell \nu q q}$, is reconstructed with a $W$ boson mass constraint on the lepton-neutrino system giving rise to a quadratic equation. If there are two solutions the one corresponding to the lower longitudinal momentum is taken; if complex the real part is used.

The dominant source of background events in the $H \rightarrow$ $W W \rightarrow \ell \nu q q$ search comes from $W+$ jets production. The contribution from QCD events is estimated by fitting the observed $E_{\mathrm{T}}^{\text {miss }}$ distribution as the sum of templates taken from simulation. Table 3 shows the expected numbers of signal and background events in the signal region, as well as the observation. In the channel with only two and no additional jets, 450 events are observed in the data passing all selection criteria compared to an expected yield from background sources of $450 \pm 41$ events. In the channel with one extra jet 263 events are observed, compared to an expected number of background events of $224 \pm 15$.

The distributions of the invariant mass for the Higgs boson candidates in data are compared to the expected distributions from simulated events in Fig. 4. The $m_{\ell \nu q q}$ background spectrum is modelled with a falling exponential function. The impact of the functional form has been investigated by replacing the single exponential with a double exponential, by histograms taken from simulation, and by a mixture of both methods without significant change in the results. It should be noted that the limit extraction is made using the
exponential fit, not by comparison with the simulated background.

Fig. 3 Distributions of the transverse mass $m_{\mathrm{T}}$ in the 0 -jet channel (a) and 1-jet channel (b) for the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ search after all selections except the transverse mass cut for the combined $e \mu$, ee and $\mu \mu$ channels. The error bars reflect Poisson asymmetric errors. A Higgs boson signal is shown for $m_{H}=170 \mathrm{GeV}$. The selections applied for $m_{H}=170 \mathrm{GeV}$ are indicated by the two vertical dotted lines

Fig. 4 Distributions of the invariant mass $m_{\ell v q q}$ for the $H \rightarrow W W \rightarrow \ell \nu q q$ search after the application of all selection criteria and the W-mass constrained fit. The background fit is shown as a continuous line. In (a) no extra jets are allowed and in (b) one additional jet is required. The Higgs boson signal is shown for $m_{H}=400 \mathrm{GeV}$ and the expected yield is scaled up by a factor of 30 for illustration purposes

Table 3 Numbers of expected signal $\left(m_{H}=400 \mathrm{GeV}\right)$ and background events and the observed numbers of events in the data passing all selections in the $H \rightarrow W W \rightarrow \ell \nu q q$ search. ## 6 Search for $\boldsymbol{H} \rightarrow \boldsymbol{Z} Z^{(*)}$

Three different $H \rightarrow Z^{(*)}$ final states are considered here: $H \rightarrow Z^{(*)} \rightarrow \ell \ell \ell \ell, H \rightarrow Z Z \rightarrow \ell \ell \nu v$ and $H \rightarrow Z Z \rightarrow$ $\ell \ell q q$. In the $H \rightarrow Z Z^{(*)} \rightarrow$ l८८८ search, the excellent energy and momentum resolutions of the ATLAS detector for electrons and muons lead to a narrow expected four-lepton invariant mass peak on top of a continuous background. The dominant background component is the irreducible $\mathrm{ZZ}^{(*)} \rightarrow$ lell process. In the low Higgs boson mass region, where one of the $Z$ bosons is off-shell and decays into a pair of low transverse momentum leptons, the reducible backgrounds from $Z+$ jets production and $t \bar{t}$ production are also important. For Higgs boson masses above $m_{H} \gtrsim 200 \mathrm{GeV}$ both $Z$ bosons are on-shell. In this region the decay modes $H \rightarrow Z Z \rightarrow \ell \ell q q$ and $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$, which have substantially larger branching ratios but also larger backgrounds compared to the $H \rightarrow Z Z^{(*)} \rightarrow \ell \ell \ell \ell$ decay, provide additional sensitivity. The analyses of the $H \rightarrow Z Z \rightarrow \ell \ell q q$ and $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ channels require that both $Z$ bosons are on-shell, which limits the contribution from the reducible backgrounds from $Z+$ jets production and $t \bar{t}$ production. In this paper the $H \rightarrow Z Z \rightarrow \ell \ell q q$ and $H \rightarrow Z Z \rightarrow \ell \ell \nu v$ search channels have been used for Higgs boson masses in the range $200 \mathrm{GeV} \leq m_{H} \leq 600 \mathrm{GeV}$, a range extending beyond the sensitivities of LEP and Tevatron experiments [4, 6]. Further details of the three analyses can be found in Refs. [10, 11].

### 6.1 Search for $H \rightarrow Z^{(*)} \rightarrow$ lौौौ

Candidate events are selected requiring two same-flavour and opposite-charge pairs of leptons. Muons with $p_{\mathrm{T}}>7 \mathrm{GeV}$ and electrons with $p_{\mathrm{T}}>15 \mathrm{GeV}$ are considered, while at least two out of the four leptons must satisfy $p_{\mathrm{T}}>20 \mathrm{GeV}$. All leptons are required to be well separated from each other, isolated from other activity in the tracking detectors and the calorimeters and have low track impact parameters with respect to the primary vertex. At least one of the lepton pairs is required to have an invariant mass within 15 GeV (within 12 GeV if the combined four-lepton mass is high) of the $Z$ boson mass. The requirement on the invariant mass of the second lepton pair varies as a function of the Higgs boson candidate mass, $m_{\ell \ell \ell \ell}$. The effective Higgs boson candidate mass resolution $\sigma\left(m_{H}\right)$, including the intrinsic width at the Higgs boson mass hypothesis being tested, is used to define an allowed range for the reconstructed Higgs boson candidate mass. The latter is required to be within $\pm 5 \sigma\left(m_{H}\right)$ of the tested Higgs boson mass for the event to be considered.

The magnitude of the $Z Z^{(*)}$ background is normalised to the measured $Z$ boson cross section multiplied by the expected ratio of the cross sections $\sigma_{Z Z} / \sigma_{Z}$ from theoretical
calculations [67]. This estimate is independent of the luminosity uncertainty, and the cross section ratio is less affected by theoretical uncertainties than the $\sigma_{Z Z}$ cross section alone. The total uncertainty on the $Z Z^{(*)}$ background estimate is $\pm 15 \%$. The reducible $Z+$ jets background arises predominantly from $Z$ boson production in association with a pair of heavy flavour quarks which decay semi-leptonically. This background is normalised using dedicated control regions in data where the lepton identification requirements are relaxed for the second pair of leptons. The final uncertainty on the $Z+$ jets background is $\pm 20 \%$. The $t \bar{t}$ background is estimated from Monte Carlo simulation and normalised to its theoretical cross section. A total uncertainty of $\pm 25 \%$ is estimated for the $t \bar{t}$ background contribution.

After the application of all selection criteria, no candidate events remain in data for the $H \rightarrow Z^{(*)} \rightarrow \ell \ell \ell \ell$ search at any Higgs boson mass. This is consistent with the small background and signal yields expected with the integrated luminosity of $40 \mathrm{pb}^{-1}$ used in this analysis. The results are shown in Table 4 for two selected Higgs boson masses of $m_{H}=130 \mathrm{GeV}$ and $m_{H}=200 \mathrm{GeV}$. The distribution of the Higgs boson candidate invariant mass, $m_{\ell \ell \ell \ell}$, before applying the lepton impact parameter and isolation requirements is shown in Fig. 5.

Table 4 Expected signal and background event yields in the $H \rightarrow$ $Z Z^{(*)} \rightarrow$ € $\ell \ell$ search within $\pm 5 \sigma\left(m_{H}\right)$ for two selected Higgs boson masses. No events are observed in the data. The dataset used corresponds to a total integrated luminosity of $40 \mathrm{pb}^{-1}$. The quoted uncertainties are combinations of the statistical and systematic uncertainties

6.2 Search for $H \rightarrow Z Z \rightarrow \ell \ell q q$

Events are selected requiring exactly two same-flavour leptons with an invariant mass $76 \mathrm{GeV}<m_{\ell \ell}<106 \mathrm{GeV}$ and at least two jets. To reduce background from top production the missing transverse energy is required to be $E_{\mathrm{T}}^{\mathrm{miss}}<$ 50 GeV . The two jets in the event with the highest individual $p_{\mathrm{T}}$ are required to have an invariant mass, $m_{j j}$, in the range $70 \mathrm{GeV}<m_{j j}<105 \mathrm{GeV}$. Additional background rejection is obtained for high mass by using the fact that the final state jets and leptons are boosted in the directions of the two $Z$ bosons. For Higgs boson searches at $m_{H} \geq 360 \mathrm{GeV}$, the two jets are required to have $p_{\mathrm{T}}>50 \mathrm{GeV}$. Furthermore, the azimuthal angles between the two jets, $\Delta \phi_{j j}$, and between the two leptons, $\Delta \phi_{\ell \ell}$, must both be less than $\pi / 2$.

The Higgs boson candidate mass is constructed from the invariant mass of the two leptons and the two jets in the event, $m_{\ell \ell j j}$. The two jets are constrained to have an invariant mass equal to the $Z$ boson mass to improve the Higgs boson candidate mass resolution.

### 6.2.1 Background estimates for the $H \rightarrow Z Z \rightarrow \ell \ell q q$ search

The dominant background in the $H \rightarrow Z Z \rightarrow \ell \ell q q$ search channel is expected to come from $Z+$ jets production. Other significant sources are $t \bar{t}$ production, multi-jet production and $Z Z / W Z$ production. All backgrounds, except for the multi-jet background, are estimated from Monte Carlo simulation. For the $Z+$ jets and the $t \bar{t}$ backgrounds the predictions from simulation are compared against data in control samples which are dominated by these backgrounds. The $Z+$ jets control region is defined by modifying the $m_{j j}$ selection to instead require $40 \mathrm{GeV}<m_{j j}<70 \mathrm{GeV}$ or $105 \mathrm{GeV}<m_{j j}<150 \mathrm{GeV}$. The $t \bar{t}$ control region is defined by reversing the $E_{\mathrm{T}}^{\text {miss }}$ selection and modifying the $m_{\ell \ell}$ selection to require $60 \mathrm{GeV}<m_{\ell \ell}<76 \mathrm{GeV}$ or $106 \mathrm{GeV}<$ $m_{\ell \ell}<150 \mathrm{GeV}$. Both the $Z+$ jets and the $t \bar{t}$ background estimates from Monte Carlo simulation are found to be in
good agreement with data in the control samples. The contribution from $W+$ jets is very small and assumed to be adequately modelled. The multi-jet background in the electron channel is derived from a sample where the electron identification requirements are relaxed. In the muon channel, the multi-jet background is taken from Monte Carlo after verifying the accuracy of the simulation using a data sample where the two muons in the event are required to have the same charge.

### 6.2.2 Results for the $H \rightarrow Z Z \rightarrow \ell$ €qq search

The $H \rightarrow Z Z \rightarrow \ell \ell q q$ analysis is performed for Higgs boson masses between 200 GeV and 600 GeV in steps of 20 GeV . Table 5 summarises the numbers of estimated background events and observed events in data for the selections below and above $m_{H}=360 \mathrm{GeV}$. The numbers of expected signal events for two representative Higgs boson masses are also shown. For the low mass search, 216 events are observed in data passing all selection criteria compared to an expected number of events from background sources only of $226 \pm 4 \pm 28$ events. The corresponding numbers for the high mass searches are 11 events observed in data compared to an expected yield of $9.9 \pm 0.9 \pm 1.5$ events from background sources only. The distribution of the reconstructed Higgs boson candidate mass $m_{\ell \ell j j}$ for the events passing all of the selection criteria is shown in Fig. 6.

### 6.3 Search for $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$

The $H \rightarrow Z Z \rightarrow \ell \ell \nu v$ final state is characterised by two charged leptons and large $E_{\mathrm{T}}^{\text {miss }}$. Events are selected by requiring exactly two leptons of the same flavour with an invariant mass $76 \mathrm{GeV}<m_{\ell \ell}<106 \mathrm{GeV}$. Events are rejected if any jet is identified as coming from a $b$-quark. The selection has been optimised separately for searches at low ( $m_{H}<280 \mathrm{GeV}$ ) and high ( $m_{H} \geq 280 \mathrm{GeV}$ ) values of the Higgs boson mass. Events are required to have $E_{\mathrm{T}}^{\text {miss }}>66(82) \mathrm{GeV}$ and $\Delta \phi_{\ell \ell}<2.64$ (2.25) radians for

$H \rightarrow Z Z \rightarrow \ell \ell q q$ search for low mass ( $m_{H}<360 \mathrm{GeV}$ ) and high mass ( $m_{H} \geq 360 \mathrm{GeV}$ ) selections. The signal, quoted at two mass points, includes small contributions from llll and $\ell \ell \nu v$ decays. Electron and muon channels are combined. The uncertainties shown are the statistical and systematic uncertainties, respectively

Fig. 6 Distribution of $m_{\ell \ell j j}$ for events passing all of the selection criteria in the $H \rightarrow Z Z \rightarrow \ell \ell q q$ search. The expected yield for a Higgs boson with a mass $m_{H}=300 \mathrm{GeV}$ is also shown, multiplied by a factor of 20 for illustrative purposes. The contribution labelled "Other" is mostly from top events but includes also QCD multijet production
the low (high) mass region. For the low mass region $\Delta \phi_{\ell \ell}>$ 1 radian is also required. The Higgs boson candidate transverse mass is obtained from the invariant mass of the two leptons and the missing transverse energy.

### 6.3.1 Background estimates for the $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ search

A major background in the $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ search channel comes from di-boson production and is estimated from Monte Carlo simulation. Background contributions from $t \bar{t}$ and $W+$ jets production are also obtained from Monte Carlo simulation, and the estimated yields are verified by comparing with the number of observed events in dedicated control samples in the data. Both the $t \bar{t}$ and the $W+$ jets con-

Table 6 Numbers of events estimated from background, observed in data and expected from signal in the $H \rightarrow Z Z \rightarrow \ell \ell \nu v$ search for low mass ( $m_{H}<280 \mathrm{GeV}$ ) and high mass ( $m_{H} \geq 280 \mathrm{GeV}$ ) selections. Electron and muon channels are combined. The expected signal events
trol regions are defined by modifying the $m_{\ell \ell}$ selection to instead require $60 \mathrm{GeV}<m_{\ell \ell}<76 \mathrm{GeV}$ or $106 \mathrm{GeV}<$ $m_{\ell \ell}<150 \mathrm{GeV}$. The $t \bar{t}$ control region also requires that the events pass $E_{\mathrm{T}}^{\text {miss }}>20 \mathrm{GeV}$ and that at least one jet is identified as coming from a $b$-quark. The $W+$ jets control region instead requires $E_{\mathrm{T}}^{\text {miss }}>36 \mathrm{GeV}$ and that no jets in the events are identified as coming from a $b$-quark. The observed event yields in the control regions for $t \bar{t}$ and $W+$ jets production are in good agreement with the predictions from the Monte Carlo simulation. The background from $Z+$ jets production is estimated from Monte Carlo simulation after comparison studies of the $E_{\mathrm{T}}^{\text {miss }}$ distribution between Monte Carlo and data. The multi-jet background in the electron channel is derived from a sample where the electron identification requirements are relaxed. In the muon channel, the multi-jet background is estimated from a simulated sample of semi-leptonically decaying $b$ - and $c$-quarks and found to be negligible after the application of the $m_{\ell \ell}$ selection. This was verified in data using leptons with identical charges.

### 6.3.2 Results for the $H \rightarrow Z Z \rightarrow \ell \ell \nu v$ search

The $H \rightarrow Z Z \rightarrow \ell \ell \nu v$ analysis is performed for Higgs boson masses between 200 GeV and 600 GeV in steps of 20 GeV . Table 6 summarises the numbers of events observed in the data, the estimated numbers of background events and the expected numbers of signal events for two selected $m_{H}$ values. For the low mass selections, five events are observed in data compared to an expected number of events from background sources only of $5.8 \pm 0.5 \pm 1.3$. The corresponding results for the high mass selections are five events observed in data compared to an expected yield of $3.5 \pm 0.4 \pm 0.8$ events from background sources only. In addition to the $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ decays, several other Higgs boson channels give a non-negligible contribution to
include minor additional contributions from $H \rightarrow Z Z \rightarrow \ell \ell q q, H \rightarrow$ $Z Z^{(*)} \rightarrow \ell \ell \ell \ell$ and one which can be large from $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$. The uncertainties shown are the statistical and systematic uncertainties, respectively

| Source | Low mass selection | High mass selection |

| Observed | 5 | 5 |

the total expected signal yield. In particular, $H \rightarrow W W^{(*)} \rightarrow$ $\ell \nu \ell \nu$ decays can lead to final states that are very similar to $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ decays. They are found to contribute significantly to the signal yield at low $m_{H}$ values. The expected number of events from $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ decays relative to that from $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ decays is $76 \%$ for $m_{H}=200 \mathrm{GeV}$ and $9 \%$ for $m_{H}=300 \mathrm{GeV}$. The kinematic selections prevent individual candidates from being accepted by both searches. The $E_{\mathrm{T}}^{\text {miss }}$ distribution before vetoing events with low $E_{\mathrm{T}}^{\text {miss }}$ is shown in Fig. 7.

Fig. 7 Distribution of missing transverse energy in the $H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ search in the electron channel before vetoing events with low $E_{\mathrm{T}}^{\text {miss }}$. The expected yield for a Higgs boson with $m_{H}=400 \mathrm{GeV}$ is also shown. The distribution in the muon channel is similar with four events seen which have $E_{\mathrm{T}}^{\text {miss }}$ above 80 GeV

Table 7 Summary of systematic uncertainties (in percent) of the signal yield. The correlated systematic uncertainties are given in detail, the uncorrelated ones are lumped together. The uncertainties are evaluated for a Higgs boson mass of 115 GeV for the $H \rightarrow \gamma \gamma$ channel, 160 GeV for $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu, 200 \mathrm{GeV}$ for the $H \rightarrow Z Z^{(*)} \rightarrow$ lell and 400 GeV for the remaining channels. Systematic errors

## 7 Combination method

The limit-setting procedure uses the power-constrained profile likelihood method known as the Power Constrained Limit, PCL [13, 14, 68]. This method is preferred to the more familiar $\mathrm{CL}_{s}[15]$ technique because the constraint is more transparently defined and it has reduced overcoverage resulting in a more precise meaning of the quoted confidence level. The resulting PCL median limits have been found to be around $20 \%$ tighter than those obtained with the $\mathrm{CL}_{s}$ method in several Higgs searches. The application of the PCL method to each of the individual Higgs boson search channels is described in Refs. [7-11]. A similar procedure is used here. The individual analyses are combined by maximising the product of the likelihood functions for each channel and computing a likelihood ratio. A single signal normalisation parameter $\mu$ is used for all analyses, where $\mu$ is the ratio of the hypothesised cross section to the expected Standard Model cross section.

Each channel has sources of systematic uncertainty, some of which are common with other channels. Table 7 lists the common sources of systematic uncertainties, which are taken to be $100 \%$ correlated with other channels. Let the search channels be labelled by $l(l=H \rightarrow \gamma \gamma, H \rightarrow W W$, $\ldots$ ), the background contribution, $j$, to channel $l$ by $j_{l}$ and the systematic uncertainties by $i$ ( $i=$ luminosity, jet energy scale, ...). The relative magnitude of the effect on the Higgs boson signal yield in channel $l$ due to systematic uncertainty $i$ is then denoted by $\epsilon_{l i}^{s}$, and on background contribution $j_{l}$, $\epsilon_{j l i}^{b}$. The $\epsilon_{l i}$ 's are constants; an individual $\epsilon_{l i}^{s}$ can be zero
marked with a dash are neglected. In the three channels, the impact of the lepton energy scale and resolution uncertainties on the efficiency was found to be negligible, but they can still influence the fit via the signal distributions. In the $H \rightarrow W W \rightarrow \ell v q q$ channel a jet energy scale uncertainty can only decrease the efficiency; the resolution uncertainty is negligible in comparison

if the channel in question is not affected by this source of systematic uncertainty. A common systematic uncertainty, i, which is shared between channels $l$ and $l^{\prime}$ implies that $\epsilon_{l i}^{s}$ and $\epsilon_{l^{\prime} i}^{s}$ are both different from zero. If a systematic source $i$ is shared between the signal in channel $l$ and background contribution $j_{l}$ then both $\epsilon_{l i}^{s}$ and $\epsilon_{j l i}^{b}$ are non-zero. For each source of systematic uncertainty $i$ there is a corresponding nuisance parameter $\delta_{i}$ and an associated auxiliary measurement $m_{i}$ on a control sample (e.g. sidebands in a mass spectrum) that is used to constrain the parameter. The $\delta_{i}$ and $m_{i}$ are scaled so that $\delta_{i}=0$ corresponds to the nominal expectation and $\delta_{i}= \pm 1$ corresponds to the $\pm 1 \sigma$ variations of the source. When constructing ensembles for statistical evaluation, each $m_{i}$ is sampled according to $G\left(m_{i} \mid \delta_{i}, 1\right)$, the standard normal distribution. Using this notation, the total number of expected events in the signal region for channel $l$ is given by:

$$
\begin{align*}
N_{l}^{\exp }= & \mu L \sigma_{l} \prod_{i}\left(1+\epsilon_{l i}^{s} \delta_{i}\right) \\
& +\sum_{j} b_{j l} \prod_{i}\left(1+\epsilon_{j l i}^{b} \delta_{i}\right) \tag{2}
\end{align*}
$$

for luminosity $L$, Standard Model cross sections $\sigma_{l}$ (including efficiencies and acceptances), and expected backgrounds $b_{j l}$. Background estimates $b_{j l}$ may come either from Monte Carlo simulations or from control regions in which the expected number of events, $\bar{n}_{j l}$, is proportional to the expected background, via $b_{j l}=\alpha_{j l} \bar{n}_{j l}$. Given the number of observed events in the signal region $N_{l}^{\text {obs }}$, the likelihood function can be written as:
$\mathcal{L}_{l}=\operatorname{Pois}\left(N_{l}^{\mathrm{obs}} \mid N_{l}^{\mathrm{exp}}\right) \prod_{j_{l}} \operatorname{Pois}\left(n_{j l} \mid \bar{n}_{j l}\right) \prod_{i} G\left(m_{i} \mid \delta_{i}, 1\right)$,
where $n_{j l}$ are the observed numbers of background events in the control regions and $\operatorname{Pois}(x \mid y)$ is the Poisson probability of observing $x$ events given an expectation $y$.

The combined likelihood is given by the product of the individual likelihoods for each channel:
$\mathcal{L}=\prod_{l} \mathcal{L}_{l}$,
where $l$ is implicitly an index over the individual histogram bins within the channels that used a binned distribution of a discriminating variable.

The profile likelihood ratio
$\tilde{\lambda}(\mu)= \begin{cases}\frac{\mathcal{L}(\mu, \hat{\hat{\theta}}(\mu))}{\mathcal{L}(\hat{\mu}, \hat{\hat{\theta}})}, & \hat{\mu} \geq 0, \\ \frac{\mathcal{L}(\mu, \hat{\hat{\theta}}(\mu))}{\mathcal{L}(0, \hat{\theta}(0))}, & \hat{\mu}<0,\end{cases}$
is computed by maximising the likelihood function twice: in the numerator $\mu$, the ratio of the hypothesised cross section to the expected Standard Model cross section, is restricted
to a particular value and in the denominator $\mu$ is allowed to float. The set of all nuisance parameters $\delta_{i}$ and $\bar{n}_{j l}$ is denoted $\theta$. The maximum likelihood estimates of $\mu$ and $\theta$ are denoted $\hat{\mu}$ and $\hat{\theta}$, while $\hat{\hat{\theta}}(\mu)$ denotes the conditional maximum likelihood estimate of all nuisance parameters with $\mu$ fixed. In this analysis the range of $\mu$ is restricted to the physically meaningful regime, i.e. it is not allowed to be negative. The test statistic $\tilde{q}_{\mu}$ is defined to be

$$
\begin{align*}
\tilde{q}_{\mu} & = \begin{cases}-2 \ln \tilde{\lambda}(\mu), & \hat{\mu} \leq \mu \\
0, & \hat{\mu}>\mu\end{cases} \\
& = \begin{cases}-2 \ln \frac{\mathcal{L}(\mu, \hat{\hat{\theta}}(\mu))}{\mathcal{L}(0, \hat{\theta}(0))}, & \hat{\mu}<0 \\
-2 \ln \frac{\mathcal{L}(\mu, \hat{\hat{\theta}}(\mu))}{\mathcal{L}(\hat{\mu}, \hat{\theta})}, & 0 \leq \hat{\mu} \leq \mu \\
0, & \hat{\mu}>\mu\end{cases} \tag{4}
\end{align*}
$$

Monte Carlo pseudo-experiments are generated to construct the probability density function $f\left(\tilde{q}_{\mu} \mid \mu, \hat{\hat{\theta}}(\mu)\right)$ under an assumed signal strength $\mu$, giving a $p$-value
$p_{\mu}=\int_{\tilde{q}_{\mu, \mathrm{obs}}}^{\infty} f\left(\tilde{q}_{\mu} \mid \mu, \hat{\hat{\theta}}(\mu)\right) \mathrm{d} \tilde{q}_{\mu}$.
To find the upper limit on $\mu$ at $95 \%$ confidence level, $\mu_{\text {up }}$, $\mu$ is varied to find $p_{\mu_{\text {up }}}=5 \%$. Similarly, background-only Monte Carlo pseudo-experiments are used to find the median $\mu_{\text {med }}$ along with the $\pm 1 \sigma$ and $+2 \sigma$ bands expected in the absence of a signal. The procedure so far can be referred to as a $\mathrm{CL}_{s b}$ limit. To protect against excluding the (signal) null hypothesis in cases of downward fluctuations of the background, the observed limit is not allowed to fluctuate below the $-1 \sigma$ expected limit. This is equivalent to restricting the interval to cases in which the statistical power of the test of $\mu$ against the alternative $\mu=0$ is at least $16 \%$. This is referred to as a Power Constrained Limit. If the observed limit fluctuates below the $16 \%$ power, the quoted limit is $\mu_{\text {med }}-1 \sigma$.

## 8 Systematic uncertainties in the combination

The systematic uncertainty related to the luminosity is $\pm 3.4 \%$ and is fully correlated among all channels. It affects background estimates that are normalised to their theoretical cross sections; for most channels this is only true for backgrounds that are known to be small. In the $H \rightarrow Z Z \rightarrow \ell \ell \nu v$ and $H \rightarrow Z Z \rightarrow \ell \ell q q$ channels major backgrounds are normalised to their theoretical cross sections, but in the latter case this is only done after comparing with control regions.

Sources of systematic uncertainty related to the event reconstruction are correlated between all the Higgs boson search channels. The uncertainty on the efficiency to reconstruct electrons varies between $2.5 \%$ (central high- $p_{\text {T }}$ elec-
trons) and $16 \%$ ( $p_{\mathrm{T}}$ near 15 GeV , the lowest value used here) but it is assumed to be completely correlated. For muons the efficiency uncertainty ranges between $0.4 \%$ and $2 \%$. The jet systematic errors are typically larger for the channels where jets are explicitly required. They are dominated by the jet energy scale as the resolution effects tend to partially cancel and the $E_{\mathrm{T}}^{\text {miss }}$ uncertainties are largely by-products of the uncertainties already discussed.

The effect on the signal yield in each channel of the major sources of systematic uncertainty is summarised in Table 7. Uncertainties are treated as either uncorrelated or $100 \%$ correlated among channels. The largest uncorrelated errors are photon isolation in $H \rightarrow \gamma \gamma$ and jet rates in $H \rightarrow W W^{(*)} \rightarrow$ $\ell \nu \ell \nu$; the latter is in principle correlated with the $H \rightarrow$ $W W \rightarrow \ell \nu q q$ channel but these channels are never used in the same mass region. Most backgrounds have been estimated by means of independent control samples; these estimates are assumed to be uncorrelated between the channels.

Systematic uncertainties on the signal shape are accounted for in the $H \rightarrow \gamma \gamma, H \rightarrow Z Z \rightarrow \ell \ell q q$ and $H \rightarrow$ $Z Z \rightarrow \ell \ell \nu \nu$ channels by considering three possible distributions and interpolating between them. Small signal shape systematic uncertainties in the $H \rightarrow Z^{(*)} \rightarrow \ell \ell \ell \ell$ and $H \rightarrow W W \rightarrow \ell \nu q q$ channels are neglected. For $m_{H} \geq$ 200 GeV the correlations in the shape systematics are taken into account and are treated as correlated with the signal normalisation uncertainties.

The width of the Higgs boson signal at high mass is taken from the PYTHIA Monte Carlo [53]. This underestimates the width and the accepted cross section is conservatively scaled down by the ratio of the widths given in Ref. [69], which reached a maximum of $8 \%$ at 600 GeV , in all plots showing a ratio to the Standard Model.

The systematic uncertainty coming from the total theoretical Higgs boson cross section is not included in the combination and is shown separately in the figures as an uncertainty on the predicted cross section.

## 9 Combination

Each Higgs boson search channel is only sensitive for a range of Higgs boson masses. The ranges in which the various channels have been analysed are detailed in Table 8.

Table 8 The Higgs boson mass regions in which individual search channels have been analysed

| Mode | Mass range, GeV |
| :--- | :--- |
| $H \rightarrow \gamma \gamma$ | $110-140$ |
| $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ | $120-200$ |
| $H \rightarrow W W \rightarrow \ell \nu q q$ | $220-600$ |
| $H \rightarrow Z Z^{(*)} \rightarrow \ell \ell \ell$ | $120-600$ |
| $H \rightarrow Z Z \rightarrow \ell \ell \nu$ | $200-600$ |
| $H \rightarrow Z Z \rightarrow \ell \ell q q$ | $200-600$ |

Fig. 8 The expected and observed cross section limits, normalized to the Standard Model cross section, as a function of the Higgs boson mass for the individual search channels. The visually most apparent difference between expected and observed is in the $H \rightarrow W W \rightarrow \ell \nu q q$ channel, which has a deficit approaching one sigma both at 320 GeV and 480 GeV . These results use the profile likelihood method with a
power constraint (PCL). The limits are calculated at the masses marked with symbols. The lines between the points are to guide the eye. The grey horizontal bands show the uncertainty on the Standard Model cross section prediction, with the inner region highlighting the contribution of QCD scale uncertainties

In the $H \rightarrow \gamma \gamma, H \rightarrow Z Z \rightarrow \ell \ell \nu \nu$ and $H \rightarrow Z Z \rightarrow \ell \ell q q$ channels, the final result is extracted from a fit of signal plus background contributions to the observed Higgs boson candidate mass distributions. In all other channels, limits are extracted from a comparison of the numbers of observed events in one or more signal regions to the numbers of estimated background events.

The individual channels are shown in Fig. 8 in terms of the observed and the expected upper limits on $\sigma / \sigma_{\mathrm{S} M}$ at the $95 \%$ confidence level. The step with which the limit is extracted, $5-10 \mathrm{GeV}$, does not match the $H \rightarrow \gamma \gamma$ resolution which has a full-width at half maximum of 4.4 GeV . However, it was established in Ref. [7] that no important fluctuations are missed.

The search channels are grouped by the primary Higgs boson decay mode searched for, $\gamma \gamma, W W$ or $Z Z$, and the limit on each mode is extracted in terms of the cross section for the process intended. Some channels have a contribution from signal modes other then the intended one. This is only significant for the $H \rightarrow Z Z \rightarrow \ell \ell \nu v$ search, as discussed in Sect. 6.3, and implies that the $Z Z$ limit assumes the Standard Model ratio between $H$ to $Z Z$ and $H$ to $W W$ decays. In addition, the $W W$ search requires zero or one jet and is essentially designed for a spin-zero object produced largely via gluon fusion. The upper limits at $95 \%$ confidence level observed and expected in the absence of a signal are compared with the cross section expected for a Standard Model Higgs boson in Fig. 9.

Fig. 9 The expected and observed $95 \%$ PCL limits on the total cross section of a particle produced like the Standard Model Higgs boson and decaying with the width predicted by PYTHIA[53] to pairs of bosons: $\gamma \gamma, W W$ or $Z Z$. The limits are calculated at the masses marked with symbols. The lines between the points are to guide the eye. The coloured bands show the cross section predictions and their uncertainties, with the inner region highlighting the contribution of QCD scale uncertainties

Fig. 10 The expected and observed upper limits on the total cross section divided by the expected Standard Model Higgs boson cross section. This is a $95 \%$ PCL limit. The green and yellow bands indicate the range in which the limit is expected to lie in the absence of a signal. The fine dotted line marks the results obtained using $\mathrm{CL}_{s b}$, and the application of the power constraint gives the solid line. The limits are calculated at the masses marked with symbols and the lines between the points are to guide the eye

Table 9 The signal cross sections, in multiples of the Standard Model cross section, that are excluded, and expected to be excluded, at $95 \% \mathrm{CL}$. The expected variation at $\pm 1 \sigma$ is also given for the PCL limits. The bold numbers show the limit which should be used; for mass of 500 and 520 GeV the power constraint is applied. The likelihood ratio of signal plus background to background is also shown, as is the $p$-value (modified to go between 0 and 1) for $\mu=0$, which can be used to estimate the discovery significance

Fig. 11 Same as Fig. 10, except that limits calculated using the $\mathrm{CL}_{s}$ procedure are added. As expected, when the observed limits fluctuate up, both methods converge, but downward fluctuations are less pronounced with $\mathrm{CL}_{s}$ due to its larger over-coverage. The fine dotted line marks the results obtained using $\mathrm{CL}_{s b}$, and the application of the power constraint gives the solid line. The limits are calculated at the masses marked with symbols. The lines between the points are to guide the eye. The regions excluded by the combined LEP experiments [4] and the Tevatron experiments [6] are indicated

Fig. 12 Same as Fig. 10, but comparing the excluded cross section to the expected one when a fourth generation of high mass quarks and leptons with Standard Model-like couplings to the Higgs boson are included in the cross section calculations. The arrows indicate the regions excluded by the CMS experiment [12] and the Tevatron experiments [70]. The point set at 500 GeV is at the limit allowed by the power constraint. The limits are calculated at the masses marked with symbols. The lines between the points are to guide the eye

| 300 | 1.5 | 0.4 | 1.1 | 1.6 | 1.9 |  |  |  |  |  |  |

The combination of all channels is tested and the $p_{\mu=0}$ in these fits varies between $7 \%$ and $89 \%$, which does not suggest the presence of a signal. The combination of all channels is shown in Fig. 10 in terms of the observed and the expected upper limit at the $95 \%$ confidence level. The statistical accuracy of the toy Monte Carlo used to extract the limits is about $5 \%$ on the observed limits and $7 \%$ on the expected ones, with somewhat larger variation on the edges of the one and two $\sigma$ bands.

The excluded signal strength as a function of $m_{H}$ is summarised in Table 9, using the PCL method. The results are also calculated using the $\mathrm{CL}_{s}$ method for comparison pur-
poses: the extracted limits from both procedures are shown in Fig. 11. Also given is the profile likelihood ratio of a Standard Model Higgs boson to background only and the consistency of the data with the background-only hypothesis,
$p_{\mu=0}$.
The results have been interpreted in terms of the heavy mass fourth generation model introduced in Sect. 3. This involves rescaling the gluon fusion component of the production cross section and the Higgs boson decay branching ratios. The limits are shown in Fig. 12. This model is excluded for Higgs boson masses between 140 GeV and 185 GeV ,
while the region in which exclusion might be expected is between 136 GeV and 208 GeV .

The excluded cross section ratios are summarised in Table 10 .

## 10 Conclusions

The ATLAS search for the Standard Model Higgs boson in the mass range from 110 GeV to 600 GeV in 35 to $40 \mathrm{pb}^{-1}$ of data recorded in 2010 has been presented. With this luminosity there is not sufficient sensitivity to exclude the Standard Model Higgs boson, nor is there any evidence of an excess of events over the predicted background rates. However, these results give the most stringent constraints to date for Higgs boson masses above 250 GeV and are close to the Tevatron limits [6] at intermediate masses.

An extension of the Standard Model, assuming the Higgs mechanism and adding a fourth generation of heavy quarks and leptons, is excluded for Higgs boson masses between 140 and 185 GeV .

Acknowledgements We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

# Search for charged Higgs bosons decaying via $H^{ \pm} \rightarrow \tau \nu$ in $t \bar{t}$ events using $p p$ collision data at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

## The ATLAS collaboration

E-mail: atlas.publications@cern.ch

Abstract: The results of a search for charged Higgs bosons are presented. The analysis is based on $4.6 \mathrm{fb}^{-1}$ of proton-proton collision data at $\sqrt{s}=7 \mathrm{TeV}$ collected by the ATLAS experiment at the Large Hadron Collider, using top quark pair events with a $\tau$ lepton in the final state. The data are consistent with the expected background from Standard Model processes. Assuming that the branching ratio of the charged Higgs boson to a $\tau$ lepton and a neutrino is $100 \%$, this leads to upper limits on the branching ratio of top quark decays to a $b$ quark and a charged Higgs boson between $5 \%$ and $1 \%$ for charged Higgs boson masses ranging from 90 GeV to 160 GeV , respectively. In the context of the $m_{h}^{\max }$ scenario of the MSSM, $\tan \beta$ above 12-26, as well as between 1 and 2-6, can be excluded for charged Higgs boson masses between 90 GeV and 150 GeV .

Keywords: Hadron-Hadron Scattering

## 1 Introduction

Charged Higgs bosons $\left(H^{+}, H^{-}\right)$are predicted by several non-minimal Higgs scenarios, such as Two Higgs Doublet Models (2HDM) [1] or models containing Higgs triplets [2-6]. As the Standard Model (SM) does not contain any elementary charged scalar particle, the observation of a charged Higgs boson ${ }^{1}$ would clearly indicate new physics beyond the SM. For instance, supersymmetric models predict the existence of charged Higgs bosons. In a type-II 2HDM, such as the Higgs sector of the Minimal Supersymmetric extension of the Standard Model (MSSM) [7-11], the main $H^{+}$production mode at the Large Hadron Collider (LHC) is through top quark decays $t \rightarrow b H^{+}$, for charged Higgs boson masses ( $m_{H^{+}}$) smaller than the top quark mass $\left(m_{\text {top }}\right)$. The dominant source of top quarks at the LHC is through $t \bar{t}$ production. The cross section for $H^{+}$production from single top quark events is much smaller and is not considered here. For $\tan \beta>2$, where $\tan \beta$ is the ratio of the vacuum expectation values of the two Higgs doublets, the charged Higgs boson decay via $H^{+} \rightarrow \tau \nu$ is dominant and remains sizeable for $1<\tan \beta<2$ [12]. In this paper, $\mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)=100 \%$ is assumed, unless otherwise specified. Under this assumption, the combined LEP lower limit for the charged Higgs boson mass is about 90 GeV [13]. The Tevatron experiments placed upper limits on $\mathcal{B}\left(t \rightarrow b H^{+}\right)$in the $15-20 \%$ range for $m_{\mathrm{H}^{+}}<m_{\text {top }}[14,15]$.

This paper describes a search for charged Higgs bosons with masses in the range 90160 GeV , using $t \bar{t}$ events with a leptonically or hadronically decaying $\tau$ lepton in the final state, i.e. with the topology shown in figure 1. Charged Higgs bosons are searched for in a model-independent way, hence exclusion limits are given in terms of $\mathcal{B}\left(t \rightarrow b H^{+}\right)$, as well as in the $m_{h}^{\max }$ scenario [16] of the MSSM. The results are based on $4.6 \mathrm{fb}^{-1}$ of data from $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$, collected in 2011 with the ATLAS experiment [17] at the LHC. Three final states, which are expected to yield the highest sensitivity, are analysed:

- lepton+jets: $t \bar{t} \rightarrow b \bar{b} W H^{+} \rightarrow b \bar{b}\left(q \bar{q}^{\prime}\right)\left(\tau_{\text {lep }} \nu\right)$, i.e. $W$ decays hadronically and $\tau$ decays into an electron or a muon, with two neutrinos;
- $\tau+$ lepton: $t \bar{t} \rightarrow b \bar{b} W H^{+} \rightarrow b \bar{b}(l \nu)\left(\tau_{\text {had }} \nu\right)$, i.e. $W$ decays leptonically (with $l=e, \mu$ ) and $\tau$ decays hadronically;
- $\tau+$ jets: $t \bar{t} \rightarrow b \bar{b} W H^{+} \rightarrow b \bar{b}\left(q \bar{q}^{\prime}\right)\left(\tau_{\text {had }} \nu\right)$, i.e. both $W$ and $\tau$ decay hadronically.

In section 2, the data and simulated samples used in this analysis are described. In section 3, the reconstruction of physics objects in ATLAS is discussed. Sections 4-6 present results obtained in the lepton + jets, $\tau+$ lepton and $\tau+$ jets channels, respectively. Systematic uncertainties are discussed in section 7 , before exclusion limits in terms of $\mathcal{B}\left(t \rightarrow b H^{+}\right)$ and $\tan \beta$ are presented in section 8 . Finally, a summary is given in section 9.

[^46]

Figure 1. Example of a leading-order Feynman diagram for the production of $t \bar{t}$ events arising from gluon fusion, where a top quark decays to a charged Higgs boson, followed by the decay $H^{+} \rightarrow \tau \nu$.

## 2 Data and simulated events

The ATLAS detector [17] consists of an inner tracking detector with a coverage in pseudorapidity ${ }^{2}$ up to $|\eta|=2.5$, surrounded by a thin 2 T superconducting solenoid, a calorimeter system extending up to $|\eta|=4.9$ for the detection of electrons, photons and hadronic jets, and a large muon spectrometer extending up to $|\eta|=2.7$ that measures the deflection of muon tracks in the field of three superconducting toroid magnets. A three-level trigger system is used. The first level trigger is implemented in hardware, using a subset of detector information to reduce the event rate to a design value of at most 75 kHz . This is followed by two software-based trigger levels, which together reduce the event rate to about 300 Hz .

Only data taken with all ATLAS sub-systems operational are used; this results in an integrated luminosity of $4.6 \mathrm{fb}^{-1}$ for the 2011 data-taking period. The integrated luminosity has an uncertainty of $3.9 \%$, measured as described in refs. [18, 19] and based on the whole 2011 dataset. Following basic data quality checks, further event cleaning is performed by demanding that no jet is consistent with having originated from instrumental effects, such as large noise signals in one or several channels of the hadronic end-cap calorimeter, coherent noise in the electromagnetic calorimeter, or non-collision backgrounds. In addition, events are discarded if the reconstructed vertex with the largest sum of squared track momenta has fewer than five associated tracks with transverse momenta $p_{\mathrm{T}}>400 \mathrm{MeV}$.

The background processes that enter this search include the SM pair production of top quarks $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$, as well as the production of single top quark, $W+$ jets, $Z / \gamma^{*}+$ jets, diboson and multi-jet events. Data-driven methods are used in order to estimate the multijet background, as well as the backgrounds with intrinsic missing transverse momentum where electrons or jets are misidentified as hadronically decaying $\tau$ leptons. The modelling of SM $t \bar{t}$ and single top quark events is performed with MC@NLO [20], except for the

[^47]| Process | Generator | Cross section [pb] |  |
| :--- | :--- | :--- | :--- |
| SM $t \bar{t}$ with at least one lepton $\ell=e, \mu, \tau$ | MC@NLO $[20]$ | 91 | $[26]$ |
| Single top quark $t$-channel (with $\ell$ ) | AcerMC | $[21]$ | 21 |
| Single top quark $s$-channel (with $\ell)$ | MC@NLO $[20]$ | 1.5 | $[27]$ |
| Single top quark $W t$-channel (inclusive) | MC@NLO $[20]$ | 16 | $[29]$ |
| $W \rightarrow \ell \nu$ | ALPGEN $[31]$ | $3.1 \times 10^{4}$ | $[33]$ |
| $Z / \gamma^{*} \rightarrow \ell$ with $m(\ell \ell)>10 \mathrm{GeV}$ | ALPGEN $[31]$ | $1.5 \times 10^{4}$ | $[34]$ |
| $W W$ | HERWIG $[23]$ | 17 | $[35]$ |
| $Z Z$ | HERWIG $[23]$ | 1.3 | $[35]$ |
| $W Z$ | HERWIG | $[23]$ | 5.5 |
| $H^{+}$signal with $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$ | PYTHIA | $[25]$ | 16 |

Table 1. Cross sections for the simulated processes and generators used to model them.
$t$-channel single top quark production where AcerMC [21] is used. The top quark mass is set to 172.5 GeV and the set of parton distribution functions used is CT10 [22]. For the events generated with MC@NLO, the parton shower, hadronisation and underlying event are added using HERWIG [23] and JIMMY [24]. PYTHIA [25] is instead used for events generated with AcerMC. Inclusive cross sections are taken from the approximate next-to-next-to-leading-order (NNLO) predictions for $t \bar{t}$ production [26], for single top quark production in the $t$-channel and $s$-channel [27, 28], as well as for $W t$ production [29]. Overlaps between $W t$ and SM $t \bar{t}$ final states are removed [30]. Single vector boson ( $W$ and $Z / \gamma^{*}$ ) production is simulated with ALPGEN [31] interfaced to HERWIG and JIMMY, using CTEQ6.1 [32] parton distribution functions. The additional partons produced in the matrix element part of the event generation can be light partons or heavy quarks. In the latter case, dedicated samples with matrix elements for the production of massive $b \bar{b}$ or $c \bar{c}$ pairs are used. Diboson events ( $W W, W Z$ and $Z Z$ ) are generated using HERWIG. The cross sections are normalised to NNLO predictions for $W$ and $Z / \gamma^{*}$ production [33, 34] and to next-to-leading-order (NLO) predictions for diboson production [35].

The SM background samples are summarised in table 1. In addition, three types of signal samples are produced with PYTHIA for $90 \mathrm{GeV}<m_{H^{+}}<160 \mathrm{GeV}: t \bar{t} \rightarrow b \bar{b} H^{+} W^{-}$, $t \bar{t} \rightarrow b \bar{b} H^{-} W^{+}$and $t \bar{t} \rightarrow b \bar{b} H^{+} H^{-}$, where the charged Higgs bosons decay as $H^{+} \rightarrow \tau \nu$. The cross section for each of these three processes depends only on the total $t \bar{t}$ production cross section ( 167 pb ) and the branching ratio $\mathcal{B}\left(t \rightarrow b H^{+}\right)$. TAUOLA [36] is used for $\tau$ decays, and PHOTOS [37] is used for photon radiation from charged leptons.

The event generators are tuned in order to describe the ATLAS data. The parameter sets AUET2 [38] and AUET2B [39] are used for events for which hadronisation is simulated using HERWIG/JIMMY and PYTHIA, respectively. To take into account the presence of multiple interactions (around nine, on average) occurring in the same and neighbouring
bunch crossings (referred to as pile-up), simulated minimum bias events are added to the hard process in each generated event. Prior to the analysis, simulated events are reweighted in order to match the distribution of the average number of pile-up interactions in the data. All generated events are propagated through a detailed GEANT4 simulation [40, 41] of the ATLAS detector and are reconstructed with the same algorithms as the data.

## 3 Physics object reconstruction

### 3.1 Electrons

Electrons are reconstructed by matching clustered energy deposits in the electromagnetic calorimeter to tracks reconstructed in the inner detector. The electron candidates are required to meet quality requirements based on the expected shower shape [42], to have a transverse energy $E_{\mathrm{T}}>20 \mathrm{GeV}$ and to be in the fiducial volume of the detector, $|\eta|<2.47$ (the transition region between the barrel and end-cap calorimeters, $1.37<|\eta|<1.52$, is excluded). Additionally, $E_{\mathrm{T}}$ and $\eta$-dependent calorimeter (tracking) isolation requirements are imposed in a cone with a radius ${ }^{3} \Delta R=0.2(0.3)$ around the electron position, excluding the electron object itself, with an efficiency of about $90 \%$ for true isolated electrons.

### 3.2 Muons

Muon candidates are required to contain matching inner detector and muon spectrometer tracks [43], as well as to have $p_{\mathrm{T}}>15 \mathrm{GeV}$ and $|\eta|<2.5$. Only isolated muons are accepted by requiring that the transverse energy deposited in the calorimeters (the transverse momentum of the inner detector tracks) in a cone of radius $\Delta R=0.2(0.3)$ around the muon amounts to less than $4 \mathrm{GeV}(2.5 \mathrm{GeV})$. The energy and momentum of the muon are excluded from the cone when applying these isolation requirements.

### 3.3 Jets

Jets are reconstructed using the anti- $k_{t}$ algorithm [44, 45] with a size parameter value of $R=0.4$. The jet finder uses reconstructed three-dimensional, noise-suppressed clusters of calorimeter cells [46]. Jets are calibrated to the hadronic energy scale with correction factors based on simulation [47, 48]. A method that allows for the identification and selection of jets originating from the hard-scatter interaction through the use of tracking and vertexing information is used [49]. This is referred to as the "Jet Vertex Fraction" (JVF), defined as the fraction of the total momentum of the charged particle tracks associated to the jet which belongs to tracks that are also compatible with the primary vertex. By convention, jets with no associated tracks are assigned a JVF value of -1 in order to keep a high efficiency for jets at large values of $\eta$, outside the range of the inner tracking detectors. The jet selection based on this discriminant is shown to be insensitive to pile-up. A requirement of $|J V F|>0.75$ is placed on all jets during event selection. In order to identify the jets initiated by $b$ quarks, an algorithm is used that combines impact-parameter information

[^48]with the explicit determination of a secondary vertex [50]. A working point is chosen that corresponds to an average efficiency of about $70 \%$ for $b$ jets with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $t \bar{t}$ events and a light-quark jet rejection factor of about 130 . Since the $b$-tagger relies on the inner tracking detectors, the acceptance region for jets is restricted to $|\eta|<2.4$.

## $3.4 \quad \tau$ jets

In order to reconstruct hadronically decaying $\tau$ leptons, anti- $k_{t}$ jets with either one or three associated tracks reconstructed in the inner detector and depositing $E_{\mathrm{T}}>10 \mathrm{GeV}$ in the calorimeter are considered as $\tau$ candidates [51]. Dedicated algorithms are used in order to reject electrons and muons. Hadronic $\tau$ decays are identified using a likelihood criterion designed to discriminate against quark- and gluon-initiated jets by using the shower shape and tracking variables as inputs. A working point with an efficiency of about $30 \%$ for hadronically decaying $\tau$ leptons with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $Z \rightarrow \tau \tau$ events is chosen, leading to a rejection factor of about $100-1000$ for jets. The rejection factor depends on the $p_{\mathrm{T}}$ and $\eta$ of the candidate and the number of associated tracks. The $\tau$ candidates are further required to have a visible transverse momentum of at least 20 GeV and to be within $|\eta|<2.3$. The selected $\tau$ candidates are henceforth referred to as " $\tau$ jets".

### 3.5 Removal of geometric overlaps between objects

When candidates selected using the criteria above overlap geometrically, the following procedures are applied, in this order: muon candidates are rejected if they are found within $\Delta R<0.4$ of any jet with $p_{\mathrm{T}}>25 \mathrm{GeV} ;$ a $\tau$ jet is rejected if found within $\Delta R<0.2$ of a selected muon or electron; jets are removed if they are within $\Delta R<0.2$ of a selected $\tau$ object or electron.

### 3.6 Missing transverse momentum

The missing transverse momentum and its magnitude $E_{\mathrm{T}}^{\text {miss }}$ [52] are reconstructed from three-dimensional, noise-suppressed clusters of cells in the calorimeter and from muon tracks reconstructed in the muon spectrometer and the inner tracking detectors. Clusters of calorimeter cells belonging to jets (including $\tau$ jets) with $p_{\mathrm{T}}>20 \mathrm{GeV}$ are calibrated to the hadronic energy scale. Calorimeter cells not associated with any object are also taken into account and they are calibrated at the electromagnetic energy scale. In order to deal appropriately with the energy deposited by muons in the calorimeters, the contributions of muons to $E_{\mathrm{T}}^{\text {miss }}$ are calculated differently for isolated and non-isolated muons.

## 4 Analysis of the lepton+jets channel

This analysis relies on the detection of lepton+jets decays of $t \bar{t}$ events, where the charged lepton $l$ (electron or muon) arises from $H^{+} \rightarrow \tau_{\text {lep }} \nu$, while the jets arise from a hadronically decaying $W$ boson, i.e. $t \bar{t} \rightarrow b \bar{b} W H^{+} \rightarrow b \bar{b}\left(q \bar{q}^{\prime}\right)\left(\tau_{\text {lep }} \nu\right)$.

### 4.1 Event selection

The lepton + jets analysis uses events passing a single-lepton trigger with an $E_{\mathrm{T}}$ threshold of $20-22 \mathrm{GeV}$ for electrons ${ }^{4}$ and a $p_{\mathrm{T}}$ threshold of 18 GeV for muons. These thresholds are low enough to guarantee that electrons and muons chosen for the analysis are in the plateau region of the trigger-efficiency curve. In addition, to select a sample of lepton+jets events enriched in $t \bar{t}$ candidates, the following requirements are applied:

- exactly one lepton having $E_{\mathrm{T}}>25 \mathrm{GeV}$ (electron) or $p_{\mathrm{T}}>20 \mathrm{GeV}$ (muon) and matched to the corresponding trigger object, with neither a second lepton nor a $\tau$ jet in the event;
- at least four jets having $p_{\mathrm{T}}>20 \mathrm{GeV}$, with exactly two of them being $b$-tagged;
- $E_{\mathrm{T}}^{\text {miss }}>40 \mathrm{GeV}$ and, in order to discriminate between $E_{\mathrm{T}}^{\text {miss }}$ arising from isolated neutrinos and from poorly reconstructed leptons, this requirement is tightened to $E_{\mathrm{T}}^{\text {miss }} \times\left|\sin \Delta \phi_{l, \text { miss }}\right|>20 \mathrm{GeV}$ if the azimuthal angle $\Delta \phi_{l \text {,miss }}$ between the lepton and $E_{\mathrm{T}}^{\mathrm{miss}}$ is smaller than $\pi / 6$.

Having selected a lepton + jets sample enriched in $t \bar{t}$ candidates, jets must be assigned correctly to the decay products of each $W$ boson (with a mass $m_{W}=80.4 \mathrm{GeV}$ ) and top quark. In particular, the hadronic side of the event is identified by selecting the combination of one $b$-tagged jet ( $b$ ) and two untagged jets $(j)$ that minimises:

$$
\begin{equation*}
\chi^{2}=\frac{\left(m_{j j b}-m_{\mathrm{top}}\right)^{2}}{\sigma_{\mathrm{top}}^{2}}+\frac{\left(m_{j j}-m_{W}\right)^{2}}{\sigma_{W}^{2}} \tag{4.1}
\end{equation*}
$$

where $\sigma_{\text {top }}=17 \mathrm{GeV}$ and $\sigma_{W}=10 \mathrm{GeV}$ are the widths of the reconstructed top quark and $W$ boson mass distributions, as measured in simulated $t \bar{t}$ events. Using information about the correctly identified combinations in the generated events, the jet assignment efficiency is found to be $72 \%$. Events with $\chi^{2}>5$ are rejected in order to select well-reconstructed hadronic top quark candidates.

### 4.2 Data-driven estimation of backgrounds with misidentified leptons

While the ATLAS lepton identification gives a very pure sample of candidates, there is a non-negligible contribution from non-isolated leptons arising from the semileptonic decay of hadrons containing $b$ or $c$ quarks, from the decay-in-flight of $\pi^{ \pm}$or $K$ mesons and, in the case of misidentified electron objects, from the reconstruction of $\pi^{0}$ mesons, photon conversions or shower fluctuations. All leptons coming from such mechanisms are referred to as misidentified leptons, as opposed to truly isolated leptons (e.g. from the prompt decay of $W$ or $Z$ bosons), which are referred to as real leptons. The data-driven estimation of the number of misidentified leptons passing the lepton selections of sections 3.1 and 3.2 is based on exploiting differences in the lepton identification between real and misidentified

[^49]electrons or muons. Two data samples are defined, which differ only in the lepton identification criteria. The tight sample contains mostly events with real leptons and uses the same lepton selection as in the analysis. The loose sample contains mostly events with misidentified leptons. This latter sample is obtained by loosening the isolation and identification requirements for the leptons. For loose electrons, the isolation requirements have an efficiency of about $98 \%$ for true isolated electrons, compared to $90 \%$ in the tight sample. For loose muons, the isolation requirement is removed. By construction, the tight sample is therefore a subset of the loose sample.

Let $N_{\mathrm{r}}^{\mathrm{L}}$ and $N_{\mathrm{m}}^{\mathrm{L}}\left(N_{\mathrm{r}}^{\mathrm{T}}\right.$ and $N_{\mathrm{m}}^{\mathrm{T}}$ ) be the number of events containing real and misidentified leptons, respectively, passing a loose (tight) selection. The numbers of events containing one loose or tight lepton are given by:

$$
\begin{align*}
& N^{\mathrm{L}}=N_{\mathrm{m}}^{\mathrm{L}}+N_{\mathrm{r}}^{\mathrm{L}},  \tag{4.2}\\
& N^{\mathrm{T}}=N_{\mathrm{m}}^{\mathrm{T}}+N_{\mathrm{r}}^{\mathrm{T}} . \tag{4.3}
\end{align*}
$$

Defining $p_{\mathrm{r}}$ and $p_{\mathrm{m}}$ as:

$$
\begin{equation*}
p_{\mathrm{r}}=\frac{N_{\mathrm{r}}^{\mathrm{T}}}{N_{\mathrm{r}}^{\mathrm{L}}} \quad \text { and } \quad p_{\mathrm{m}}=\frac{N_{\mathrm{m}}^{\mathrm{T}}}{N_{\mathrm{m}}^{\mathrm{L}}} \text {, } \tag{4.4}
\end{equation*}
$$

the number of misidentified leptons passing the tight selection $N_{\mathrm{m}}^{\mathrm{T}}$ can then be written as:

$$
\begin{equation*}
N_{\mathrm{m}}^{\mathrm{T}}=\frac{p_{\mathrm{m}}}{p_{\mathrm{r}}-p_{\mathrm{m}}}\left(p_{\mathrm{r}} N^{\mathrm{L}}-N^{\mathrm{T}}\right) \tag{4.5}
\end{equation*}
$$

The main ingredients of this data-driven method are thus the relative efficiencies $p_{\mathrm{r}}$ and $p_{\mathrm{m}}$ for a real or a misidentified lepton, respectively, to be detected as a tight lepton. The lepton identification efficiency $p_{\mathrm{r}}$ is measured using a tag-and-probe method on $Z \rightarrow l l$ data events with a dilepton invariant mass between 86 GeV and 96 GeV , where one lepton is required to fulfill tight selection criteria. The rate at which the other lepton passes the same tight selection criteria defines $p_{\mathrm{r}}$. The average values of the electron and muon identification efficiencies are $80 \%$ and $97 \%$, respectively. On the other hand, a control sample with misidentified leptons is selected by considering events in the data with exactly one lepton passing the loose criteria. In order to select events dominated by multi-jet production, $E_{\mathrm{T}}^{\text {miss }}$ is required to be between 5 GeV and 20 GeV . Residual true leptons contribute at a level below $10 \%$ and are subtracted from this sample using simulation. After this subtraction, the rate at which a loose lepton passes tight selection criteria defines the misidentification rate $p_{\mathrm{m}}$. The average values of the electron and muon misidentification probabilities are $18 \%$ and $29 \%$, respectively. In the final parameterisation of $p_{\mathrm{r}}$ and $p_{\mathrm{m}}$, dependencies on the pseudorapidity of the lepton, its distance $\Delta R$ to the nearest jet and the leading jet $p_{\mathrm{T}}$ are taken into account.

### 4.3 Reconstruction of discriminating variables after the selection cuts

The analysis uses two variables that discriminate between leptons produced in $\tau \rightarrow l_{l} \nu_{\tau}$ and leptons coming directly from $W$ boson decays. The first discriminating variable is the
invariant mass $m_{b l}$ of the $b$ jet and the charged lepton $l$ coming from the same top quark candidate, or more conveniently, $\cos \theta_{l}^{*}$ defined as:

$$
\begin{equation*}
\cos \theta_{l}^{*}=\frac{2 m_{b l}^{2}}{m_{\mathrm{top}}^{2}-m_{W}^{2}}-1 \simeq \frac{4 p^{b} \cdot p^{l}}{m_{\mathrm{top}}^{2}-m_{W}^{2}}-1 . \tag{4.6}
\end{equation*}
$$

Both $m_{b}^{2}$ and $m_{l}^{2}$ are neglected, hence $m_{b l}^{2} \simeq 2 p^{b} \cdot p^{l}$, where $p^{b}$ and $p^{l}$ are the four-momenta of the $b$ jet and of the charged lepton $l$, respectively. The presence of a charged Higgs boson in a leptonic top quark decay reduces the invariant product $p^{b} \cdot p^{l}$, when compared to $W$-mediated top quark decays, leading to $\cos \theta_{l}^{*}$ values closer to -1 .

The second discriminating variable is the transverse mass $m_{\mathrm{T}}^{H}$ [53], obtained by fulfilling the constraint $\left(p^{\text {miss }}+p^{l}+p^{b}\right)^{2}=m_{\text {top }}^{2}$ on the leptonic side of lepton + jets $t \bar{t}$ events. More than one neutrino accounts for the invisible four-momentum $p^{\text {miss }}$ and its transverse component $\overrightarrow{p_{\mathrm{T}}}{ }^{\text {miss }}$. By construction, $m_{\mathrm{T}}^{H}$ gives an event-by-event lower bound on the mass of the leptonically decaying charged ( $W$ or Higgs) boson produced in the top quark decay, and it can be written as:

$$
\begin{equation*}
\left(m_{\mathrm{T}}^{H}\right)^{2}=\left(\sqrt{m_{\mathrm{top}}^{2}+\left({\overrightarrow{p_{\mathrm{T}}}}^{l}+{\overrightarrow{p_{\mathrm{T}}}}^{b}+{\overrightarrow{p_{\mathrm{T}}}}^{\text {miss }}\right)^{2}}-p_{\mathrm{T}}^{b}\right)^{2}-\left({\overrightarrow{p_{\mathrm{T}}}}^{l}+{\overrightarrow{p_{\mathrm{T}}}}^{\text {miss }}\right)^{2} . \tag{4.7}
\end{equation*}
$$

The $\cos \theta_{l}^{*}$ distribution measured in the data is shown in figure 2a, superimposed on the predicted background, determined with a data-driven method for the multi-jet background and simulation for the other SM backgrounds. In the presence of a charged Higgs boson in the top quark decays, with a branching ratio $\mathcal{B}\left(t \rightarrow b H^{+}\right)$, the contribution of $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$events in the background is scaled according to this branching ratio. A control region enriched in $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$events is defined by requiring $-0.2<\cos \theta_{l}^{*}<1$. In section 8 , this sample is used to fit the branching ratio $\mathcal{B}\left(t \rightarrow b H^{+}\right)$and the product of the cross section $\sigma_{b b W W}$, the luminosity, the selection efficiency and acceptance for $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$, simultaneously with the likelihood for the signal estimation. In turn, this ensures that the final results, and in particular the upper limit on $\mathcal{B}\left(t \rightarrow b H^{+}\right)$, are independent of the assumed theoretical production cross section for $t \bar{t}$. With a branching fraction $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$, the signal contamination in the control region would range from $1.3 \%$ for $m_{H^{+}}=90 \mathrm{GeV}$ to $0.4 \%$ for $m_{H^{+}}=160 \mathrm{GeV}$. The signal region is defined by requiring $\cos \theta_{l}^{*}<-0.6$ and $m_{\mathrm{T}}^{W}<60 \mathrm{GeV}$, where:

$$
\begin{equation*}
m_{\mathrm{T}}^{W}=\sqrt{2 p_{\mathrm{T}}^{l} E_{\mathrm{T}}^{\mathrm{miss}}\left(1-\cos \Delta \phi_{l, \mathrm{miss}}\right)} . \tag{4.8}
\end{equation*}
$$

This is done in order to suppress the background from events with a $W$ boson decaying directly into electrons or muons. For events in the signal region, $m_{\mathrm{T}}^{H}$, shown in figure 2 b , is used as a discriminating variable to search for charged Higgs bosons. Table 2 lists the contributions to the signal region of the SM processes and of $t \bar{t}$ events with at least one decay $t \rightarrow b H^{+}$, assuming $m_{H^{+}}=130 \mathrm{GeV}$ and $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$. When including signal in the prediction, the simulated SM $t \bar{t}$ contribution is scaled according to this branching ratio. The data are consistent with the predicted SM background and no significant deformation of the $m_{\mathrm{T}}^{H}$ distribution is observed.

| Sample | Event yield (lepton+jets) |  |  |
| :--- | :---: | :--- | :--- |
| $t \bar{t}$ | 840 | $\pm 20$ | $\pm 150$ |
| Single top quark | 28 | $\pm 2$ | ${ }_{-6}^{+8}$ |
| $W+$ jets | 14 | $\pm 3$ | ${ }_{-3}^{+6}$ |
| $Z+$ jets | 2.1 | $\pm 0.7$ | ${ }_{-0.4}^{+1.2}$ |
| Diboson | 0.5 | $\pm 0.1$ | $\pm 0.2$ |
| Misidentified leptons | 55 | $\pm 10$ | $\pm 20$ |
| All SM backgrounds | 940 | $\pm 22$ | $\pm 150$ |
| Data | 933 |  |  |
| $t \rightarrow b H^{+}(130 ~ G e V)$ | 120 | $\pm 4$ | $\pm 25$ |
| Signal+background | 990 | $\pm 21 \pm 140$ |  |

Table 2. Expected event yields in the signal region of the lepton+jets final state, and comparison with $4.6 \mathrm{fb}^{-1}$ of data. A cross section of 167 pb is assumed for the $\mathrm{SM} t \bar{t}$ background. The numbers shown in the last two rows, for a hypothetical $H^{+}$signal with $m_{H^{+}}=130 \mathrm{GeV}$, are obtained with $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$. Both statistical and systematic uncertainties are shown, in this order.

(a)

(b)

Figure 2. Distribution of (a) $\cos \theta_{l}^{*}$ and (b) $m_{\mathrm{T}}^{H}$, in the signal region ( $\cos \theta_{l}^{*}<-0.6, m_{\mathrm{T}}^{W}<60 \mathrm{GeV}$ ) for the latter. The dashed line corresponds to the SM-only hypothesis and the hatched area around it shows the total uncertainty for the SM backgrounds, where "Others" refers to the contribution of all SM processes except $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$. The solid line shows the predicted contribution of signal+background in the presence of a 130 GeV charged Higgs boson, assuming $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$ and $\mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)=100 \%$. The light area below the solid line corresponds to the contribution of the $H^{+}$signal, stacked on top of the scaled $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$background and other SM processes.

## 5 Analysis of the $\tau+$ lepton channel

This analysis relies on the detection of $\tau+$ lepton decays of $t \bar{t}$ events, where the hadronically decaying $\tau$ lepton arises from $H^{+} \rightarrow \tau_{\text {had }} \nu$, while an electron or muon comes from the decay of the $W$ boson, i.e. $t \bar{t} \rightarrow b \bar{b} W H^{+} \rightarrow b \bar{b}(l \nu)\left(\tau_{\text {had }} \nu\right)$.

### 5.1 Event selection

The $\tau+$ lepton analysis relies on the same single-lepton trigger signatures as the lepton+jets analysis presented in section 4. In order to select $\tau+$ lepton events, the following requirements are made:

- exactly one lepton, having $E_{\mathrm{T}}>25 \mathrm{GeV}$ (electron) or $p_{\mathrm{T}}>20 \mathrm{GeV}$ (muon) and matched to the corresponding trigger object, and no other electron or muon;
- exactly one $\tau$ jet having $p_{\mathrm{T}}>20 \mathrm{GeV}$ and an electric charge opposite to that of the lepton;
- at least two jets having $p_{\mathrm{T}}>20 \mathrm{GeV}$, including at least one $b$-tagged jet;
- $\sum p_{\mathrm{T}}>100 \mathrm{GeV}$ in order to suppress multi-jet events, where $\sum p_{\mathrm{T}}$ is the sum of the transverse momenta of all tracks associated with the primary vertex. Tracks entering the sum must pass quality cuts on the number of hits and have $p_{\mathrm{T}}>1 \mathrm{GeV}$. As this variable is based on tracks from the primary vertex (as opposed to energy deposits in the calorimeter), it is robust against pile-up.
$E_{\mathrm{T}}^{\text {miss }}$ is used as the discriminating variable to distinguish between SM $t \bar{t}$ events and those where top quark decays are mediated by a charged Higgs boson, in which case the neutrinos are likely to carry away more energy.

### 5.2 Data-driven estimation of backgrounds with misidentified leptons

The estimation of the backgrounds with misidentified leptons uses the data-driven method described in section 4.2. When implementing the method, the dependence of real and misidentification rates on the $b$-tagged jet multiplicity are taken into account, as well as the requirement for one $\tau$ jet (instead of a $\tau$ jet veto).

### 5.3 Backgrounds with electrons and jets misidentified as $\tau$ jets

The background with electrons misidentified as $\tau$ jets is estimated using a $Z \rightarrow e e$ control region in the data [51], where one electron is reconstructed as a $\tau$ jet. The measured misidentification probabilities, which have an average value of $0.2 \%$, are then applied to all simulated events in the $\tau+$ lepton analysis. Simulation studies show that this application is valid, as the misidentification probabilities for $Z \rightarrow e e$ and $t \bar{t}$ events are similar.

A data-driven method applied to a control sample enriched in $W+$ jets events is used to measure the probability for a jet to be misidentified as a hadronically decaying $\tau$ lepton. This measured probability is used to predict the yield of background events due to jet $\rightarrow \tau$ misidentification. Like jets from the hard process in the dominant $t \bar{t}$ background, jets in the
control sample originate predominantly from quarks instead of gluons. The main difference between $t \bar{t}$ and $W+$ jets events is the different fraction of $b$ jets, which is smaller in $W+$ jets events. However, the probability for a $b$ jet to be misidentified as a $\tau$ jet is smaller than the corresponding probability for a light-quark jet, because the average track multiplicity is higher for $b$ jets. Moreover, the visible mass measurement used in the $\tau$ identification provides further discrimination between $b$ jets and $\tau$ jets. Differences in jet composition (e.g. the ratio of gluons to quarks) between $t \bar{t}$ and $W+$ jets, assessed using simulation, are taken into account as systematic uncertainties. These also cover the dependence of the probability on whether a $b$ jet or a light-quark jet is misidentified as a $\tau$ jet. Events in the control region are required to pass the same single-lepton trigger, data quality and lepton requirements as in the $\tau+$ lepton event selection. Additionally, a $\tau$ candidate and $E_{\mathrm{T}}^{\mathrm{miss}}>40 \mathrm{GeV}$ are required, and events with $b$-tagged jets are vetoed. Simulated events with a true $\tau$ contribute at a level below $0.5 \%$ and are subtracted. The $\tau$ candidates are required to have $p_{\mathrm{T}}>20 \mathrm{GeV},|\eta|<2.3$, and cannot be within $\Delta R=0.2$ of any electron or muon. They are also not required to pass $\tau$ identification. The jet $\rightarrow \tau$ misidentification probability is defined as the number of objects passing the full $\tau$ identification divided by the number prior to requiring identification. This misidentification probability is evaluated separately for $\tau$ candidates with one or three associated tracks (the corresponding average values are about $7 \%$ and $2 \%$, respectively) and, in addition, it is measured as a function of both $p_{\mathrm{T}}$ and $\eta$.

In order to predict the background for the charged Higgs boson search, the measured jet $\rightarrow \tau$ misidentification probability is applied to simulated $t \bar{t}$, single top quark, $W+$ jets, $Z / \gamma^{*}+$ jets and diboson events, all of which are required to pass the full event selection except for the $\tau$ identification. For these events, $\tau$ candidates not overlapping with a true $\tau$ lepton or a true electron, but otherwise fulfilling the same requirements as in the denominator of the misidentification probability, are identified. Each of them is considered separately to be potentially misidentified as a $\tau$ jet. In order to avoid counting the same object twice, each jet that corresponds to a $\tau$ candidate is removed from the event. The number of reconstructed jets and the number of $b$-tagged jets are adjusted accordingly. If, after taking this into consideration, the event passes the $\tau+$ lepton selection, it is counted as a background event with a weight given by the misidentification probability corresponding to the $p_{\mathrm{T}}$ and $\eta$ of the $\tau$ candidate. The predicted numbers of events from this datadriven method and from simulation are shown in table 3. The backgrounds arising from the jet $\rightarrow \tau$ misidentification are not well modelled in simulation, which is why they are estimated using data-driven methods.

### 5.4 Event yields and $E_{\mathrm{T}}^{\text {miss }}$ distribution after the selection cuts

Table 4 shows the expected number of background events for the SM-only hypothesis and the observation in the data. The total number of predicted events (signal+background) in the presence of a 130 GeV charged Higgs boson with $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$ is also shown. The $\tau+$ lepton analysis relies on the theoretical $t \bar{t}$ production cross section $\sigma_{t \bar{t}}=167_{-18}^{+17} \mathrm{pb}[26]$ for the background estimation. In the presence of a charged Higgs boson in the top quark decays, with a branching ratio $\mathcal{B}\left(t \rightarrow b H^{+}\right)$, the contributions of $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$events in the backgrounds with true or misidentified $\tau$ jets are scaled according to this branching

| Sample | Data-driven method [events] | Simulation [events] |
| :--- | :---: | :---: |
| $t \bar{t}$ | $900 \pm 15$ | $877 \pm 6$ |
| $W+$ jets | $150 \pm 3$ | $145 \pm 9$ |
| Single top quark | $81 \pm 1$ | $61 \pm 2$ |
| $Z / \gamma^{*}+$ jets | $44 \pm 1$ | $69 \pm 4$ |
| Diboson | $6 \pm 1$ | $8 \pm 1$ |

Table 3. Application of the misidentification probability obtained from $W+$ jets events in the data, for the $\tau+$ lepton channel. The predictions of the background contributions based on data-driven misidentification probabilities and on simulation are given, with statistical uncertainties only. In both cases, all top quarks are assumed to decay via $t \rightarrow b W$.

| Sample | Event yield ( $\tau+$ lepton) |  |
| :--- | ---: | ---: |
|  | $\tau+e$ | $\tau+\mu$ |
| True $\tau+$ lepton | $430 \pm 14 \pm 59$ | $570 \pm 15 \pm 75$ |
| Misidentified jet $\rightarrow \tau$ | $510 \pm 23 \pm 86$ | $660 \pm 26 \pm 110$ |
| Misidentified $e \rightarrow \tau$ | $33 \pm 4 \pm$ | 5 |
| Misidentified leptons | $39 \pm 4 \pm \pm$ | 6420 |
| All SM backgrounds | $1010 \pm 30 \pm 110$ | $1360 \pm 30 \pm 140$ |
| Data | 880 | 1219 |
| $t \rightarrow b H^{+}(130 \mathrm{GeV})$ | $220 \pm 6 \pm 29$ | $310 \pm 7 \pm 39$ |
| Signal+background | $1160 \pm 30 \pm 100$ | $1570 \pm 30 \pm 130$ |

Table 4. Expected event yields after all selection cuts in the $\tau+l$ lepton channel and comparison with $4.6 \mathrm{fb}^{-1}$ of data. The numbers in the last two rows, obtained for a hypothetical $H^{+}$signal with $m_{H^{+}}=130 \mathrm{GeV}$, are obtained with $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$. All other rows assume $\mathcal{B}(t \rightarrow b W)=100 \%$. Both statistical and systematic uncertainties are shown, in this order.
ratio. The background with correctly reconstructed $\tau$ jets is obtained with simulation. The data are found to be consistent with the expectation for the background-only hypothesis. The $E_{\mathrm{T}}^{\text {miss }}$ distributions for the $\tau+e$ and $\tau+\mu$ channels, after all selection cuts are applied, are shown in figure 3 .

## 6 Analysis of the $\tau+$ jets channel

The analysis presented here relies on the detection of $\tau+$ jets decays of $t \bar{t}$ events, where the hadronically decaying $\tau$ lepton arises from $H^{+} \rightarrow \tau_{\text {had }} \nu$, while the jets come from a hadronically decaying $W$ boson, i.e. $t \bar{t} \rightarrow b \bar{b} W H^{+} \rightarrow b \bar{b}\left(q \bar{q}^{\prime}\right)\left(\tau_{\text {had }} \nu\right)$.

Figure 3. $E_{\mathrm{T}}^{\text {miss }}$ distribution after all selection cuts in the $\tau+$ lepton channel, for (a) $\tau+$ electron and (b) $\tau+$ muon final states. The dashed line corresponds to the SM-only hypothesis and the hatched area around it shows the total uncertainty for the SM backgrounds. The solid line shows the predicted contribution of signal+background in the presence of a 130 GeV charged Higgs boson with $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$ and $\mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)=100 \%$. The contributions of $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$events in the backgrounds with true or misidentified $\tau$ jets are scaled down accordingly.

### 6.1 Event selection

The $\tau+$ jets analysis uses events passing a $\tau+E_{\mathrm{T}}^{\mathrm{miss}}$ trigger with a threshold of 29 GeV on the $\tau$ object and 35 GeV on calorimeter-based $E_{\mathrm{T}}^{\mathrm{miss}}$. The following requirements are applied, in this order:

- at least four jets (excluding $\tau$ jets) having $p_{\mathrm{T}}>20 \mathrm{GeV}$, of which at least one is b-tagged;
- exactly one $\tau$ jet with $p_{\mathrm{T}}^{\tau}>40 \mathrm{GeV}$, found within $|\eta|<2.3$ and matched to a $\tau$ trigger object;
- neither a second $\tau$ jet with $p_{\mathrm{T}}^{\tau}>20 \mathrm{GeV}$, nor any electrons with $E_{\mathrm{T}}>20 \mathrm{GeV}$, nor any muons with $p_{\mathrm{T}}>15 \mathrm{GeV}$;
- $E_{\mathrm{T}}^{\mathrm{miss}}>65 \mathrm{GeV}$;
- to reject events in which a large reconstructed $E_{\mathrm{T}}^{\mathrm{miss}}$ is due to the limited resolution of the energy measurement, the following ratio based on the $\sum p_{\mathrm{T}}$ definition of section 5 must satisfy:

$$
\frac{E_{\mathrm{T}}^{\mathrm{miss}}}{0.5 \mathrm{GeV}^{1 / 2} \cdot \sqrt{\sum p_{\mathrm{T}}}}>13
$$

- a topology consistent with a top quark decay: the combination of one $b$-tagged jet ( $b$ ) and two untagged jets $(j)$ with the highest $p_{\mathrm{T}}^{j j b}$ must satisfy $m_{j j b} \in[120,240] \mathrm{GeV}$.

For the selected events, the transverse mass $m_{\mathrm{T}}$ is defined as:

$$
\begin{equation*}
m_{\mathrm{T}}=\sqrt{2 p_{\mathrm{T}}^{\tau} E_{\mathrm{T}}^{\mathrm{miss}}\left(1-\cos \Delta \phi_{\tau, \mathrm{miss}}\right)} \tag{6.1}
\end{equation*}
$$

where $\Delta \phi_{\tau, \text { miss }}$ is the azimuthal angle between the $\tau$ jet and the direction of the missing momentum. This discriminating variable is related to the $W$ boson mass in the $W \rightarrow \tau \nu$ background case and to the $H^{+}$mass for the signal hypothesis.

### 6.2 Data-driven estimation of the multi-jet background

The multi-jet background is estimated by fitting its $E_{\mathrm{T}}^{\mathrm{miss}}$ shape (and the $E_{\mathrm{T}}^{\mathrm{miss}}$ shape of other backgrounds) to data. In order to study this shape in a data-driven way, a control region is defined where the $\tau$ identification and $b$-tagging requirements are modified, i.e. $\tau$ candidates must pass a loose $\tau$ identification but fail the tight $\tau$ identification used in the signal selection, and the event is required not to contain any $b$-tagged jet. Hence, the requirement on $m_{j j b}$ is also removed. Assuming that the shapes of the $E_{\mathrm{T}}^{\text {miss }}$ and $m_{\mathrm{T}}$ distributions are the same in the control and signal regions, the $E_{\mathrm{T}}^{\mathrm{miss}}$ shape for the multi-jet background is measured in the control region, after subtracting the simulated background contributions from other processes. These other processes amount to less than $1 \%$ of the observed events in the control region. The $E_{\mathrm{T}}^{\mathrm{miss}}$ shapes obtained with the $\tau+$ jets selection of section 6.1 or in the control region are compared just before the $E_{\mathrm{T}}^{\mathrm{miss}}$ requirement in the baseline selection in figure 4a. The differences between the two distributions are accounted for as systematic uncertainties. For the baseline selection, the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution measured in the data is then fit using two shapes: the multi-jet model and the sum of other processes (dominated by $t \bar{t}$ and $W+$ jets), for which the shape and the relative normalisation are taken from simulation, as shown in figure 4 b . The ratio between the numbers of multi-jet background events in the control and signal regions enters the likelihood function for the signal estimation (see section 8) as a nuisance parameter while the shape of the multi-jet background is measured in the same region after additionally requiring $E_{\mathrm{T}}^{\mathrm{miss}}>65 \mathrm{GeV}$.

### 6.3 Backgrounds with electrons and jets misidentified as $\tau$ jets

The methods described in section 5.3 are used to estimate the probability for electrons or jets to be misidentified as $\tau$ jets. The estimated contribution to the background from the jet $\rightarrow \tau$ misidentification after the $\tau+$ jets selection is given in table 5 . The backgrounds arising from the jet $\rightarrow \tau$ misidentification are not expected to be well modelled in simulation, which is why they are estimated using data-driven methods.

### 6.4 Data-driven estimation of backgrounds with correctly reconstructed $\tau$ jets

An embedding method [54] is used to estimate the backgrounds that contain correctly reconstructed $\tau$ jets. The method consists of selecting a control sample of $t \bar{t}$-like $\mu+$ jets events and replacing the detector signature of the muon by a simulated hadronic $\tau$ decay. These new hybrid events are then used for the background prediction. In order to select this control sample from the data, the following event selection is applied:

- event triggered by a single-muon trigger with a $p_{\mathrm{T}}$ threshold of 18 GeV ;

Figure 4. (a) Shape of $E_{\mathrm{T}}^{\mathrm{miss}}$ in a control region of the data or using the baseline selection, after subtracting the expectation from $t \bar{t}, W+$ jets, and single top quark processes estimated from simulation. The distributions are compared just before the $E_{\mathrm{T}}^{\text {miss }}$ requirement in the baseline selection of section 6.1, with the exception that, in the control region, the $\tau$ selection and the $b$-tagging requirements are modified, see text. (b) Fit of the $E_{\mathrm{T}}^{\text {miss }}$ template to data, in the signal region. Only statistical uncertainties are shown.

| Sample | Data-driven method [events] | Simulation [events] |
| :--- | :---: | :---: |
| $t \bar{t}$ | $33 \pm 1$ | $37 \pm 1$ |
| $W+$ jets | $2.5 \pm 0.1$ | $3.9 \pm 1.5$ |
| Single top quark | $1.3 \pm 0.1$ | $2.0 \pm 0.3$ |

Table 5. Application of the misidentification probability obtained from a control region in the data enriched in $W+$ jets events, for the $\tau+$ jets channel. The predictions of the background contributions based on data-driven misidentification probabilities and on simulation are given, with statistical uncertainties only. In both cases, all top quarks decay via $t \rightarrow b W$.

- exactly one isolated muon with $p_{\mathrm{T}}>25 \mathrm{GeV}$, no isolated electron with $E_{\mathrm{T}}>20 \mathrm{GeV}$;
- at least four jets with $p_{\mathrm{T}}>20 \mathrm{GeV}$, at least one of which is $b$-tagged;
- $E_{\mathrm{T}}^{\mathrm{miss}}>35 \mathrm{GeV}$.

This selection is looser than the selection defined in section 6.1 in order not to bias the control sample. The impurity from the background with muons produced in $\tau$ decays and non-isolated muons (dominantly $b \bar{b}$ and $c \bar{c}$ events) is about $10 \%$. However, this contribution is greatly reduced as these events are much less likely to pass the $\tau+$ jets selection, in particular the $p_{\mathrm{T}}^{\tau}$ requirement.

The shape of the $m_{\mathrm{T}}$ distribution for the backgrounds with true $\tau$ jets is taken from the distribution obtained with the embedded events, after having applied the $\tau+$ jets event selection. The normalisation is then derived from the number of embedded events:

$$
\begin{equation*}
N_{\tau}=N_{\text {embedded }} \cdot\left(1-c_{\tau \rightarrow \mu}\right) \frac{\epsilon^{\tau+E_{\mathrm{T}}^{\text {miss }}-\text { trigger }}}{\epsilon^{\mu-\mathrm{ID}, \text { trigger }}} \cdot \mathcal{B}(\tau \rightarrow \text { hadrons }+\nu), \tag{6.2}
\end{equation*}
$$

Figure 5. Comparison of the $m_{\mathrm{T}}$ distribution for correctly reconstructed $\tau$ jets, predicted by the embedding method and simulation. Combined statistical and systematic uncertainties (as described in section 7) are shown.
where $N_{\tau}$ is the estimated number of events with correctly reconstructed $\tau$ jets, $N_{\text {embedded }}$ is the number of embedded events in the signal region, $c_{\tau \rightarrow \mu}$ is the fraction of events in which the selected muon is a decay product of a $\tau$ lepton (taken from simulation), $\epsilon^{\tau+E_{\mathrm{T}}^{\text {miss }} \text {-trigger }}$ is the $\tau+E_{\mathrm{T}}^{\mathrm{miss}}$ trigger efficiency (as a function of $p_{T}^{\tau}$ and $E_{\mathrm{T}}^{\text {miss }}$, derived from data), $\epsilon^{\mu-\mathrm{ID}, \text { trigger }}$ is the muon trigger and identification efficiency (as a function of $p_{T}$ and $\eta$, derived from data) and $\mathcal{B}(\tau \rightarrow$ hadrons $+\nu)$ is the branching ratio of the $\tau$ lepton decays involving hadrons. The $m_{\mathrm{T}}$ distribution for correctly reconstructed $\tau$ jets, as predicted by the embedding method, is shown in figure 5 and compared to simulation.

### 6.5 Event yields and $m_{\mathrm{T}}$ distribution after the selection cuts

Table 6 shows the expected number of background events for the SM-only hypothesis and the observation in the data. The total number of predicted events (signal+background) in the presence of a 130 GeV charged Higgs boson with $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$ is also shown. The number of events with a correctly reconstructed $\tau$ jet is derived from the number of embedded events and does not depend on the cross section of the $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$process. On the other hand, the $\tau+$ jets analysis relies on the theoretical inclusive $t \bar{t}$ production cross section $\sigma_{t \bar{t}}=167_{-18}^{+17} \mathrm{pb}[26]$ for the estimation of the background with electrons or jets misidentified as $\tau$ jets. In the presence of a charged Higgs boson in the top quark decays, with a branching ratio $\mathcal{B}\left(t \rightarrow b H^{+}\right)$, the contributions of $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$events in these backgrounds are scaled according to this branching ratio. The data are found to be consistent with the estimation of the SM background. The $m_{\mathrm{T}}$ distribution for the $\tau+$ jets channel, after all selection cuts are applied, is shown in figure 6.

| Sample | Event yield $(\tau+$ jets $)$ |
| :--- | :---: |
| True $\tau$ (embedding method) | $210 \pm 10 \pm 44$ |
| Misidentified jet $\rightarrow \tau$ | $36 \pm 6 \pm 10$ |
| Misidentified $e \rightarrow \tau$ | $3 \pm 1 \pm 1$ |
| Multi-jet processes | $74 \pm 3 \pm 47$ |
| All SM backgrounds | $330 \pm 12 \pm 65$ |
| Data | 355 |
| $t \rightarrow b H^{+}(130 \mathrm{GeV})$ | $220 \pm 6 \pm 56$ |
| Signal + background | $540 \pm 13 \pm 85$ |

Table 6. Expected event yields after all selection cuts in the $\tau+$ jets channel and comparison with $4.6 \mathrm{fb}^{-1}$ of data. The numbers in the last two rows, obtained for a hypothetical $H^{+}$signal with $m_{H^{+}}=130 \mathrm{GeV}$, are obtained with $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$. The rows for the backgrounds with misidentified objects assume $\mathcal{B}(t \rightarrow b W)=100 \%$. Both statistical and systematic uncertainties are shown, in this order.

Figure 6. Distribution of $m_{\mathrm{T}}$ after all selection cuts in the $\tau+$ jets channel. The dashed line corresponds to the SM-only hypothesis and the hatched area around it shows the total uncertainty for the SM backgrounds. The solid line shows the predicted contribution of signal + background in the presence of a charged Higgs boson with $m_{H^{+}}=130 \mathrm{GeV}$, assuming $\mathcal{B}\left(t \rightarrow b H^{+}\right)=5 \%$ and $\mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)=100 \%$. The contributions of $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$events in the backgrounds with misidentified objects are scaled down accordingly.

## $7 \quad$ Systematic uncertainties

### 7.1 Systematic uncertainties arising from the detector simulation

Systematic uncertainties arising from the simulation of pile-up and object reconstruction are considered. The latter arise from the simulation of the trigger, from the reconstruction and identification efficiencies, as well as from the energy/momentum scale and resolution for the objects described in section 3. To assess the impact of most sources of systematic uncertainty, the selection cuts for each analysis are re-applied after shifting a particular parameter by its $\pm 1$ standard deviation uncertainty. The systematic uncertainties related to the electrons and muons are discussed in, respectively, ref. [42] and refs. [43, 55]. For the jets, see ref. [48] and, in particular, ref. [50] for the b-tagging calibration. The systematic uncertainties related to $\tau$ jets are discussed in ref. [51]. Finally, for the reconstruction of $E_{\mathrm{T}}^{\mathrm{miss}}$, see ref. [52]. All studies of systematic uncertainties have been updated with the full dataset collected in 2011. The dominant instrumental systematic uncertainties arise from the jet energy resolution ( $10-30 \%$, depending on $p_{\mathrm{T}}$ and $\eta$ ), the jet energy scale (up to $14 \%$, depending on $p_{\mathrm{T}}$ and $\eta$, to which a pile-up term of $2-7 \%$ and a $b$ jet term of $2.5 \%$ are added in quadrature), as well as the $b$-tagging efficiency ( $5-17 \%$, depending on $p_{\mathrm{T}}$ and $\eta$ ) and misidentification probability ( $12-21 \%$, depending on $p_{\mathrm{T}}$ and $\eta$ ). In comparison, the systematic uncertainties arising from the reconstruction and identification of electrons and muons are small. All instrumental systematic uncertainties are also propagated to the reconstructed $E_{\mathrm{T}}^{\mathrm{miss}}$.

### 7.2 Systematic uncertainties arising from the generation of $t \bar{t}$ events

In order to estimate the systematic uncertainties arising from the $t \bar{t}$ generation and the parton shower model, the acceptance is computed for $t \bar{t}$ events produced with MC@NLO interfaced to HERWIG/JIMMY and POWHEG [56] interfaced to PYTHIA. For the signal samples, which are generated with PYTHIA (i.e. without higher-order corrections), no alternative generator is available. Instead, the systematic uncertainty for the signal samples is set to the relative difference in acceptance between $t \bar{t}$ events generated with MC@NLO interfaced to HERWIG/JIMMY and with AcerMC, which is also a leading-order generator, interfaced to PYTHIA. The systematic uncertainties arising from initial and final state radiation are computed using $t \bar{t}$ samples generated with AcerMC interfaced to PYTHIA, where initial and final state radiation parameters are set to a range of values not excluded by the experimental data [57]. The largest relative differences with respect to the reference sample after full event selections are used as systematic uncertainties. The systematic uncertainties arising from the modelling of the $t \bar{t}$ event generation and the parton shower, as well as initial and final state radiation, are summarised in table 7 for each analysis.

### 7.3 Systematic uncertainties arising from data-driven background estimates

The systematic uncertainties arising from the data-driven methods used to estimate the various backgrounds are summarised in table 8 , for each of the three channels considered in the analysis.

| Source of uncertainty | Normalisation uncertainty |
| :--- | ---: |
| lepton+jets: |  |
| Generator and parton shower $\left(b \bar{b} W H^{+}\right.$, signal region) | $10 \%$ |
| Generator and parton shower $\left(b \bar{b} W^{+} W^{-}\right.$, signal region) | $8 \%$ |
| Generator and parton shower $\left(b \bar{b} W H^{+}\right.$, control region) | $7 \%$ |
| Generator and parton shower $\left(b \bar{b} W^{+} W^{-}\right.$, control region) | $6 \%$ |
| Initial and final state radiation (signal region) | $8 \%$ |
| Initial and final state radiation (control region) | $13 \%$ |
| $\tau+$ lepton: |  |
| Generator and parton shower $\left(b \bar{b} W H^{+}\right)$ | $2 \%$ |
| Generator and parton shower $\left(b \bar{b} W^{+} W^{-}\right)$ | $5 \%$ |
| Initial and final state radiation | $13 \%$ |
| $\tau+$ jets: |  |
| Generator and parton shower $\left(b \bar{b} W H^{+}\right)$ | $5 \%$ |
| Generator and parton shower $\left(b \bar{b} W W^{+} W^{-}\right)$ | $5 \%$ |
| Initial and final state radiation | $19 \%$ |

Table 7. Systematic uncertainties arising from the modelling of $t \bar{t} \rightarrow b \bar{b} W^{+} W^{-}$and $t \bar{t} \rightarrow b \bar{b} W H^{+}$ events and the parton shower, as well as from initial and final state radiation.

For backgrounds with misidentified leptons, discussed in sections 4.2 and 5.2 , the main systematic uncertainties arise from the simulated samples used for subtracting true leptons in the determination of the misidentification probabilities. These are sensitive to the instrumental systematic uncertainties and to the sample dependence (misidentification probabilities are calculated in a control region dominated by gluon-initiated events, but later used in a data sample with a higher fraction of quark-initiated events).

The dominant systematic uncertainties in the estimation of the multi-jet background in the $\tau+$ jets channel, described in section 6.2, are the statistical uncertainty of the fit due to the limited size of the data control sample and uncertainties due to potential differences of the $E_{\mathrm{T}}^{\text {miss }}$ shape in the signal and control regions. The dominant systematic uncertainties in estimating the contribution of events with electrons misidentified as $\tau$ jets in sections 5.3 and 6.3 arise from the subtraction of the multi-jet and electroweak backgrounds in the control region enriched with $Z \rightarrow e e$ events and from potential correlations in the selections of the tag and probe electrons. For the estimation of backgrounds with jets misidentified as hadronically decaying $\tau$ leptons, also discussed in sections 5.3 and 6.3 , the dominant systematic uncertainties on the misidentification probability are the statistical uncertainty due to the limited control sample size and uncertainties due to the difference of the jet composition (gluon- or quark-initiated) in the control and signal regions, which is estimated

| Source of uncertainty | Normalisation uncertainty | Shape uncertainty |
| :---: | :---: | :---: |
| lepton+jets: lepton misidentification |  |  |
| Choice of control region | 6\% | - |
| $Z$ mass window | $4 \%$ | - |
| Jet energy scale | 16\% | - |
| Jet energy resolution | 7\% | - |
| Sample composition | $31 \%$ | - |
| $\tau+$ lepton: jet $\rightarrow \tau$ misidentification |  |  |
| Statistics in control region | 2\% | - |
| Jet composition | 11\% | - |
| Object-related systematics | 23\% | $3 \%$ |
| $\tau+$ lepton: $e \rightarrow \tau$ misidentification |  |  |
| Misidentification probability | 20\% | - |
| $\tau+$ lepton: lepton misidentification |  |  |
| Choice of control region | $4 \%$ | - |
| $Z$ mass window | 5\% | - |
| Jet energy scale | $14 \%$ | - |
| Jet energy resolution | 4\% | - |
| Sample composition | 39\% | - |
| $\tau+$ jets: true $\tau$ |  |  |
| Embedding parameters | 6\% | 3\% |
| Muon isolation | 7\% | $2 \%$ |
| Parameters in normalisation | 16\% | - |

| $\tau+$ jets: $e \rightarrow \tau$ misidentification |  |  |
| Misidentification probability | 22\% | - |
| $\tau+$ jets: multi-jet estimate |  |  |
| Fit-related uncertainties | $32 \%$ | - |
| $E_{\mathrm{T}}^{\text {miss }}$-shape in control region | 16\% | - |

Table 8. Dominant systematic uncertainties on the data-driven estimates. The shape uncertainty given is the relative shift of the mean value of the final discriminant distribution. A "-" in the second column indicates negligible shape uncertainties.
using simulation. Other uncertainties come from the impurities arising from multi-jet background events and from true hadronic $\tau$ decays in the control sample. The systematic uncertainties affecting the estimation of the background from correctly reconstructed $\tau$ jets in the $\tau+$ jets channel, discussed in section 6.4 , consist of the potential bias introduced by the embedding method itself, uncertainties from the trigger efficiency measurement, uncertainties associated to simulated $\tau$ jets ( $\tau$ energy scale and identification efficiency) and uncertainties on the normalisation, which are dominated by the statistical uncertainty of the selected control sample and the $\tau+E_{\mathrm{T}}^{\text {miss }}$ trigger efficiency uncertainties.

## 8 Results

In order to test the compatibility of the data with background-only and signal+background hypotheses, a profile likelihood ratio [58] is used with $m_{\mathrm{T}}^{H}$ (lepton+jets), $E_{\mathrm{T}}^{\text {miss }}$ ( $\tau+$ lepton) and $m_{\mathrm{T}}(\tau+$ jets $)$ as the discriminating variables. The statistical analysis is based on a binned likelihood function for these distributions. The systematic uncertainties in shape and normalisation are incorporated via nuisance parameters, and the one-sided profile likelihood ratio, $\tilde{q}_{\mu}$, is used as a test statistic. No significant deviation from the SM prediction is observed in any of the investigated final states in $4.6 \mathrm{fb}^{-1}$ of data. Exclusion limits are set on the branching fraction $\mathcal{B}\left(t \rightarrow b H^{+}\right)$and, in the context of the $m_{h}^{\max }$ scenario of the MSSM, on $\tan \beta$, by rejecting the signal hypothesis at the $95 \%$ confidence level (CL) using the $\mathrm{CL}_{s}$ procedure [59]. These limits are based on the asymptotic distribution of the test statistic [58]. The combined limit is derived from the product of the individual likelihoods, and systematic uncertainties are treated as correlated where appropriate. The exclusion limits for the individual channels, as well as the combined limit, are shown in figure 7 in terms of $\mathcal{B}\left(t \rightarrow b H^{+}\right)$with the assumption $\mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)=100 \%$. In figure 8 , the combined limit on $\mathcal{B}\left(t \rightarrow b H^{+}\right) \times \mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)$ is interpreted in the context of the $m_{h}^{\max }$ scenario of the MSSM. The following relative theoretical uncertainties on $\mathcal{B}\left(t \rightarrow b H^{+}\right)$are considered [60, 61]:5\% for one-loop electroweak corrections missing from the calculations, $2 \%$ for missing two-loop QCD corrections, and about $1 \%$ (depending on $\tan \beta$ ) for $\Delta_{b}$-induced uncertainties, where $\Delta_{b}$ is a correction factor to the running $b$ quark mass [62]. These uncertainties are added linearly, as recommended by the LHC Higgs cross section working group [61].

## 9 Conclusions

Charged Higgs bosons have been searched for in $t \bar{t}$ events, in the decay mode $t \rightarrow b H^{+}$followed by $H^{+} \rightarrow \tau \nu$. For this purpose, a total of $4.6 \mathrm{fb}^{-1}$ of $p p$ collision data at $\sqrt{s}=7 \mathrm{TeV}$, recorded in 2011 with the ATLAS experiment, is used. Three final states are considered, which are characterised by the presence of a leptonic or hadronic $\tau$ decay, $E_{\mathrm{T}}^{\mathrm{miss}}, b$ jets, and a leptonically or hadronically decaying $W$ boson. Data-driven methods and simulation are employed to estimate the number of background events. The observed data are found to be in agreement with the SM predictions. Assuming $\mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)=100 \%$, upper limits at the $95 \%$ confidence level have been set on the branching ratio $\mathcal{B}\left(t \rightarrow b H^{+}\right)$between $5 \%\left(m_{H^{+}}=90 \mathrm{GeV}\right)$ and $1 \%\left(m_{H^{+}}=160 \mathrm{GeV}\right)$. This result constitutes a significant

Figure 7. Expected and observed $95 \%$ CL exclusion limits on $\mathcal{B}\left(t \rightarrow b H^{+}\right)$for charged Higgs boson production from top quark decays as a function of $m_{H^{+}}$, assuming $\mathcal{B}\left(H^{+} \rightarrow \tau \nu\right)=100 \%$. Shown are the results for: (a) lepton+jets channel; (b) $\tau+$ lepton channel; (c) $\tau+$ jets channel; (d) combination.
improvement compared to existing limits provided by the Tevatron experiments [14, 15] over the whole investigated mass range, but in particular for $m_{H^{+}}$close to the top quark mass. Interpreted in the context of the $m_{h}^{\max }$ scenario of the MSSM, $\tan \beta$ above 12-26, as well as between 1 and 2-6, can be excluded in the mass range $90 \mathrm{GeV}<m_{H^{+}}<150 \mathrm{GeV}$.

## Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

Figure 8．Combined $95 \%$ CL exclusion limits on $\tan \beta$ as a function of $m_{H^{+}}$．Results are shown in the context of the MSSM scenario $m_{h}^{\max }$ for the region $1<\tan \beta<60$ in which reliable theoretical predictions exist．The theoretical uncertainties described in the text are shown as well．

The 10 Gigabit Ethernet (10GbE) link model is examined and conservative link power penalties are predicted. We conduct parameter sensitivity analyses and find that the transmitter characteristics affect the link power penalties most. Power penalty differences of multi-mode and single-mode commerical transceiver modules over different fiber lengths are tested to be within the simulation limits. The optical power budgets are then proposed for different Versatile Link variants.

## 1 Introducion

The Versatile Link project aims to provide a radiation and magnetic field tolerant, high-speed (4.8 Gbps tentative) optical link for the readout and control of SLHC experiments [1]. For a large scale integration project like this, a system level specification is required to ensure the functionality, environmental resistance and operational reliability of the Versatile Link in the proposed applications. One of the most important metrics to be determined is the optical power budget, which specifies a link's signal strengths and power allocations for a given level of performance. On one hand, the distribution of the available power among the link segments should take into account the full range of transmission penalties, the radiation induced degradations as well as a safety margin for unexpected losses. On the other hand, the required optical power levels of the link transceivers should not exceed the manufacturability of these components.

Relevant industrial standards are 10GBASE-SR and 10GBASE-LR as well as fiber channel 400-SM-LC and 400-M5E-SN [2, 3], which have gained international support over the years and to which the commercial components, namely, the back-end, of the Versatile Link will comply. Due to the design philosophy of "worst case" operations and the "interoperability" use of components, optical power budget recommendations by these standards are quite conservative and leave no margins for customization. Since the Versatile Link operates at a lower data rate and a shorter target length (around 150 meters from the front-end detector to the back-end counting room), it is beneficial to re-evaluate the link penalties. More importantly, since the Versatile Link frontend components are expected to suffer significant power degradation from radiation during their lifetimes, and the total losses cannot be accommodated by the existing margins, it is necessary to re-examine the power level limits on the link components. The goal is to propose a conservative yet realistic power budget.

In section 2, the typical Versatile Link transmission scheme and the optical link budget process are described. The IEEE 10GbE link model is investigated in section 3, where bit error rate (BER)

Figure 1. Block diagram of a possible data transmission scheme using the Versatile Link.
measurements on reference links with commercial transceivers are also reported. A crucial part of the power budget is based on the knowledge of device radiation tolerance. This is discussed in section 4. The overall Versatile Link power budget is proposed in section 5 followed by a concluding discussion in section 6 .

## 2 Optical link power budget

The physical layer of a typical optical link comprises the laser-based transmitter circuitry, the PIN photodiode-based receiver circuitry and the fiber medium. A block diagram of a possible transmission scheme deployed by the Versatile Link is shown in figure 1. The central red block encompasses the Versatile Link components. The link is bi-directional and accommodates devices that support both multi-mode operation with a center-wavelength of 850 nm and single-mode operation with a center-wavelength of 1310 nm .

Two types of electro-optical transceivers are used in the Versatile Link. The on detector module, the versatile transceiver (VTRx), will be custom designed. It consists of a radiation tolerant laser driver (LDD) and a qualified laser diode on the transmitting side; a qualified PIN diode and a radiation tolerant post-amplifier (TIA) on the receiving side. The off detector module, the standard transceiver (TRx), will be procured commercial-off-the-shelf (COTS), as will be the fiber cables.

Given the on and off detector transceiver differences and the two wavelengths of operation, four link variants are specified individually. In the MM_VTx_Rx and the SM_VTx_Rx configurations, data flow from the versatile transmitter on detectors to a standard receiver in the counting room, using multi-mode and single-mode transceiver modules and over multi-mode and singlemode fibers, respectively. In the MM_Tx_VRx and the SM_Tx_VRx configurations, data flow in the opposite direction from standard transmitters in the counting room to the versatile receivers on detector.

To ensure a link BER below $10^{-12}$ at the target data rate and fiber length, across operation temperatures and throughout life cycle, the optical power budget must be carefully planned ahead so that an adequate receiving signal-to-noise ratio is maintained under all conditions. The process is mapped as the allocation of available power among various loss components, as shown in figure 2. The amount of optical power launched into the link is deduced from the difference between the transmitter minimum output, i.e., Tx_OMA_min (OMA - optical modulation am-

Figure 2. Power budget process in an optical link.

Table 1. Key characteristics in support of the Versatile Link model simulation.

|  | MM_VL | SM VL |
| :--- | :---: | :---: |
| Data rate (Gbps) | 5 | 5 |
| Link length (meter) | 150 | 150 |
| Center wavelength (nm) | 850 | 1310 |
| RMS spectral width (nm) | 0.49 | 0.2 |
| Optical rise/fall time (ps) | 75 | 75 |
| Relative intensity noise (dB/Hz) | -130 | -130 |
| Mode partition noise coefficient | 0.3 | 0 |
| Reflection coefficient | 0 | 0.6 |

plitude) and the receiver minimum power input, i.e. Rx_sensitivity_OMA. The proposed Versatile Link transceiver power levels are discussed in section 5. Link penalties arising from various mechanisms are discussed in section 3. Since the Versatile Link is designed to meet the requirements of SLHC experiments, allowance must be allocated to radiation degradations, as are described in section 4 . Finally, engineering judgment is called for in the assignment of a safety margin.

## 3 Link model and BER test

An open source 10 GbE link model has been developed by the IEEE high speed working group as a tool to facilitate optical physical layer specifications. The model calculates impairments caused by inter-symbol-interference (ISI), mode partition noise (MPN), relative intensity noise (RIN), duty-cycle-distortion (DCD), etc. These nonlinear effects result in an increased aggregated link power penalty as the data rate and link length increase.

The link model is populated with key parameter values that represent the Versatile Link operation conditions, as summarized in table 1 . The simulation renders a maximum penalty of 1.0 dB for the multi-mode versatile link and a maximum penalty of 1.5 dB for the single-mode versatile link operations. Compared to 4.7 dB and 3.2 dB in the 10GBASE-S and 10GBASE-L budgets, the allocation for link penalties are largely reduced since the Versatile Link operates at a lower data rate and shorter reach.

Power penalty dependence on the transmitter, fiber and receiver characteristics was examined and two sets of sensitivity charts are shown in figure 3 . We found that in the multi-mode link, power penalty is most sensitive to the optical rise/fall time, $\mathrm{T}_{r / f}(20 \%-80 \%)$, in the sense that the power penalty change is steep in a wide working range. Whereas for the other parameters, i.e., RIN noise, RMS spectral width and receiver bandwidth, the power penalty change is relatively flat in certain working ranges. In the single-mode link, reflection is another sensitive parameter. But the reflection can be controlled through isolators or angle polished connectors to be less than -12 dB .

Figure 3. Top: MM_VL link and bottom: SM_VL link characteristic sensitivity charts.

Figure 4. Link power penalties deduced from BER measurements. Left: differences among multi-mode links; right: differences among single-mode links (OMA - optical modulation amplitude measured at the receiver input).

In the previous table, the optical rise/fall time is set to the high end of the target working range to ensure the conservativeness of the link analyzed.

Measurement of link power penalty requires comparison of BER over a typical range since the power penalty is manifested as the horizontal shift in the BER curves. Both multi-mode and single-mode links are constructed using a batch of commercial transceiver modules. A number of different transmitters are launched into different fibers and connected to one reference receiver. The fibers range from 2 meters to 150 meters. Figure 4 shows that power penalty differences among these links are all below 1.5 dB . It further shows that the performance variations of the transmitters have a slightly larger impact on power penalties than the performance and length variations of the fibers at this range. The link model predictions correlate well with these experimental results and are hence adapted in the power budget calculations presented in section 5 .

## 4 Radiation degradation

Qualified Versatile Link front-end components must withstand a level of radiation up to the SLHC level. In addition, their radiation induced power degradation must fit in the allowance allocated in the overall link budget. Candidate laser, PIN, driver, amplifier and fibers are examined in [5, 6].

Table 2. Versatile Link power budget table with 4 variants.

| configuration/parameter | MM_VTx_Rx | $M_{M}$ _Tx_VRx | SM_VTx_Rx | SM_Tx_VRx |
| :--- | :---: | :---: | :---: | :---: |
| Transceiverpower level |  |  |  |  |
| Tx OMA min | -3.8 dBm | -2.0 dBm | -3.2 dBm | -2.8 dBm |
| Rx Sensitivity OMA | -11.1 dBm | -13.1 dBm | -12.6 dBm | -15.4 dBm |
| Power budget (Tx - Rx) | 7.3 dB | 7.3 dB | 9.4 dB | 9.4 dB |
| Fiber attenuation | 0.6 dB | 0.6 dB | 0.1 dB | 0.1 dB |
| Connection and splice loss | 1.5 dB | 1.5 dB | 2.0 dB | 2.0 dB |
| Link penalties | 1.0 dB | 1.0 dB | 1.5 dB | 1.5 dB |
| Tx irradiation degradation | - | - | - | - |
| Rx irradiation degradation | - | 7.0 dB | - | 9.0 dB |
| Fiber irradiation degradation | 1.0 dB | 1.0 dB | - | - |
| Margin | 3.2 dB | 0.0 dB | 5.8 dB | 0.0 dB |

Sources of degradations are described below. Tested or extrapolated to a maximum exposed radiation of $6 \times 10^{15} \mathrm{~cm}^{-2}$ neutron fluence, the corresponding degradation allowances are also allocated.

Both the vertical cavity surface emitting (VCSEL) based multi-mode lasers and the FabryPerot (FP) based single-mode lasers show increased threshold current and decreased slope efficiency. Yet the transmitter power loss should be compensated by increasing drive current and should not exceed 0.05 dB . Both GaAs based multi-mode PIN diodes and InGaAs based singlemode PIN diodes show decreased responsivity, while the InGaAs PIN diodes also suffer from increased leakage current. Overall receiver sensitivity degradations should not exceed 9.6 dB for GaAs devices and 5.4 dB for InGaAs devices. PIN diode and post amplifier circuits are also vulnerable to single event upsets (SEU). A customized coding scheme successfully demonstrated the resistance against SEU induced single and burst errors. Different fiber types degrade differently. Radiation induced attenuation is worse at cold temperatures. A few radiation resistant grade candidates are identified and expected to perform most optimistically. Qualified fiber radiation induced attenuation should not exceed 1.0 dB for multi-mode fibers and 0.05 dB for single-mode fibers.

## 5 Power penalty specification

Power budget specifications are then proposed for the four variants of the Versatile Link, as listed in table 2. In addition to link penalties and radiation degradations described in the previous sections, fiber attenuation is $3.5 \mathrm{~dB} / \mathrm{km}$ for multi-mode and $0.4 \mathrm{~dB} / \mathrm{km}$ for single-mode. Connector and splice loss is 1.5 dB for multi-mode and 2.0 dB for single-mode, which supports 3 or 4 connections with an insertion loss of no more than 0.5 dB each.

Standard 10GbE compliant transmitter power and receiver sensitivity specifications are applied to the two uplinks, MM_VTx_Rx and SM_VTx_Rx. After the modification on link penalties and the insertion of radiation degradations, these two uplinks meet budget with an increased safety margin. In the two downlinks, MM_Tx_VRx and SM_Tx_VRx, the specifications of the versatile receiver and the corresponding transmitter must exceed those of the standard modules in order to compensate for the large radiation deficits. These elevated power requirements on the downlink transceivers are within technology limits, but mandate individual screening tests. And the safety margin is reduced to zero.

## 6 Conclusion

Link model simulations and BER tests are performed to evaluate the optical power penalties in the Versatile Link power budget. The results conform well and support a sizable reduction in the allocation for link penalties. However, to accommodate the radiation degradation of the front-end components, power levels of the downlink transceivers still need to be elevated.

Currently there are not enough safety margins to cover environmental and other unexpected losses in the down links. Several further explorations are possible. At the system level, receiver degradation can be relieved by positioning the components further away from detector. At the component level, extra power can be garnered by modest redesign of the laser coupling interface. At the data transmission level, custom coding is known to provide single event upset resistance, which can be quantified as potential power gain.

## Acknowledgments

The authors acknowledge the US-ATLAS R\&D program and the US Department of Energy for funding this work. We would also like to acknowledge Dr. Gary Evans from SMU, Dr. Jim Tatum from Finisar and John Chramowicz from FNAL for beneficial discussions.

ABSTRACT: The radiation response of a $0.25 \mu \mathrm{~m}$ silicon-on-sapphire CMOS technology is characterized at the transistor and circuit levels utilizing both standard and enclosed layout devices. The threshold-voltage shift is less than 170 mV and the leakage-current increase is less than 1 nA for individual standard-layout nMOSFET and pMOSFET devices at a total dose of $100 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$. The increase in power supply current at the circuit level was less than $5 \%$, consistent with the small change in off-state transistor leakage current. The technology exhibits good characteristics for use in the electronics of the ATLAS experiment at the Large Hadron Collider.

## 1 Introduction

Silicon-on-sapphire (SoS) complementary metal-oxide-semiconductor (CMOS) technology has been used in radiation-tolerant applications since the 1970s. SoS technologies exhibit several characteristics that make them attractive for use in radiation environments, including an insulating sapphire layer below the active silicon that eliminates the parasitic inter-device bipolar structure associated with latchup in bulk devices. SoS technologies also have been reported to have smaller singleevent upset cross-sections than equivalent bulk processes [1]. However, radiation-induced leakage currents along the edges of the device and the back channel, where the active silicon meets the sapphire substrate, are important issues in these technologies [2]. The ATLAS experiment at the Large Hadron Collider is one example of an application for which SoS technology is very promising; the radiation environment is quite challenging compared to typical space and defense applications [3].

In this work, the radiation response of a $0.25 \mu \mathrm{~m}$ SoS CMOS technology is characterized at the transistor and circuit levels. Devices are evaluated in both standard and enclosed layout geometries. Radiation-induced charge trapping in the gate oxide results in threshold voltage shifts less than 170 mV for standard-layout transistors irradiated to a total dose of $100 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$. Additionally, increases in radiation-induced leakage current are less than 1 nA for standard-layout nMOSFET and pMOSFET devices. Circuit-level evaluation of these structures is consistent with these results.

## 2 Test structures and experimental conditions

The Peregrine $0.25 \mu \mathrm{~m}$ SoS process is a thin-film technology with both partially depleted and fully depleted devices. The epitaxial silicon layer is 80 nm thick with a $200 \mu \mathrm{~m}$ sapphire insulating substrate. The gate oxide thickness is 6 nm , and the process uses LOCOS for device isolation. Individual transistors and a set of shift registers were fabricated on a test chip.

Structures were fabricated in either standard or enclosed layout geometries. Three different transistor types were used with high, regular, or intrinsic threshold voltages. Devices with regular and high threshold voltages are partially depleted, while the intrinsic devices are fully depleted. Devices were packaged and subsequently baked for twelve hours at $150^{\circ} \mathrm{C}$ in preparation for irradiation. nMOSFET and pMOSFET irradiation bias conditions were $V_{D}=2.5 \mathrm{~V}$ and -2.5 V ,

Figure 1. $I_{D}-V_{G}$ characteristics of an enclosed layout; regular threshold voltage nMOS SOS transistor.

Figure 2. $I_{D}-V_{G}$ characteristics of an enclosed layout; regular threshold voltage pMOS SOS transistor.
respectively; all other terminals were grounded. This off-state condition is the worst case for inverters exposed to total ionizing dose [4]. The transistors were irradiated with 10 keV x -rays at a dose rate of $31.5 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$ per minute using an ARACOR Model 4100 irradiator. $I_{D}-V_{G}$ sweeps were performed to characterize the leakage current and threshold voltage of irradiated devices. Device characterization was performed with an HP 4156A parameter analyzer with an applied drain bias of $\pm 0.1 \mathrm{~V}$ for nMOS and pMOS transistors, respectively. Gate voltages were swept between -1.5 V and 1.5 V . The source and sapphire substrate were grounded during device characterization and irradiation.

Two types of shift registers, consisting of 32 D-flip-flop stages, one using standard layout transistors, the other enclosed layout transistors, were fabricated for circuit-level evaluation of radiation-induced leakage current. The power supply voltage for the shift registers was 2.5 V with the substrate grounded. The shift registers were irradiated with 198 MeV protons to a total fluence of $1.27 \times 10^{13} \mathrm{~cm}^{-2}$ [5]. The operating frequency during irradiation was 40 MHz ; the power supply current for each shift register was monitored with a Keithley 2700 multi-channel digital multimeter.

## 3 Experimental results

Typical pre- and post-irradiation $I_{D}-V_{G}$ characteristics are shown in figures 1 and 2 for nMOS and pMOS transistors. These devices are enclosed layout, regular threshold voltage devices, corresponding to $V_{T}=0.55 \mathrm{~V}$ and -0.35 V , for nMOS and pMOS transistors, respectively.

An initial positive shift in threshold voltage, with a maximum value of 170 mV , was observed at less than $1 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$ in both nMOSFET and pMOSFET devices, as seen in figure 3. This initial shift is due to radiation-induced electron trapping in the sapphire substrate [6]. These trapped electrons accumulate the back channel of nMOSFETs, and the front to back coupling results in a shift in threshold voltage. In pMOSFETs the trapped electrons couple the front and back gate similarly; however, they deplete the n-type body, leading to additional leakage current. No additional threshold-voltage shifts were observed following the initial exposure of $10 \operatorname{krad}\left(\mathrm{SiO}_{2}\right)$, up to the largest dose considered here ( $100 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$ ).

Figure 3. $\Delta V_{T}$ as a function of dose for partially depleted nMOS and pMOS devices.

Figure 4. Change in leakage current with dose for high and regular threshold pMOSFETs with standard and enclosed layouts.

Figure 5. Change in leakage current with dose for high and regular threshold nMOSFETs with standard and enclosed layouts.

The radiation-induced leakage currents for standard and enclosed layout devices are shown in figures 4 and 5 for pMOSFETs and nMOSFETs, respectively. nMOS transistors in a standard layout configuration exhibit a parasitic conductive path along the edge of the device [7]. The enclosed layout transistors eliminate the edge leakage paths present in the standard layout nMOS devices. The edge leakage is associated with hole trapping in the isolation oxide, which affects nMOS transistors. Conversely, leakage paths exist for pMOS transistors primarily along the back channel of the device due to electron trapping, which impacts the threshold voltage of both nMOS and pMOS transistors. This back-channel leakage path exists and impacts both standard and enclosed layout device geometries.

The post-irradiation increase in power supply current at the circuit level is less than $5 \%$ (see figure 6), which is consistent with the relatively small radiation-induced change in off-state transistor leakage (less than 1 nA at $100 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$ for both nMOSFET and pMOSFET devices). Leakage current was consistently higher for standard-layout devices than for enclosed-layout devices following irradiation because of the elimination of the parasitic edge leakage path in the enclosedlayout devices. The increase in circuit-level leakage current with increasing dose is caused by the formation of a back channel in the pMOS devices along the sapphire-silicon interface.

Figure 6. Normalized power supply current of standard and enclosed layout shift registers irradiated with 198 MeV protons.

## 4 Conclusions

Single transistors and shift registers fabricated in a $0.25 \mu \mathrm{~m}$ SoS CMOS technology were irradiated with 10 keV x-rays and 198 MeV protons, respectively. Radiation-induced electron trapping at the silicon-sapphire interface results in a shift in threshold voltage for both nMOS and pMOS transistors. The magnitude of the threshold-voltage shift was less than 170 mV , and saturated within $1 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$. At the transistor level, standard-layout pMOSFETs exhibited the largest increases in leakage current due to electron trapping at the back-channel interface. Radiation-induced leakage current was 1 nA or less for all device variants. This result is consistent with circuit-level results during proton irradiation of shift registers, and had little impact on circuit operation. These results indicate that this $0.25 \mu \mathrm{~m}$ SoS technology exhibits stable operating characteristics in a total dose environment of $100 \mathrm{krad}\left(\mathrm{SiO}_{2}\right)$, and appears to be very well suited for operating in the ATLAS TID environment.

#### Abstract

Optical fibers in the readout system for the Large Hadron Collider (LHC) upgrades will operate in a harsh radiactive environment. The fibers within 12 meters from the front-end detectors are exposed up to total ionizing dose of $250 \mathrm{kGy}(\mathrm{Si})$ in their 10 year operational lifetime. In some applications, the fibers within the tracking volume are kept in a cold environment near $-25^{\circ} \mathrm{C}$. The paper presents the identification of suitable optical fibers for the LHC detector upgrades. Several optical fibers have been tested to $650 \mathrm{kGy}(\mathrm{Si})$ at room temperature with various dose rates of 60Co gamma rays. Two multi-mode fibers and one single-mode fiber have been qualified for use in the LHC upgrades for warm operations. Four optical fibers have been tested to $500 \mathrm{kGy}(\mathrm{Si})$ at $-25^{\circ} \mathrm{C}$ with $27 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr} 60 \mathrm{Co}$ gamma rays. Two SM fibers have been qualified for the LHC upgrades for cold operations. Several optical fibers, including two MM fibers, have been tested up to $11 \mathrm{kGy}(\mathrm{Si})$ at $-25^{\circ} \mathrm{C}$ with $70 \mathrm{~Gy}(\mathrm{Si}) / \mathrm{hr} 60 \mathrm{Co}$ gamma rays and exhibited moderate radiation induced attenuation (RIA, indicating that all tested fibers are potential candidates for the LHC upgrades for warm and cold operations.

Response to Reviewers: Reviewers' comments:
"Reviewer \#1: I think the manuscript is almost okay for the publication. But I have still a few questions and comments. I am happy if the authors think my comments and revise slightly the manuscript.

1. Figure 1(a),(b) and (c): I don't think readers will get so much information from the figures. The context can be understood without these figures actually. It may be better not to shown. I don't think the photographs are essential for the interpretation of data taken in BNL (Fig.5). But this is just my comment and to follow or ignore my idea is up to you.
2. In Page 5, a formula of RIA depicted in 3 Experimental Results must be rewritten: RIA $=10$ *log_10... should be RIA=10log_10... or $10 \times \log \_10 \ldots$ Usually "*" does not mean the multiplication operator.
3. Please discuss why you set threshold as about $0.1 \mathrm{~dB} / \mathrm{m}$ for robust fibers to be used in the future LHC experiment.
4. Please discuss how much dose rate is expected in the actual LHC experiment. I don't think there is an explicit value written in the paper. If you cannot evaluate the value precisely, then give just (even rough) range of expectation (In Page 10 Line 7)." [Numbering mine.]

Response to Reviewer Comment No. 1: I decided to keep these figures, as they provide a visual representation of the experiment setups. Also, Figure 1(a) in particular is very helpful for understanding the cooling system used at SCK-CEN.

Response to Reviewer Comment No. 2: The * symbol in the RIA formula was replaced with a x symbol.
Response to Reviewer Comment No. 3: To my knowledge, the paper does not explicitly mention a 0.1 $\mathrm{dB} / \mathrm{m}$ threshold; figures with this $\mathrm{dB} / \mathrm{m}$ unit only appear in discussions of the results. However, I did add the following sentence to paragraph 4 of the introduction (page 2), "The total RIA should not exceed 1.0 dB for MM fibers or 0.05 dB for SM fibers; these limits are set by the power budget of the link system [6]."

Response to Reviewer Comment No. 4: The paper does provide estimates of the actual LHC total dose and dose rate. An estimated total dose of 250 kGy is mentioned in the abstract and in paragraph 3 of the introduction (page 2), and an estimated dose rate of $9 \mathrm{~Gy} / \mathrm{hr}$ is given in paragraph 1 of page 7 . I reiterated this dose rate estimate in the conclusion.

## 1. Introduction

Optical fibers are materials with a high refractive index used to transmit data in the form of light over long distances. Utilizing dielectric wave guide techniques, optical fibers allow for such data transmission to occur with a negligible loss of signal strength. They most commonly consist of a silica glass core surrounded with cladding of a slightly different refractive index; this construction induces total internal reflection. Light propagates through optical fibers with little attenuation, and the signal can be modulated at a very high rate. The two main categories of optical fiber are multi-mode (MM) and single-mode (SM). MM fibers have a larger core diameter and support many propagation paths or transverse modes. They are generally used for short-distance communication links. SM fibers have a much smaller core diameter, usually less than ten times the propagating wavelength, and support only one transverse mode. They are typically used for longer links. To meet the detector data transmission objectives, both MM and SM systems have been proposed [1].

The ATLAS [2] (A Toroidal LHC Apparatus) and CMS [3] (Compact Muon Solenoid) particle physics experiments at the European Organization for Nuclear Research (CERN) seek to learn about the forces that formed and still act on the universe. Using the Large Hadron Collider (LHC), scientists from all over the world monitor collisions of high-energy particles that replicate the state of the universe at its very beginnings. Detection systems identify the particles involved and record their energy and momentum. Amongst other objectives, ATLAS and CMS seek to discover the Higgs boson, extra dimensions, and dark matter.

Both the ATLAS and CMS experiments use optical fibers to transfer data between front-end detectors and back-end computers. The fibers within 12 meters of the front-end detectors are exposed to a total ionizing dose of up to $250 \mathrm{kGy}(\mathrm{Si})$ in their 10 -year operational lifetime [4]. In some applications, the 2 meters closest to the front end are kept in a cold environment near $-25^{\circ} \mathrm{C}$. Ionizing radiation damages the molecular structure of the fibers' glass cores, creating charged scattering sites. These sites cause the light transmitted down the fiber to scatter into non-propagating modes, resulting in radiation-induced absorption (RIA) along the length of the fiber [4]. The fibers within the ATLAS and CMS detectors would need to maintain a pre-qualified attenuation while withstanding high radiation doses and low temperatures.

The Versatile Link Project was founded in April 2008 to develop a radiation-tolerant optical interface for the proposed LHC upgrades. This interface requires bidirectional data transmission capabilities of up to $5 \mathrm{~Gb} / \mathrm{s}$ via optical fibers that are qualified to withstand radiation doses of up to $500 \mathrm{kGy}(\mathrm{Si})$ at room temperature and at low temperatures of approximately $-25^{\circ} \mathrm{C}$ [5]. The upgrade is to utilize either MM fibers with an operational wavelength of 850 nm or SM fibers with an operational wavelength of 1310 nm . The total RIA should not exceed 1.0 dB for MM fibers or 0.05 dB for SM fibers; these limits are set by the power budget of the link system [6]. The total RIA should be calculated via a worst-case piecewise fiber routing. Scientists from CERN, Oxford University, Fermi National Laboratory, and Southern Methodist University (SMU) work on the project.

## 2. Experimental Setup

As an important step towards achieving its goals, the Versatile Link Project is testing off-the-shelf optical fibers for radiation tolerance. As of TIPP 2011, four experiments have been conducted, subjecting the fibers to various radiation doses at either room temperature or at approximately $-25^{\circ} \mathrm{C}$. Table 1 lists the fibers that have been tested thus far. The Corning fibers were commercially available as of the tests described in this paper, although the Infinicor SX+ can no longer be purchased. None of the Draka fibers tested reached the open market, but instead served as prototypes for the DrakaElite ${ }^{\text {TM }}$ line of MM and SM
fibers. Some of these fibers will be tested in the future. Fibres X and Y are patent-pending designs produced by CERN and undisclosed companies.

Table 1. Fibers tested

| Manufacturer | Part number | MM/SM | Operational wavelength (nm) |
| :---: | :---: | :---: | :---: |
| Corning [7] | ClearCurve OM3 | MM | 850 |
|  | Infinicor SX+ | MM | 850 |
|  | SMF-28 | SM | 1310 |
|  | SMF-28e+ | SM | 1310 |
|  | SMF-28XB | SM | 1310 |
| Draka [8] | Draka-1 | MM | 850 |
|  | RHP-1 | MM | 850 |
|  | RHP-1 SRH | MM | 850 |
|  | RHP-2 | MM | 850 |
| Manufacturer X | Fibre X | SM | 1310 |
| Manufacturer Y | Fibre Y | SM | 1310 |

The Belgian Nuclear Research Center (SCK-CEN) near Mol, Belgium is one of two facilities at which the Versatile Link Project has carried out its fiber radiation tests. Two gamma radiation sources at SCKCEN bombarded the fibers to simulate the LHC's radioactive environment. The "Brigitte" source utilized rods of ${ }^{60} \mathrm{Co}$ to deliver high dose rates of up to $27 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$. The "Rita" source, also ${ }^{60} \mathrm{Co}$, provided dose rates of up to $1.01 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$. As a side note, gamma radiation sources were chosen for safety reasons; once the sources were covered, the radiation dissipated within seconds.

No temperature control system was used for the experiments conducted at room temperature. For the tests conducted at $-25^{\circ} \mathrm{C}$, however, a dual-phase temperature control system was developed at Oxford for use at SCK-CEN. Carbon dioxide $\left(\mathrm{CO}_{2}\right)$ entered the system at a pressure of 50 bar and condensed into a liquid via the Joule-Kelvin Effect; the work done by high-pressure $\mathrm{CO}_{2}$ to overcome the impedance of very narrow capillary tubes caused the temperature to decrease. The fibers were then cooled as $\mathrm{CO}_{2}$ evaporated in liquid-gas dual-phase. A Back Pressure Regulator regulated the dual-phase system's pressure, which in turn allowed the fibers' temperature to be controlled. After cooling the fibers, the cold, low pressure $\mathrm{CO}_{2}$ was also used to cool the incoming high pressure gas in a double-pipe heat exchanger; this last process increased the system's efficiency [9]. Figure 1(a) provides a graphical representation of this cooling system.

The other fiber testing site was Brookhaven National Laboratory (BNL) in Upton, New York. A ${ }^{60} \mathrm{Co}$ gamma source, housed within a cylindrical containment vessel, provided a dose rate of up to 0.4 $\mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$ at a 20 cm by 20 cm window in the source container. The dose rate was adjusted by placing the fibers at different distances from the source; higher doses could be obtained by placing a sample inside the window. Figure 1(b) illustrates this setup. For the low temperature experiments, the fibers were placed in a chest freezer in order to keep them at an ambient temperature of $-25^{\circ} \mathrm{C}$ [10]. The freezer's control electronics were shielded with lead bricks so that they would not be damaged by radiation. The fibers were routed into the freezer and coiled within the path of the radiation. Figure 1(c) shows the freezer's interior.

## 3. Experimental Results

To evaluate the effectiveness of each fiber under radiation, a signal was propagated at one end and then measured at the other. Vertical Cavity Surface-Emitting Lasers (VCSEL's) channelled light of a 850 nm wavelength through the MM fibers, while Edge-Emitting Lasers (EEL's) directed light of a $1,310 \mathrm{~nm}$ wavelength through the SM fibers. At the end of each fiber opposite the light source, the remaining signal was converted to a voltage and measured. Each voltage was then translated into optical power, and each power result was used in Equation 1, where $P(t)$ is optical power at time $t$ and $t_{0}$ is the time the irradiation started, to determine the fiber's radiation-induced attenuation (RIA) at its particular time.

$$
\begin{equation*}
R I A=10 \times \log _{10}\left[\frac{P_{t_{0}}}{P t}\right] \tag{1}
\end{equation*}
$$

Figure 2 depicts the results of an experiment conducted in 2008 at the SCK-CEN "Brigitte" and BNL facilities. When tested to a total dose of $650 \mathrm{kGy}(\mathrm{Si})$ at a dose rate of $22.5 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$, all of the MM fibers tested (the Infinicor SX+, Draka-1, Draka-RHP-1, and Draka RHP-2) performed reasonably well. The RIA that they experienced was between 0.1 and $0.5 \mathrm{~dB} / \mathrm{m}$ [4]. The Infinicor SX+ was also tested at BNL to a total dose of $10 \mathrm{kGy}(\mathrm{Si})$, at dose rates of $0.424,0.343$, and $0.0265 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$; peak RIA was $0.06 \mathrm{~dB} / \mathrm{m}$ in these conditions [4]. Of the fibers tested, only the Infinicor SX+ and Draka-RHP-1 were judged sufficiently robust to be qualified for warm operations at the LHC. The only SM fiber tested, the Corning SMF-28, was a standout performer; its peak RIA was less than $0.07 \mathrm{~dB} / \mathrm{m}$ when tested to 650 $\mathrm{kGy}(\mathrm{Si})$ at $22.5 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}[4]$.

Fig. 2. (a) Results at room temperature under a dose rate of $22.5 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$ for Draka-1 (green), Draka-RHP-2 (blue), Infinicor SX+ (red), and Draka-RHP-1 (black); SCK-CEN

Fig. 2. (b) SM results at room-temperature; SCK-CEN

An interesting result of the high-dose experiments was an early attenuation spike, which was followed by a less rapid decrease in RIA and then another increase. The reason for the pattern is not clear, but it is probably due to two different damage processes. The high initial attenuation is due to the incoming radiation filling naturally-occurring defects within the fibers, known as Self-Trapped Holes (STH). In a high dose environment, these holes fill within minutes of exposure to radiation, bringing RIA to a maximum. At the same time, the corresponding annealing process works to break the STH bonds, eventually causing the attenuation to fall. This latter process is dependent on both the nature of the fiber and the ambient temperature. For the high dose experiments depicted in Figure 2, the fibers were constrained by three solid aluminium disks, each 220 mm in diameter and 10 mm in thickness. The high energy gamma ray photons resulting from ${ }^{60} \mathrm{Co}$ decay Compton scattered off the aluminium's electrons. Since the gamma rays were of high enough energy, the Compton scattering produced measurable heat. At the start of the RIA decline for each of the fibers, temperature had increased by $5^{\circ} \mathrm{C}$; it possible that this rise in temperature spurred the annealing process to a higher rate than the attenuation. The other damage process is the newly induced radiation damage to the fiber's core. This process eventually took over in the high dose experiments, after the temperature stabilized and the STH annealing ended. The annealing of newly induced radiation damage had little effect, as evidenced by the consistent increase in RIA until the end of the experiment [4]. Continued monitoring of the fibers after the tests, though, revealed that RIA decreased over time after irradiation. Ultimately, these processes are still not well understood. However, the Versatile Link Project is concerned with dose rates on the order of $9 \mathrm{~Gy}(\mathrm{Si}) / \mathrm{hr}$, calculated by dividing the estimated 250 kGy total dose by $10^{8}$ seconds of operation over the course of 10 years. Since the STH effect only occurs at high dose rates, it was ignored in the route specific RIA calculations.

Figure 3 depicts the results of an experiment conducted in 2009 at the SCK-CEN "Rita" facility. The Draka-RHP-1 fiber was tested to a total dose of $30 \mathrm{kGy}(\mathrm{Si})$ at a dose rate of $0.5 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$, at temperatures of -4 and $-25.5^{\circ} \mathrm{C}$. This experiment was the first in which the RIA of candidate fibers was studied near the operating temperature of optical fibers in the ATLAS and CMS experiments. The maximum RIA was $\sim 0.05 \mathrm{~dB} / \mathrm{m}$; the fiber experienced this RIA at the lower temperature of $-25.5^{\circ} \mathrm{C}$ [11]. This temperature dependence is a result of the ambient temperature's effect on the annealing process. At lower temperatures the rate of annealing is significantly reduced, resulting in a higher RIA.

Fig. 3. RIA of Draka-RHP-1 at -4 (red) and -25 (blue) ${ }^{\circ} \mathrm{C}$

Figure 4 depicts the results of an experiment conducted in 2010 at the SCK-CEN "Brigitte" facility, in which several fibers were tested at $-25^{\circ} \mathrm{C}$ and $27 \mathrm{kGy}(\mathrm{Si}) / \mathrm{hr}$ to $500 \mathrm{kGy}(\mathrm{Si})$, approximately twice the total lifetime dose the fibers would experience in operation at the LHC. Two of the SM fibers tested, Fibres X and Y, experienced very low RIA and, as such, were qualified for use at the LHC. The other SM fiber, the SMF-28e+, and the one MM fiber tested, the Infinicor SX+, saturated almost immediately; the RIA for both of these fibers fluctuated between $\sim 1 \mathrm{~dB} / \mathrm{m}$, the maximum possible value, and $\sim 0.8 \mathrm{~dB} / \mathrm{m}$ [11]. If such an RIA were to occur in service at the LHC, the fibers would be rendered inoperative. However, because of the experiment's very high dose rate, the Infinicor and SMF-28e+ cannot necessarily be excluded as candidates for the LHC upgrades.

Fig. 4. (a) RIA of Fibre Y

Fig. 4. (b) RIA of Fibre X

Fig. 4. (c) RIA of Infinicor SX+

Fig. 4. (d) SMF-28e+
Figure 5 depicts the results of an experiment conducted in 2011 at BNL, in which fibers were tested at $-25^{\circ} \mathrm{C}$ to a dose of $10 \mathrm{kGy}(\mathrm{Si})$ at a dose rate of $\sim 60 \mathrm{~Gy}(\mathrm{Si}) / \mathrm{hr}$. In this experiment, two new fibers, the SMF-28XB (SM) and ClearCurve OM3 (MM), were tested, as they could potentially render some of the previously-tested fibers obsolete. These same two fibers performed better than their older counterparts, the SMF-28 (SM) and Infinicor SX+ (MM). The ClearCurve experienced a maximum RIA of $0.03 \mathrm{~dB} / \mathrm{m}$, while the SMF-28XB experienced a peak RIA of $0.057 \mathrm{~dB} / \mathrm{m}$ [12]. However, all of the fibers tested were qualified for low-dose operations at the LHC. As a side note, one of the ClearCurve fibers, labelled OSA in the Figure, was removed during the course of the experiment for other purposes.

Fig. 5. RIA of fibers for the 2011 BNL experiment

## 4. Conclusions

Since 2008, the Versatile Link Project has tested multiple optical fibers for use in fiber optic data links, as part of the proposed LHC upgrades. Two MM fibers (the Infinicor SX+ and Draka-RHP-1) and one SM fiber (SMF-28) have been qualified for warm operations at the LHC. Two SM fibers (Fibres X and Y) were qualified for low-temperature operations at the LHC in a high-dose test. During this experiment, the MM fibers experienced very high RIA. The Infinicor SX+, despite experiencing high RIA at a high dose rate, is still a viable MM candidate; it exhibits low RIA at a low dose rate, and the dose rate used in the high dose experiment was far higher than the $\sim 9 \mathrm{~Gy}(\mathrm{SI}) / \mathrm{hr}$ that the fiber would experience in operation at the LHC. The newer ClearCurve OM3 and SMF-28XB perform even better at a low dose rate than their older counterparts, but still must be tested at high doses. Another fiber radiation test was conducted during the summer of 2011, subjecting fibers to a relatively high radiation dose of 220 $\mathrm{kGy}(\mathrm{Si})$, but at a lower dose rate. The results are currently being analyzed. All of these experiments contribute to the knowledge pool of radiation-tolerant optical fibers, opening the door for applications in particle physics, space exploration, and many other scientific endeavors.

# Electron and photon reconstruction and identification in ATLAS: expected performance at high energy and results at 900 GeV 

The ATLAS Collaboration

#### Abstract

This note presents the first study of electron and photon candidates in the 900 GeV collision data collected by ATLAS at the end of 2009, the collision events analysed corresponding to a total integrated luminosity of approximately $9 \mu b^{-1}$. Good agreement is demonstrated between observation and expectation for low- $p_{T}$ electron and photon reconstruction and identification. The expected performance of the reconstruction and identification algorithms used for this purpose and optimised for high- $p_{T}$ physics are described for reference in the first part of this note.

## 1 Introduction

At the end of 2009, ATLAS enjoyed a series of stable LHC runs at a centre-of-mass energy of 900 GeV , successfully recording and analysing the many collisions which took place. A significant number of low- $p_{T}$ electron and photon candidates were reconstructed in these events, the majority being ascribed to photons from $\pi^{0}$ decays, electrons from photon conversions, and hadrons faking electrons or photons. Whilst the transverse energies of the candidates observed in these data are well below those for which the reconstruction and identification algorithms have been optimised, the measurements already provide a quantitative test of both the algorithms themselves and the reliability of the performance predictions in the transverse energy range from the reconstruction threshold of 2.5 GeV to almost 10 GeV .

The electron and photon reconstruction and identification algorithms used in ATLAS are designed to achieve both a large background rejection and a high and uniform efficiency over the full acceptance of the detector and for transverse energies above 20 GeV . Isolated electrons need to be separated from hadrons in QCD jets, from background electrons (originating mostly from photon conversions in the tracker material), and from non-isolated electrons from heavy flavour decays. At transverse energies above 20 GeV , neutral hadron decays, mainly the decay $\pi^{0} \rightarrow \gamma \gamma$, are responsible for the majority of background photons. Section 2 of this note gives an overview of the expected performance for electrons and photons, covering reconstruction, identification and calibration.

In Section 3, this note describes the observed electron and photon candidates at 900 GeV , and compares them to those obtained from high-statistics samples of non-diffractive minimum bias simulation. Specifically, this section compares the observed and predicted distributions of the electromagnetic calorimeter and tracker observables and of the match between them. In the case of the simulation, the predicted background is broken down into its different components, and these are compared in the case of electrons to a data-driven determination of each of the two major background components.

## 2 Expected reconstruction and identification performance

The ATLAS electromagnetic (EM) calorimeter has a fine segmentation in both the lateral ( $\eta \times \phi$ space) and longitudinal directions of the showers [1]. At high energy, most of the EM shower energy is collected in the second layer which has a lateral granularity of $0.025 \times 0.025$ in $\eta \times \phi$ space. The first layer consists of finer-grained strips in the $\eta$-direction (with a coarser granularity in $\phi$ ), which offer excellent $\gamma-\pi^{0}$ discrimination. These two layers are complemented by a presampler layer placed in front with coarse granularity to correct for energy lost in the material before the calorimeter, and by a back layer behind, which enables a correction to be made for the tail of very highly energetic EM showers.

The transition region between the barrel and end-cap EM calorimeters, $1.37<|\eta|<1.52$, is expected to have poorer performance than the fiducial regions discussed in this note because of the large amount of material in front of the first active calorimeter layers. The presampler layer covers only the range $|\eta|<1.8$. The end-cap EM calorimeters (EMEC) are divided into two wheels, the outer and inner wheels covering the ranges $1.375<|\eta|<2.5$ and $2.5<|\eta|<3.2$, respectively. The forward calorimeters (FCal) cover the range $3.1<|\eta|<4.9$ and also provide some EM shower identification thanks to their longitudinal segmentation into three layers.

The ATLAS inner detector provides precise track reconstruction over $|\eta|<2.5$ [2]. It consists of three layers of pixel detectors close to the beam-pipe, four layers of silicon microstrip detectors (SCT) providing eight hits per track at intermediate radii, and a transition radiation tracker (TRT) at the outer radii,
providing about 35 hits per track (in the range $|\eta|<2.0$ ). The TRT also provides substantial discriminating power between electrons and pions over a wide energy range (between 0.5 and 100 GeV ). The pixel vertexing layer (also called the B-layer) is located just outside the beam-pipe at a radius of 50 mm , and provides precision vertexing and significant rejection of photon conversions (through a requirement of a track with a hit in this layer).

All performance numbers quoted in this section are based on simulated samples at $\sqrt{s}=10 \mathrm{TeV}$ and are calculated in the absence of pile-up. Electron and photon reconstruction begins with the creation of a preliminary set of clusters in the EM calorimeter. The size of these seed clusters corresponds to $3 \times 5$ cells in $\eta \times \phi$ in the middle layer of the EM calorimeter. Electron and photon reconstruction is seeded from such clusters with $E_{T}>2.5 \mathrm{GeV}$, using a sliding window algorithm over the full acceptance of the EM calorimeter.

### 2.1 Electron reconstruction

Electrons are reconstructed from the sliding window clusters if there is a suitable match with a track of $p_{T}>0.5 \mathrm{GeV}$. The "best" track is the one lying with an extrapolation closest in $(\eta, \phi)$ to the cluster barycentre in the middle EM calorimeter layer. These reconstructed electron candidates are then subjected to an identification procedure designed to ensure that true electrons are selected with a high and uniform efficiency, whilst background electrons from photon conversions and fake electrons from QCD jets are strongly suppressed. Electron candidates with $|\eta|>2.5$ are termed "forward" electrons; they lie outside the range of the ATLAS tracking systems and are therefore reconstructed using an alternative algorithm. Focus is given in what follows to central electron reconstruction (see Sections 2.6 and 3.5 for details of forward electron reconstruction). For the barrel EM calorimeter, the optimal cluster size for electron candidates is $3 \times 7$ cells in $\eta \times \phi$, whereas it is $5 \times 5$ cells for the end-cap EM calorimeters.

### 2.2 Photon reconstruction

Photons are reconstructed from the sliding window clusters if there is no reconstructed track matched to the cluster (unconverted photon candidates) or if there is a reconstructed conversion vertex matched to the cluster (converted photon candidates). Converted photon candidates are efficiently reconstructed only if the conversion radius is below 800 mm and high efficiency in this range can only be achieved if one considers, in addition to double-track conversions, the so-called single-track conversions, i.e. those for which only one track is reconstructed and does not have any hit in the B-layer (see ref. [3] for details). A large fraction of single-track conversion candidates corresponds to a track reconstructed only in the TRT detector. Such tracks have no associated silicon detector information and have therefore poorer momentum resolution and $\eta$ information.

For the barrel EM calorimeter, the optimal cluster size for unconverted photon candidates is $3 \times 5$ cells in $\eta \times \phi$ whereas it is $3 \times 7$ cells for converted photon candidates. For the end-cap EM calorimeters, the optimal cluster size is $5 \times 5$ cells for all photon candidates.

### 2.3 Electron-photon ambiguities

In order to maximise the electron and photon reconstruction efficiencies simultaneously, a significant fraction of the converted photon candidates are considered also as electrons. The fraction of these ambiguous candidates is large and varies with $\eta$ due to the material distribution in the tracker. Two examples are given here:

- approximately $0.9 \%$ of electrons with $E_{T}>20 \mathrm{GeV}$ and $|\eta|<2.5$ from $Z \rightarrow e e$ decay are not reconstructed at all and a larger fraction of $\sim 2.1 \%$ are reconstructed as photons. Among those reconstructed successfully as electron candidates, a significant fraction of $\sim 10.1 \%$ are ambiguous, and almost all of these are also reconstructed as converted photons;
- less than $0.1 \%$ of photons with $E_{T}>20 \mathrm{GeV}$ and $|\eta|<2.5$ from $H \rightarrow \gamma \gamma$ decay ( $m_{H}=120 \mathrm{GeV}$ ) are not reconstructed at all and a larger fraction of $\sim 2.1 \%$ are reconstructed as electrons. Among those reconstructed successfully as photon candidates, a large fraction of $\sim 42.1 \%$ are ambiguous, and about $72.5 \%$ of these are reconstructed as converted photons. Approximately $93.5 \%$ of the converted photons are also reconstructed as electrons.

Since these ambiguous candidates often correspond to early showers in the tracker material, the efficiency of the identification cuts described below may be significantly reduced relative to the rest of the electrons and photons.

### 2.4 Calibration

In addition to identifying efficiently EM showers, the ATLAS EM calorimeter measures their energies with high accuracy and with a linearity better than $0.5 \%$ over a large energy range, from 10 GeV to a few TeV . The procedure to measure the energy of an incident electron or photon is described in detail in [4]. Each step of the energy reconstruction has been validated by a series of beam tests over several years, using not only the calorimeter alone [5], but also a combination of representative components from the tracker in front of the barrel calorimeter [6]. This has led to considerable refinements of the calorimeter simulation, which has been used in recent years to model the behaviour of the full detector in situ and to provide precise calibration corrections over the full pseudorapidity and energy range required. One of the key ingredients for the description of the detector performance is the amount and position of the upstream material (tracker material, cryostats, solenoid coil).

The cluster energy is determined precisely by computing and summing four different contributions: the energy deposited in the material in front of the EM calorimeter (including the energy between the cold calorimeter wall and the first accordion compartment), that deposited in the calorimeter inside the cluster, that deposited outside the cluster (lateral leakage) and the energy deposited beyond the EM calorimeter (longitudinal leakage). The four terms are parametrised as a function of the cluster measured energies in the presampler (where it is present) and in the three accordion longitudinal layers. The parameters are computed at each pseudorapidity value corresponding to the centre of a cell in the middle layer. Symmetry between positive and negative pseudorapidity values and in azimuth is assumed.

Figure 1 shows the linearity of the response, defined as the ratio between the reconstructed and the true particle energy, for different particle types as a function of pseudorapidity and at different energies. The deviation from linearity is less than $\pm 0.5 \%$ for electrons and unconverted photons at almost all values of $|\eta|$. For converted photons, the deviation from linearity lies within $\pm 1 \%$ over most of the simulated samples, reaching $+1.5 \%$ at low energies in the interval $|\eta|=1.7-2.2$, where the material impact is largest (the last bin in pseudorapidity is missing for converted photons due to lack of statistics).

The fractional energy resolution $\sigma / E$ as a function of $|\eta|$ is shown in Fig. 2 for different energies and for electrons, converted and unconverted photons separately. The resolution deteriorates as a function of the number of radiation lengths in front of the EM calorimeter. This effect is particularly visible for the lower-energy electrons and converted photons and is due to the combined effect of the bremsstrahlung radiation and the magnetic field. At large values of $|\eta|$, the resolution is similar to the one obtained in the

Figure 1: Expected linearity of response of the EM calorimeter for electrons (a), converted photons (b) and unconverted photons (c) as a function of pseudorapidity.

Figure 2: Expected fractional energy resolution of the EM calorimeter for electrons (a), converted photons (b) and unconverted photons (c) of different energies as a function of pseudorapidity.

Figure 3: Expected fraction of electrons (a), converted photons (b) and unconverted photons (c) with an energy measured in the EM calorimeter more than $1.5 \sigma$ below the fitted value of the Gaussian mean as a function of pseudorapidity and energy.
central region. The resolution at high energies $(\geq 200 \mathrm{GeV})$ is $\sim 1 \%$ over the whole $|\eta|$ range, dominated by an estimated global constant term of $0.7 \%$.

The energy resolution shown in Fig. 2 corresponds to the fitted gaussian core of the distribution; the non-gaussian nature of the energy losses due to bremsstrahlung and the magnetic field make it important to illustrate the expected performance additionally in terms of the fraction of events with measured energy significantly below the true energy. The fraction of events with a reconstructed energy smaller than the true energy minus $1.5 \sigma$ is illustrated as a function of pseudorapidity for different particle types and different energies in Fig. 3. The fraction of events in the tails approaches the value expected for a gaussian distribution for the low $|\eta|$ and high-energy points, but it is significantly higher at lower energies and higher pseudorapidity values.

### 2.5 Electron and photon identification

The baseline electron and photon identification algorithms in ATLAS rely on rectangular cuts using variables which deliver good separation between isolated electrons/photons and fake signatures from QCD jets. These variables include information from the calorimeter and, in the case of electrons, tracker and combined calorimeter/tracker information. Three reference sets of cuts have been defined for electrons: loose, medium and tight, and two sets for photons: loose and tight, as listed in Table 1. The cut values are optimised in bins of $E_{T}$ and $\eta$ for electrons and only in bins of $\eta$ for photons, but separately for unconverted photons and converted photons.

For trigger purposes, electrons and photons share a common set of loose cuts and cut thresholds. This basic selection includes shower-shape variables based on information from the middle calorimeter layer, together with hadronic leakage, the fraction of the cluster energy deposited in the hadronic calorimeter layers (see Table 1) beyond the EM calorimeter. Although these loose cuts are shared, the electron candidates will consist of clusters associated to a loosely matching track whereas the photon candidate clusters will in general lack such a track. Photon identification rejects $\pi^{0}$ decays using the fine granularity of the first layer of the EM calorimeter. Consequently, photon candidates are required to lie within $|\eta|<2.37$. Electron candidates are required to lie within the region covered by the tracker and the precision region of the EM calorimeter, $|\eta|<2.47$.

Loose electron candidates can be selected further using the medium selection, which consists of requirements on their energy deposits in the strip layer of the EM calorimeter and on the track quality and track-cluster match. The tight electron requirements are explicitly optimised to exploit the full potential of the ATLAS electron identification with the purpose of specifically rejecting charged hadrons, by using the ratio between measured cluster energy and track momentum, $\mathrm{E} / \mathrm{p}$, and the fraction of high-threshold hits in the TRT, and background electrons from photon conversions, by requiring the presence of a hit on the track in the pixel vertexing layer and rejecting candidates with a matching conversion vertex. They also comprise tighter track-matching cuts and impact parameter cuts. For robustness, cut choices (including thresholds) are based on the expected level of understanding of the detector performance at start-up.

The tight photon requirements are also optimised to provide good rejection of the most dangerous background consisting of isolated leading $\pi^{0} \mathrm{~s}$. They comprise tighter cuts on the variables used for the loose cut selection and additional cuts on the middle layer and especially the strip layer with its fine granularity which provides good $\gamma-\pi^{0}$ separation. A more detailed description of the identification cuts can be found in refs. [7] and [8] for electrons and photons, respectively.

Table 1: Definition of variables used for all electron and photon identification cuts.

| Type | Description | Name |
| :---: | :---: | :---: |
| Loose electron and photon cuts |  |  |
| Acceptance of the detector | $\|\eta\|<2.47$ for electrons, $\|\eta\|<2.37$ for photons (1.37<\| $\eta \mid<1.52$ excluded) | - |
| Hadronic leakage | Ratio of $E_{T}$ in the 1st sampling of the hadronic calorimeter to $E_{T}$ of the EM cluster (used over the range $\|\eta\|<0.8$ and $\|\eta\|>1.37$ ) Ratio of $E_{T}$ in the hadronic calorimeter to $E_{T}$ of the EM cluster (used over the range $\|\eta\|>0.8$ and $\|\eta\|<1.37$ ) | $\begin{aligned} & R_{\text {had } 1} \\ & R_{\text {had }} \end{aligned}$ |
| Middle layer of the EM calorimeter | Ratio in $\eta$ of cell energies in $3 \times 7$ versus $7 \times 7$ cells. Lateral width of the shower | $\begin{aligned} & R_{\eta} \\ & w_{2} \end{aligned}$ |
| Medium electron cuts (in addition to the loose cuts) |  |  |
| Strip layer of the EM calorimeter | Total lateral shower width (20 strips) <br> Ratio of the energy difference between the largest and second largest energy deposits over the sum of these energies | $w_{\text {stot }}$ <br> $E_{\text {ratio }}$ |
| Track quality | Number of hits in the pixel detector (at least one) Number of hits in the pixels and SCT (at least seven) Transverse impact parameter $(<5 \mathrm{~mm})$ | $\begin{aligned} & - \\ & - \\ & d_{0} \end{aligned}$ |
| Track matching | $\Delta \eta$ between the cluster and the track in the strip layer of the EM calorimeter | $\Delta \eta_{1}$ |
| Tight electron cuts (in addition to the medium electron cuts) |  |  |
| B-layer | Number of hits in the B-layer (at least one) |  |
| Track matching | $\Delta \phi$ between the cluster and the track in the middle layer of the EM calorimeter Ratio of the cluster energy to the track momentum | $\begin{aligned} & \Delta \phi_{2} \\ & \mathrm{E} / \mathrm{p} \\ & \hline \end{aligned}$ |
| TRT | Total number of hits in the TRT (used over the acceptance of the TRT, $\|\eta\|<2.0$ ) <br> Ratio of the number of high-threshold hits to the total number of TRT hits (used over the acceptance of the TRT, $\|\eta\|<2.0$ ) | - |

Tight photon cuts (in addition to the loose cuts, applied with stricter thresholds)

| Middle layer of the | Ratio in $\phi$ of cell energies |  |
| :--- | :--- | :--- |
| in $3 \times 3$ and $3 \times 7$ cells |  | $R_{\phi}$ |
| EM calorimeter | Shower width for three strips around maximum strip |  |
| Strip layer of the | Total lateral shower width | $w_{s 3}$ |
| EM calorimeter | Fraction of energy outside core of three central strips but within seven strips | $w_{\text {stot }}$ |

|  | energy deposit and the energy of the strip with the smallest energy deposit between | $\Delta E$ |
|  | the two leading strips |  |
|  | Ratio of the energy difference associated with the largest and second largest |  |
|  | $E_{\text {ratio }}$ |  |

### 2.5.1 Expected performance

The electron or photon identification efficiency is defined as:

$$
\begin{equation*}
\varepsilon_{e, \gamma}^{\text {truth }}=\frac{N_{e, \gamma}^{\text {reco }}}{N_{e, \gamma}^{\text {truth }},} \tag{1}
\end{equation*}
$$

where $N_{e, \gamma}^{\text {truth }}$ is the total number of true electrons or photons within the acceptance of simple kinematic cuts on transverse energy and pseudorapidity, and $N_{e, \gamma}^{r e c o}$ is the number of reconstructed signal electrons or photons passing identification cuts. The quoted jet rejections are normalised with respect to the number of truth particle jets. The jet rejection is defined as:

$$
\begin{equation*}
R_{\mathrm{jet}}=\frac{N_{\text {truth jets }}}{N_{\text {fakes }}}, \tag{2}
\end{equation*}
$$

where $N_{\text {truth }}$ jets is the number of true jets in the initial sample and $N_{\text {fakes }}$ is the number of candidates passing a specific selection. Truth jets are defined by summing particle four-momenta within a cone size $\Delta R=0.4$ and the number of truth jets per event is derived from an unfiltered sample of important hard processes, mainly di-jet events (referred to loosely in what follows as di-jets). The total number of truth jets is then obtained through:

$$
\begin{equation*}
N_{\text {truth jets }}=N_{\text {total }} \times F_{\text {jets }}, \tag{3}
\end{equation*}
$$

where $N_{\text {total }}$ is the number of events used in the analysis and $F_{\text {jets }}$ the number of truth jets per generated event.

The electron efficiencies and jet rejections, for $E_{T}>20 \mathrm{GeV}$ and averaged over $|\eta|$, are given in Table 2 for the loose, medium and tight selections. Figure 4 shows in more detail how the overall efficiency of each set of cuts varies with $E_{T}$ and $|\eta|$. Not surprisingly, because of the large amount of material in the tracker and in front of the EM calorimeter, the efficiency is lower at intermediate pseudorapidity values and decreases rapidly for transverse energies below $\sim 15 \mathrm{GeV}$. Nevertheless, medium cuts are expected to have an efficiency approaching $90 \%$. Table 2 also shows that the specific cuts optimised for the tight selection successfully remove the large backgrounds from hadrons and converted photons, which are largely dominant after the medium selection. The resulting sample should be dominated by prompt electrons, most of them non-isolated electrons from $b, c$ decays and a significant fraction of them isolated electrons from decays of $W / Z$ bosons.

The corresponding results for the loose and tight photon selections are shown in Table 3 and in Fig. 5. The overall efficiency of the tight selection decreases rapidly for transverse energies below $\sim 30 \mathrm{GeV}$. The jet rejections shown in Table 3 are averaged over the jet flavours expected in di-jet events with $E_{T}>20 \mathrm{GeV}$. It is important to note that the rejection expected against gluon jets is higher by a factor of $\sim 5$ than that expected against light-quark jets because of the broader and softer fragmentation properties of gluon jets. The specific cuts based on the strip-layer information provide a rejection of a factor of three against isolated $\pi^{0}$ decays.

### 2.6 Forward electrons

Electron identification in the forward region $(|\eta|>2.5)$ will be important in many physics analyses, including electroweak measurements and searches for new phenomena. In the range $2.5<|\eta|<4.9$ the calorimeters are the only source of information (the ATLAS tracking system being limited to the range $|\eta|<2.5$ ). Therefore such electrons can only be identified clearly above the background in specific topologies, such as $Z \rightarrow e e$ or $H \rightarrow e e e e$ decays. Electron candidates in the forward calorimeters are

Table 2: Expected jet rejections with overall isolated and non-isolated electron efficiencies for the three sets of identification cuts and an $E_{\mathrm{T}}$-threshold of 20 GeV . The total jet rejection includes hadron fakes and background electrons from photon conversions and Dalitz decays. The last four columns give the fraction of surviving electron candidates in the di-jet sample after each selection level. Isolated electrons correspond to electrons from $W, Z$ decays, non-isolated electrons to heavy flavour semi-leptonic decays and background electrons originate from photon conversions and Dalitz decays. Hadrons denote the remaining QCD jet background, which is dominated by charged hadrons faking an electron signature. The quoted errors are statistical.

|  | Efficiency (\%) |  | Jet rejection (total) | Surviving candidates in jets (percentage of total) |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $Z \rightarrow e e$ | $b, c \rightarrow e$ |  | Isolated <br> electrons | Non-isolated <br> electrons | Background <br> electrons | Hadrons |
| Reconstructed | $97.56 \pm 0.03$ | - | $91.5 \pm 0.1$ | 0.1 | 0.8 | 23.3 | 75.8 |
| Loose | $94.30 \pm 0.03$ | $36.8 \pm 0.5$ | $1066 \pm 4$ | 1.0 | 2.0 | 56.7 | 40.3 |
| Medium | $89.97 \pm 0.03$ | $31.5 \pm 0.5$ | $6821 \pm 69$ | 5.9 | 9.8 | 50.7 | 33.6 |
| Tight | $71.52 \pm 0.03$ | $25.2 \pm 0.5$ | $(1.38 \pm 0.06) \times 10^{5}$ | 29.6 | 44.8 | 11.5 | 14.1 |

Figure 4: Expected electron efficiency versus $|\eta|(a)$ and $E_{T}$ (b) shown for loose, medium and tight selection criteria.
reconstructed based on EM topological clusters with $E_{T}>5 \mathrm{GeV}$. The direction of the electron is defined by the barycentre of the cells belonging to the calorimeter cluster. The electron candidates in this region correspond to clusters reconstructed in the end-cap EM calorimeter (EMEC) and the hadronic end-cap calorimeter behind it in the range $2.5<|\eta|<3.2$ and to clusters reconstructed much further away from the interaction point in the forward calorimeters (FCal) in the range $3.1<|\eta|<4.9$. In both ranges, the total cluster energy reconstructed in the calorimeters is taken to be that of the electron candidate.

In order to distinguish electrons from hadrons, the differences between their EM showers must be exploited. These differences are apparent in the energy deposition and the shower shapes produced by the two types of particles. The good transverse and longitudinal calorimeter segmentation provides additional particle identification capability. Most of the variables used in the identification algorithm are the individual cluster moments themselves or a combination of these moments.

Table 3: Expected overall photon efficiencies and jet background rejections for the two sets of identification cuts and an $E_{T}$-threshold of 20 GeV .

|  |  | Efficiency (\%) | Jet rejection |
| ---: | ---: | :--- | :---: |
|  | All | $95.45 \pm 0.01$ | $908 \pm 4$ |
| Loose | Unconverted | $97.80 \pm 0.01$ |  |
|  | Converted | $91.73 \pm 0.01$ |  |
|  | All | $82.88 \pm 0.02$ | $4770 \pm 40$ |
| Tight | Unconverted | $85.04 \pm 0.03$ |  |
|  | Converted | $79.44 \pm 0.04$ |  |

## 3 Results from collisions at $900 \mathbf{~ G e V}$

### 3.1 Event samples

The analysis is based on a data sample collected at $\sqrt{s}=900 \mathrm{GeV}$. The events are triggered during LHC stable beams using the Minimum-Bias-Trigger-Scintillators (MBTS), which cover the pseudorapidity range, $2.09<|\eta|<3.84$, and are located in front of the end-cap EM calorimeters. Collision candidates are selected using additional timing requirements to provide further rejection against beam backgrounds: either coincident signals from the EM calorimeter end-caps or from the MBTS. Events are selected for which the tracker, electromagnetic calorimeter and hadronic calorimeters recorded data with high quality and the solenoidal field was at its nominal value. The obtained data sample consists of 384,186 collision candidates and corresponds to an integrated luminosity of approximately $9 \mu b^{-1}$. The Monte Carlo event sample used throughout this note is composed of $10^{7}$ non-diffractive minimum bias events generated with Pythia, using the ATLAS mc09 tune [9], and passed through the full ATLAS simulation and reconstruction software. The contribution from single and double diffractive events is negligible in this regime.

This study considers all reconstructed electron and photon candidates with cluster $E_{T}>2.5 \mathrm{GeV}$. Initially, electron candidates with a cluster $|\eta|<2.47$ and photons with cluster $|\eta|<2.37$ are selected and investigated (the cluster $\eta$ is defined here as the barycentre of the cluster cells in the middle layer of the EM calorimeter). A separate study of forward electrons then follows in Section 3.5, these electron candidates satisfying $|\eta|>2.5$. Electron and photon candidates in the EM calorimeter transition region $(1.37<|\eta|<1.52)$ are not considered. In what follows, the barrel region is defined as the range $|\eta|<1.37$ and the end-cap region as the range $1.52<|\eta|<2.37$ for photons and $1.52<|\eta|<2.47$ for electrons. For the comparisons presented here, the Monte Carlo distributions are always normalised to the sample of data events.

### 3.2 Electron candidates

Table 4 presents the numbers of reconstructed electron candidates, over the full acceptance and in each region defined above, as a function of the selection cuts applied. These selection cuts are not optimised for such low-energy electron candidates (see Section 2.5). Figure 6 displays for all selected electron candidates the transverse energy and pseudorapidity spectra. Both Table 4 and Fig. 6 show agreement between data and simulation, given the large uncertainties expected in the kinematic regime considered here. The Monte Carlo sample is sub-divided into its two dominant components: hadrons and electrons from conversions, as shown in Fig. 6. The latter component corresponds to $\sim 33 \%$ of all the electron candidates and is largely dominated by electrons from photon conversions, but also includes a small component ( $\sim 3 \%$ ) of background electrons from other sources, such as Dalitz decays, and an even smaller one (below $1 \%$ ) of prompt electrons from $b, c \rightarrow e$ decays. As can be seen in Table 4, the fractions of hadrons and conversions expected, as a function of the cuts applied and the $\eta$-range considered, vary according to the amount of material in the tracker and to the specific kinematic features of these backgrounds at these low transverse energies. The low statistics available here do not allow quantitative comparisons of variables between data and simulation after tight selection cuts, for which the expectation is that a significant fraction of the electron candidates in Table 4 are prompt electrons from $b, c$ decay. Approximately $15 \%$ of the Monte Carlo electron candidates passing the tight cuts are expected to be prompt electrons, which means that three out of the twenty electron candidates passing tight cuts in the data would be expected to originate from heavy flavour decay. In the following, distributions will be compared between data and simulation for all selected candidates unless specified otherwise.

Table 4: Breakdown of electron candidates according to identification cuts applied and to $\eta$-range: the whole $\eta$-range is considered (left), as well as the $\eta$-ranges of the barrel (middle) and end-cap (right) EM calorimeters. The first row gives the total numbers of electron candidates reconstructed in data in the three different $\eta$-ranges. For each of these $\eta$-ranges, the percentages of identified loose, medium and tight candidates in data are compared to those predicted by Monte Carlo (MC). The numbers in brackets give the percentage of Monte Carlo electron candidates which are electrons from photon conversions or prompt electrons (the remainder are charged hadrons).

### 3.3 Photon candidates

Table 5 presents the numbers of reconstructed photon candidates, over the full acceptance and in each region defined above, as a function of the selection cuts applied. A total fraction of only $14 \%$ of the photon candidates are reconstructed as converted photons and almost all of them, $\sim 98 \%$, are ambiguous and also reconstructed as electron candidates, which is not surprising at these low energies since the two electrons from conversions rarely end up with their energy collected in a single EM cluster. Transverse energy and pseudorapidity spectra for all selected photon candidates are displayed in Fig. 7 and found to be in agreement between data and Monte Carlo. The Monte Carlo sample is sub-divided in this case into four components of decreasing importance: approximately $71 \%$ of the candidates correspond to photons from $\pi^{0}$ decay, whereas $\sim 14 \%$ are from $\eta, \eta^{\prime}$ or $\omega$ decay into two photons, and $\sim 14 \%$ are from other hadrons with complex decay processes and particles interacting in the tracker material. Only a very small fraction of $\sim 0.7 \%$ of all photon candidates are expected to be "prompt" at these energies, i.e. from initial or final state radiation of quarks. Other sources of prompt photons, e.g. from $p p \rightarrow \gamma+\mathrm{jet}$, are not included in the Monte Carlo. In the following, as in the case of the electron candidates discussed above, the distributions will be compared between data and simulation for all selected candidates unless specified otherwise.

Table 5: Breakdown of photon candidates according to identification cuts applied and to $\eta$-range considered: the whole $\eta$-range is considered (left), as well as the $\eta$-ranges of the barrel (middle) and end-cap (right) EM calorimeters. ### 3.4 Electron and photon identification

### 3.4.1 Calorimeter variables

In this section, various calorimeter variables are illustrated for the photon candidates, the equivalent distributions for electron candidates display very similar features. Figure 8 illustrates the longitudinal development of the shower in the successive layers of the EM calorimeter, based on the measured layer energies before cluster corrections are applied. For the observed photon candidates before identification cuts, which almost all have transverse energies below 10 GeV and correspond predominantly to photons from $\pi^{0}$ decays, approximately half of the total energy ( $55 \%$ ) is deposited on average in the middle layer, a third in the strip layer, and $9 \%$ in the presampler (a negligible amount is deposited in the back layer). In the presampler part, a noticeable disagreement between data and simulation can be seen for values higher than 0.6. In the simulation, this part of the distribution is populated mostly by hadrons. This feature also explains the observed small but systematic disagreement in the first bins for the fractions in the other layers, since the various fractions are correlated.

The fraction of the cluster energy deposited in the first layer of the hadronic calorimeter (or hadronic leakage) is shown in Fig. 9(a), demonstrating agreement between data and simulation. This is not surprising for the low cluster energies discussed here, since most of the energy is deposited in the first layers of the EM calorimeter (see Fig. 8) and the hadronic leakage is clearly dominated by noise. The lateral development of the shower, as detailed by the variables $w_{2}, R_{\eta}$ and $R_{\phi}$ described in Section 2.5 and

Figure 8: Fraction of energy deposited by photon candidates in each layer of the electromagnetic calorimeter for data and simulation. These fractions are labelled as $f_{0}$ for the presampler layer (a), $f_{1}$ for the strip layer ( $b$ ), $f_{2}$ for the middle layer ( $c$ ) and $f_{3}$ for the back layer (d).
in Table 1 [8], is illustrated for the photon candidates in Figs. 9(b)-(d). These variables all display small shifts between the shapes observed in data and those expected from simulation. The shower width $w_{2}$ is slightly larger in the data: preliminary studies show that including the cross-talk between neighbouring middle layer cells $(\sim 0.5 \%)$ [10] in the simulation would explain part of the observed difference.

The most illustrative shower-shape variables in the strip layer of the EM calorimeter are presented in Fig. 10 for all photon candidates. At the low energies measured in these data, the variables $\Delta E$ and $E_{\text {ratio }}$ (Figs. 10(a) and 10(b)) are mainly sensitive to the noise description. As discussed for the middle layer, the variables sensitive to the shower lateral width in the strip layer, $F_{\text {side }}$ and $w_{s 3}$, display distributions shifted slightly towards higher values in the data than in the simulation. The current simulation accounts for the measured cross-talk of $\sim 5 \%$ between neighbour strips and of $\sim 0.1 \%$ between middle and strip cells, as obtained from test-beam measurements [10]. Figure 11 shows comparisons between data and simulation for the lateral profile of the shower in the strips. Compared in Fig. 11(a) are the distributions of 3 GeV energy test-beam electrons at $\eta \sim 0.44$ and of the corresponding single electron MC simulation. In Figures 11(b) to 11(d) all photon candidates in the collision events are compared to the non-diffractive minimum bias MC events for three different $\eta$ regions. The lateral profiles of the

Figure 9: Distributions of calorimeter variables compared between data and simulation for all photon candidates. Shown are the hadronic leakage in the first layer of the hadronic calorimeter (a), the variables used for the loose selection cuts in the middle layer of the EM calorimeter, $w_{2}(b)$ and $R_{\eta}(c)$, and the variable used in tight selection, $R_{\phi}(d)$, as explained in Table 1.
showers for the test-beam (Fig. 11(a)) and for collision events with $|\eta|<0.8$ (Fig. 11(b)) are in good agreement between data and simulation. This agreement degrades significantly as $\eta$ varies, as can be seen in Figs. 11(c) and 11(d). This disagreement, a slightly wider distribution observed for data than for simulation, could account for a large fraction of the differences observed in Figs. 10(c) and 10(d) between the collision data and the simulation. Neither an inaccurate cross-talk description (the effect observed is too large) nor an incorrect description of the material in front of the EM calorimeter (different set-ups in the test-beam and in ATLAS itself) are likely to explain entirely this effect. In the end-cap, however, the amount of upstream material is likely to be one of the most significant causes of the observed discrepancies. More data will be required to understand whether a combination of such effects, an incorrect modelling of the simulation of the EM calorimeter, or an insufficiently accurate simulation of the physics processes in the shower simulation are responsible for these effects.

Figure 10: Distributions of shower-shape variables in the strip layer of the EM calorimeter compared between data and simulation for all photon candidates. Shown are several of the variables used for the tight photon cuts, $\Delta E(a), E_{\text {ratio }}(b), F_{\text {side }}(c)$ and $w_{s 3}(d)$, as explained in Table 1.

### 3.4.2 Tracking and track-cluster matching variables

Electron and converted photon reconstruction and identification rely heavily on tracking performance. Figure 12 illustrates two of the track-calorimeter matching variables used in identification for all electron candidates reconstructed in data and simulation. Figure 12(a) shows the difference in azimuth, $\Delta \phi_{2}$, between the track extrapolated to the middle layer of the EM calorimeter and the barycentre of the cell energies in this layer. In order to optimise the efficiency of the matching cut in the frequent case of large energy losses due to bremsstrahlung in the tracker material, this matching variable is sign-corrected to account for the opposite curvatures of electrons and positrons in the magnetic field and an asymmetric cut is applied in the selection to keep most of the candidates with large negative $\Delta \phi_{2}$. In contrast and as expected, Figure 12(b), which shows the difference in $\eta, \Delta \eta_{1}$, between the track extrapolated to the strip layer of the EM calorimeter and the barycentre of the cell energies in this layer, does not display any significant asymmetric tails due to bremsstrahlung. The two main components of the background, namely hadrons and electrons from conversions are also shown in Fig. 12: as expected, the asymmetric tails at large negative values of $\Delta \phi_{2}$ are more pronounced for the electrons than for the hadrons, whereas such tails do not appear in the $\Delta \eta_{1}$ distribution.

Figure 11: Lateral shower profile in the strip layer for 3 GeV electrons at $\eta \sim 0.44$ in test beam and simulation (a) and for all photon candidates in collision data and simulation for three $\eta$-ranges (b), (c), (d). The histograms are normalised to the bin with the highest value.

Figure 13 shows four of the tracking variables compared between data and simulation for all electron candidates. The agreement between data and simulation is good for all four distributions, despite the complications expected at these low energies due to material effects and track reconstruction inefficiencies. Figures 13(a) and 13(b) show the numbers of hits on the reconstructed tracks in the pixel and SCT detectors, respectively. As expected, a large fraction of the electrons from conversions in the simulation correspond to tracks with no hits in these detectors. A significant fraction of the hadrons also have no hits in these detectors, indicating that the track-matching algorithm is picking up tracks from secondaries in the TRT detector. Figure 13(c) displays the fraction of high-threshold TRT hits belonging to the track for electron candidates with $|\eta|<2.0$ and with a total number of TRT hits larger than ten: even at these low energies for which the transition radiation yield of electrons is not optimal, a very clear difference can be seen between the distributions expected for hadrons (lying mostly at low values of this fraction) and for electrons from conversions (a large fraction of which lie at high values of this fraction). Finally, Fig. 13(d) shows the distribution of the transverse impact parameter, $d_{0}$, of the electron track with respect to the reconstructed primary vertex position in the transverse plane: whereas the hadrons in the simulation display a distribution peaked around zero with a resolution of $\sim 100 \mu \mathrm{~m}$, the electrons from conversions have large impact parameters, which is to be expected from conversions occurring at

Figure 12: Distributions of track-calorimeter matching variables in $\phi$ (a) and $\eta$ (b) for all electron candidates compared between data and simulation.
large radii.

Figure 14(a) shows the distribution of the ratio E/p of cluster energy in the calorimeter to track momentum for all electron candidates and for data and simulation. The simulation shows that the expected peak from the electron component lies slightly above unity, with a tail expected toward high values of $\mathrm{E} / \mathrm{p}$ from bremsstrahlung losses in the tracker material. However, the observed peak shift and the extent of the high tail are not entirely due to bremsstrahlung losses. An additional contribution arises from an overestimate of the cluster energy, in the cases where it includes energy from nearby particles. The large fraction of electrons with small values of $\mathrm{E} / \mathrm{p}$ is due mostly to tracks reconstructed without silicon hits, which are poorly measured in the TRT detector (see Section 2.2 ). The hadron component surprisingly also peaks at values just below unity: this is simply due to the fact that hadrons reconstructed as electron candidates deposit most of their energy in the EM calorimeter at these low energies. In a similar fashion, Fig. 14(b) illustrates the properties of the reconstructed converted photon candidates in terms of the same E/p ratio, where the converted photon momentum is estimated from the combination of the track momenta for double-track conversions and from the track momentum measurement available for single-track conversions. As for the electron candidates, the tails at low $\mathrm{E} / \mathrm{p}$ are mostly due to tracks reconstructed only in the TRT detector. Approximately $20 \%$ of the converted photon candidates are reconstructed as single-track conversions in this kinematic regime.

### 3.4.3 Data-driven background estimation for electrons

As already discussed in Section 3.2, at the low energies considered here, the electron candidate data sample is expected to consist predominantly of two components: charged hadrons faking electrons, denoted here as $h \rightarrow e$, and electrons from photon conversions, denoted here as $\gamma \rightarrow e$. These two components can be separated in the data by using the known discriminatory power of the TRT between electrons and pions, based on the measured fraction of high-threshold TRT hits on the electron track (see Fig. 13(c)). To perform such a measurement, the electron candidates are required to lie within the TRT acceptance, i.e. $|\eta|<2.0$, and to have a reconstructed track with a total of at least ten TRT hits (no requirements are made on the number of silicon hits).

Figure 13: Distributions of tracking variables for all electron candidates compared between data and simulation. Shown are the number of pixel (a) and SCT (b) hits on the electron track, the fraction of high-threshold TRT hits for candidates with $|\eta|<2.0$ and with a total number of TRT hits larger than ten (c), and the transverse impact parameter, $d_{0}$, with respect to the reconstructed primary vertex (d).

This method has been applied to the electron data sample before identification cuts by separating the sample into a pion-enriched sub-sample with a fraction of high-threshold TRT hits below 0.06 and an electron-enriched sub-sample with a fraction of high-threshold TRT hits above 0.10 . The fraction of electrons falling into these sub-samples is predicted from simulation to be $6 \%$ for the pion-enriched sample and $80 \%$ for the electron-enriched sample. These fractions are predicted to be very different, $70 \%$ and $10 \%$ respectively, for pions. The response of the TRT to electrons and pions has been carefully modeled in the simulation based on test-beam measurements and varies significantly with energy and pseudorapidity in the kinematic regime consider here.

The respective efficiencies discussed above for pions and electrons to fall into these sub-samples are denoted by $\varepsilon_{T R<0.06}^{e, \pi}$ and $\varepsilon_{T R>0.10}^{e, \pi}$. If one defines the number of electron candidates of type $h \rightarrow e$ as $N^{\pi}$ and those of type $\gamma \rightarrow e$ as $N^{e}$, then one can predict the total number of electron candidates falling in the two categories above for the fraction of high-threshold TRT hits on the track:

$$
\begin{equation*}
N_{T R<0.06}=\varepsilon_{T R<0.06}^{e} N^{e}+\varepsilon_{T R<0.06}^{\pi} N^{\pi} \tag{4}
\end{equation*}
$$

Figure 14: Ratio, E/p, between cluster energy and track momentum for electron candidates (a) and for converted photon conversions (b).

$$
\begin{equation*}
N_{T R>0.10}=\varepsilon_{T R>0.10}^{e} N^{e}+\varepsilon_{T R>0.10}^{\pi} N^{\pi} \tag{5}
\end{equation*}
$$

The sample of 717 electron candidates considered here is thus predicted to contain 501 electron candidates of type $h \rightarrow e$ and 216 electron candidates of type $\gamma \rightarrow e$. Clearly, the extraction of these contributions can be refined as a function of the kinematic properties of the electron candidates (spectrum in $E_{T}$ and $\eta$ ). In addition, they can be compared to the composition found in the simulated events, in terms of the shapes predicted for electron identification variables which are not correlated to the identification through transition radiation. Such comparisons would provide a more precise validation of the agreement between data and simulation than that described in the previous sections since they would be obtained separately for each component of the sample.

Two examples of comparisons between the shapes of variables extracted for each of the two components, using the method described above (for each bin individually), and for the truth from simulation are shown in Figs. 15 and 16 respectively, for two of the most sensitive variables: the fraction of the cluster energy measured in the strip layer and the ratio $\mathrm{E} / \mathrm{p}$. The results are in good agreement, both in terms of the quite different shapes and the overall rates expected for each component. Clearly, more statistics will be required to probe the background components in more detail than outlined here.

The fraction of high-threshold TRT hits could be combined with the additional requirement of at least one B-layer hit associated to the reconstructed track to achieve a clean separation between the two components described here and the expected small fraction of prompt electrons from heavy flavour decays. In contrast to electrons from photon conversions, the latter are expected almost always to have a pixel hit measured on the track in the vertexing layer. With the statistics presented here, the estimated contribution from heavy flavours in the sample before identification cuts is consistent with zero within errors.

### 3.5 Forward electrons

Following the specific algorithm outlined in Section 2.6, a total of 369 forward electron candidates were reconstructed, with 234 candidates in the EMEC and 135 candidates in the FCal. These forward elec-

Figure 15: Distribution of the energy fraction in the strip layer of the EM calorimeter as extracted from data compared to the truth from simulation. The results are shown for both true (MC) and extracted (data) electrons from conversions (a) and hadron fakes (b).

Figure 16: Distribution of the E/p as extracted from data compared to the truth from simulation. The results are shown for both true (MC) and extracted (data) electrons from conversions (a) and hadron fakes (b).
tron candidates are predominantly photons and their transverse energy spectrum is shown in Fig. 17(a) for both data and simulation. Clusters induced by noise from problematic channels in the hadronic calorimeter are removed through a requirement that the energy fraction in the EM part of the cluster be greater than $0.5 \%$. Figure 17 (b) shows the second moment of the distance $R_{i}$ of each cell $i$ to the shower axis, which is sensitive to the lateral profile of the shower. The shower shape in the longitudinal direction is described by the second moment of the distance of each cell $i$ to the shower centre, as illustrated in Fig. 17(c). Finally, Fig. 17(d) displays the fraction of energy deposited in the EM layers of the calorimeters. The majority of candidates with a low EM-fraction are charged pions, whilst the majority of those with a high EM-fraction are photons from $\pi^{0} / \eta$ decays (as discussed in previous sections).

Figure 17: For forward electron candidates in data and simulation, distributions of transverse energy (a), of the lateral shower profile (b), the longitudinal shower profile (c) and the fraction of energy deposited in the EM layers of the calorimeters (d).

## 4 Conclusions

The data sample collected by ATLAS at $\sqrt{s}=900 \mathrm{GeV}$ at the end of 2009 has yielded samples of 879 electron candidates and 1694 photon candidates reconstructed with $E_{T}>2.5 \mathrm{GeV}$ before identification cuts. The performance of the reconstruction and identification algorithms on these data has been compared with expectations from simulation. Most of the features of the candidates are in remarkable agreement between data and simulation, including the background composition for electrons. This note also outlines the expected performance of the algorithms at the higher energies for which they have been optimised in terms of efficiency for the signal and rejection of the very large backgrounds expected from QCD jets.

Despite its limitations due to low statistics and the very low energies discussed here, this first experimental validation of the ATLAS electron and photon reconstruction and identification performance supports the expectation that the ATLAS inner detector and calorimeters will provide excellent data for electron and photon early physics at the LHC.

# Photon Conversions at $\sqrt{s}=900 \mathrm{GeV}$ measured with the ATLAS Detector 

The ATLAS collaboration

#### Abstract

This note presents the first study of converted photons reconstructed with the ATLAS detector in the $\sqrt{s}=900 \mathrm{GeV}$ run in 2009. The analysis of the photon conversions demonstrates the excellent performance of the conversion reconstruction algorithm. The threedimensional distribution of the photon conversion vertices has been extracted and used to provide a first cross-check of the amount of material in the ATLAS tracker using collision data. A few Dalitz decays from neutral mesons have also been reconstructed and their rate is in agreement with expectations from simulation. Finally, the $\pi^{0}$ mass peak has been extracted from pairs of one converted and one unconverted photon.

## 1 Introduction

At the end of 2009, ATLAS enjoyed a series of stable LHC runs at a centre-of-mass energy of 900 GeV , successfully recording and analyzing the many collisions which took place. A significant number of low$p_{T}$ photon conversions were reconstructed and analyzed using dedicated algorithms. The reconstruction of electrons and of photon conversions is a particular challenge for the ATLAS inner detector, since electrons have lost on average between $20 \%$ and $50 \%$ of their energy (depending on their pseudorapidity $\eta$ ) when they leave the SemiConductor Tracker (SCT) and, in the same region, between $10 \%$ and $50 \%$ of photons convert into an electron-positron pair [1] [2].

This note describes in Section 3 the reconstruction of low- $p_{T}$ photon conversion candidates. This sample is used in Section 4 to compare its measured properties to those expected from simulation and to perform a first coarse estimate of the material in the inner tracking layers. Section 5 describes the few candidates found which are compatible with Dalitz decays of neutral mesons and Section 6 finally concludes with the extraction of a $\pi^{0}$ mass peak using one unconverted photon candidate and one photon conversion candidate.

## 2 The ATLAS Detector and Data Set

The ATLAS inner detector (ID) provides precise track reconstruction over $|\eta|<2.5$ [3]. It consists of three layers of pixel detectors close to the beam pipe, four layers of silicon microstrip detectors (SCT) providing eight hits per track at intermediate radii, and a transition radiation tracker (TRT) at the outer radii, providing about 30 hits per track (in the range $|\eta|<2.0$ ). The TRT also provides substantial discriminating power between electrons and pions over the wide energy range between 0.5 and 100 GeV by utilizing transition radiation (TR) in polypropylene foils and fibres. The innermost pixel layer (also called the B-layer) is located (just outside the beam pipe) at a radius of 50 mm , and provides precision vertexing.

The ATLAS electromagnetic (EM) calorimeter has a fine segmentation in both the lateral ( $\eta \times$ $\phi$ space) and longitudinal directions of the showers [4]. At high energy, most of the EM shower energy is collected in the second layer which has a lateral granularity of $0.025 \times 0.025$ in $\eta \times \phi$ space. The first layer consists of finer-grained strips in the $\eta$-direction (with a coarser granularity in $\phi$ ). These two layers are complemented by a presampler layer with coarse granularity placed in front to correct for energy lost in the material before the calorimeter, and by a back layer behind.

The analysis is based on a data sample collected at $\sqrt{s}=900 \mathrm{GeV}$. The events are triggered during LHC stable beams using the Minimum-Bias-Trigger-Scintillators (MBTS), which cover the pseudorapidity range $2.09<|\eta|<3.84$. Collision candidates are selected using additional timing requirements to provide further rejection against beam backgrounds: either coincident signals from the EM calorimeter end-caps or from the MBTS. Events are required to have good data quality for the tracker, electromagnetic calorimeter and hadronic calorimeter and to have been recorded with the solenoidal field at its nominal value. The data sample obtained consists of 384,186 collision candidates and corresponds to an integrated luminosity of approximately $9 \mu \mathrm{~b}^{-1}$. The Monte Carlo event sample used throughout this note is composed of $10^{7}$ non-diffractive minimum-bias events generated with Pythia, using the ATLAS tune [5], and passed through the full ATLAS simulation and reconstruction software.

## 3 Reconstruction of Converted Photons

The reconstruction of photon conversions uses tracks found by the different track-reconstruction algorithms in ATLAS [6]. The standard inside-out tracking is seeded with hits in the Pixel detector and in the SCT. Tracks found in the silicon detectors are extended outwards into the TRT. The back-tracking

Table 1: Selection criteria for track pairs and fitted vertices in the photon conversion candidate reconstruction.

|  | Silicon-Silicon | Silicon-TRT | TRT-TRT |
| :--- | :---: | :---: | :---: |
| Distance of closest approach | 10 mm | 50 mm | 50 mm |
| $\Delta \cot \theta$ | 0.3 | 0.5 | 0.5 |
| $\Delta \Phi$ | 0.05 | 0.5 | 0.5 |
| $\left(D-R_{1}-R_{2}\right)_{\min }$ | -5 mm | -25 mm | -50 mm |
| $\left(D-R_{1}-R_{2}\right)_{\max }$ | 5 mm | 10 mm | 10 mm |
| $\chi_{\mathrm{vtx}}^{2}$ | 50 | 50 | 50 |

algorithm is seeded from the TRT and the segments found are extended inwards towards the silicon detectors, yielding tracks with silicon hits if the extension has been successful, and stand-alone TRT tracks otherwise.

The photon conversion reconstruction algorithm is described in detail elsewhere [7]. In the following, the basic steps of the algorithm are recalled together with an updated list of selection criteria. The algorithm begins by selecting single tracks with transverse momentum $p_{T}>500 \mathrm{MeV}$ and a significant fraction of high-threshold hits in the TRT, as expected from transition radiation. Photon conversion candidates are then created by pairing oppositely-charged tracks. Three possible combinations of track pairs are considered: two tracks with at least four silicon hits each (Silicon-Silicon track pairs), two stand-alone TRT tracks (TRT-TRT track pairs) and pairs with one track with at least for silicon hits and one stand-alone TRT track (Silicon-TRT track pairs). To reduce the combinatorial background, several selection criteria are applied taking advantage of the specific features expected for secondary vertices from photon conversions. Since the photon is massless, the emerging tracks are almost parallel at the vertex. The tracks are therefore required to be close in space and to have a small opening angle. An additional cut requires the sum of the radii of the helices of the electron and positron tracks, $R_{1}$ and $R_{2}$, to be comparable to the distance between the centers of the two helices, $D$. The selected track pairs are then fitted to a common vertex with the constraint that they be parallel at the vertex. The final set of photon conversion candidates is then selected based on the quality of the vertex fit. The selection criteria for the different track-pair categories are listed in Table 1.

The breakdown of the photon conversions in the different categories of track pairs is given in Table 2. Most of the photon conversion candidates at this stage originate from combinatorial background, which is much lower for pairs containing two precisely measured tracks with silicon hits than for pairs containing TRT stand-alone tracks. Since the determination of the material close to the beam pipe is the most critical for the reconstruction of high-energy photons and electrons, the study focuses in what follows on the 3662 silicon-silicon track-pair candidates.

The agreement between data and Monte Carlo simulation is shown in Fig. 1 where the comparison is presented for a few quantities used to reconstruct photon conversions, shown after the reconstruction cuts, and the transverse momentum of the photon conversion candidates. Given the complexity of the reconstruction of converted photons and the impact of bremsstrahlung of the electrons in the tracker material, the consistency between the data and the simulation for the selection variables is good.

## 4 Estimation of Inner Detector Material

An accurate and high-granularity map of the ID material is necessary for a precise reconstruction of high-energy photons and electrons. The ID material affects both the track trajectories (especially through

Table 2: Breakdown of the number of reconstructed photon conversion candidates built with two tracks with at least four silicon hits each, one track with at least four silicon hits and one stand-alone TRT track and pairs with two stand-alone TRT tracks.

|  | Silicon-Silicon | Silicon-TRT | TRT-TRT | total |
| :---: | :---: | :---: | :---: | :---: |
| Data | $6.7 \% \pm 1.7 \%$ | $31.7 \pm 0.9 \%$ | $61.5 \pm 0.7 \%$ | 54549 |
| Simulation | $10.4 \% \pm 0.3 \%$ | $31.8 \pm 0.2 \%$ | $57.8 \pm 0.1 \%$ | 1364828 |

Figure 1: Comparison between converted photon candidates with at least four silicon hits per track in data and non-diffractive minimum-bias Monte Carlo simulation. Top-left: opening angle in the $R z$ plane between the two tracks $(\Delta(1 / \tan \theta))$; top-right: 3D distance of closest approach between the two tracks; bottom-left: normalised $\chi^{2}$ of the vertex fit; bottom-right: converted photon candidate $p_{T}$. The points show the distribution for all photon conversion candidates in data; the open histograms, the corresponding distributions from the Monte Carlo simulation and the filled histograms show the contribution of true photon conversions as predicted from the Monte Carlo simulation. The distributions are normalized to the same number of photon conversion candidates in data and Monte Carlo simulation.
bremsstrahlung effects) and the electromagnetic shower development (because of the magnetic field and the energy lost in the ID material). This section describes the use of photon conversions as a tool to map precisely the position and amount of material in the tracker.

The radiation length, $\frac{X}{X_{0}}$, of a localized amount of material is related to the fraction of photons, $F_{\text {conv }}$, that convert in it through the relation:

$$
\begin{equation*}
\frac{X}{X_{0}}=-\frac{9}{7} \ln \left(1-F_{\text {conv }}\right) \tag{1}
\end{equation*}
$$

where $F_{\text {conv }}$ can be estimated as

$$
\begin{equation*}
F_{\mathrm{conv}}=\frac{N_{\mathrm{reco}}}{N_{\mathrm{tot}}} \frac{F_{\mathrm{comb}} F_{\mathrm{mis}}}{\varepsilon} \frac{1}{\exp \left(-7 / 9 M_{\mathrm{up}}\right)} \tag{2}
\end{equation*}
$$

In the above, $N_{\text {reco }}$ is the number of reconstructed photon conversions in the slice of material under investigation; $F_{\text {comb }}$ is a correction factor accounting for the contamination from combinatorial background, while $F_{\text {mis }}$ corrects for resolution effects that lead to migration of photon conversion candidates between different detector layers; $N_{\text {tot }}$ is the total number of photons produced at the primary vertex; $\varepsilon$ is the conversion reconstruction and selection efficiency and $M_{\text {up }}$ is the integrated radiation length of the material in front of the slice of material under consideration.

In the following, only tracks with at least four silicon hits are used to reconstruct photon conversions. To further reduce the combinatorial background, each track is required to pass a stricter cut on the TRT particle identification and the normalised $\chi^{2}$ is required to be smaller than 5 . The requirement on the TRT particle identification is based on a likelihood ratio constructed from Monte Carlo simulation of electron and pion tracks and calibrated on test-beam measurements.

To quantify the agreement between data and Monte Carlo simulation, the number of converted photons measured from data is compared to the number expected from Monte Carlo simulation in different regions of the inner detector. Due to the limited statistics, even a coarse comparison is only possible within the volume delimited by the first layer of the SCT.
The number of photon conversions reconstructed within $R<340 \mathrm{~mm}$ is 244 in a total of 384,186 events; the corresponding number for the $10^{7}$ events Monte Carlo sample is 9218 , which corresponds to 354 photon conversions for the equivalent data statistics.

The number of photon conversions per event is not well reproduced by the Monte Carlo simulation, which can be attributed to the simulation of the photon production or the overall reconstruction efficiency. Neither of these is the focus of this study. For this reason, in what follows, the total number of photon conversions in Monte Carlo simulation are normalized to total number of photon conversions reconstructed in data.

In Tables 3 and 4, the comparison between the number of photon conversions reconstructed in data and simulation are compared for different volumes. The model used for the simulation appears to be correctly describing the detector.

The results for the distributions of the photon conversion vertices in the radial direction and in $\eta$ (defined with respect to the centre of the detector) in Fig. 2 show, albeit with limited statistics, a good match between the measured material distribution and the Monte Carlo model. The observed asymmetry in the $\eta$ distribution can be attributed to an $\eta$-asymmetry in the number of inoperable Pixel detector modules. The effect is well-modeled by the simulation.

Using Eqs. 1 and 2 it is possible to extract the amount of material in any volume of the detector. The remaining combinatorial background and the migration of reconstructed converted photon candidates between different silicon layers due to mis-reconstruction of the vertex and the efficiencies are estimated using the Monte Carlo simulation. The efficiency (quoted in Tab. 5) represents the reconstruction and selection efficiency after applying the cuts used to map the tracker material. The efficiency can be broken

Table 3: Comparison of the number of photon conversions reconstructed in data and Monte Carlo simulation for different volumes in the ID. The values are integrated within the limits shown in each row. The distributions are normalized to the same number of photon conversion candidates in data and Monte Carlo simulation.

|  | $\phi$ | Data | MC | Data/MC |
| :---: | :---: | :---: | :---: | :---: |
| $R<500 \mathrm{~mm}$ | $-\pi \leq \phi<-\pi / 2$ | 67 | 61 | $1.09 \pm 0.13$ |
|  | $-\pi / 2 \leq \phi<0$ | 59 | 62 | $0.95 \pm 0.12$ |
|  | $0 \leq \phi<\pi / 2$ | 74 | 68 | $1.09 \pm 0.13$ |
|  | $\pi / 2 \leq \phi \leq \pi$ | 53 | 62 | $0.85 \pm 0.12$ |

|  | $-\pi / 2 \leq \phi<0$ | 55 | 59 | $0.93 \pm 0.13$ |
|  | $0 \leq \phi<\pi / 2$ | 73 | 65 | $1.12 \pm 0.13$ |
|  | $\pi / 2 \leq \phi \leq \pi$ | 51 | 60 | $0.85 \pm 0.12$ |
| $R<240 \mathrm{~mm}$ | $-\pi \leq \phi<-\pi / 2$ | 57 | 51 | $1.12 \pm 0.15$ |
|  | $-\pi / 2 \leq \phi<0$ | 46 | 52 | $0.88 \pm 0.13$ |
|  | $0 \leq \phi<\pi / 2$ | 60 | 58 | $1.03 \pm 0.13$ |
|  | $\pi / 2 \leq \phi \leq \pi$ | 46 | 52 | $0.88 \pm 0.13$ |

Table 4: The first half of the table shows the number of photon conversions reconstructed in data on the beam pipe and on the first four silicon layers; the second half shows the ratio with respect to the Monte Carlo simulation. The values are integrated over the entire azimuthal angle and over the $\eta$ ranges specified in each column.

|  | $\|\eta\|<2.5$ | $\|\eta\|<0.7$ | $0.7<\|\eta\|<1.4$ | $1.4<\|\eta\|<2.5$ |
| :--- | :---: | :---: | :---: | :---: |
| Beam pipe | 9 | 1 | 3 | 5 |
| Pixel B-layer | 46 | 5 | 17 | 24 |
| Pixel layer 1 | 65 | 16 | 17 | 32 |
| Pixel layer 2 | 55 | 10 | 15 | 30 |
| SCT layer 1 | 25 | 9 | 5 | 11 |
| Beam pipe | $0.90_{-0.29}^{+0.41}$ | $0.50_{-0.41}^{+1.1}$ | $1.00_{-0.54}^{+0.97}$ | $0.83_{-0.36}^{+0.85}$ |
| Pixel B-layer | $0.85 \pm 0.13$ | $0.38_{-0.17}^{+0.26}$ | $1.13 \pm 0.27$ | $0.89 \pm 0.18$ |
| Pixel layer 1 | $1.16 \pm 0.14$ | $1.23 \pm 0.31$ | $1.06 \pm 0.26$ | $1.14 \pm 0.20$ |
| Pixel layer 2 | $0.96 \pm 0.13$ | $0.83_{-0.26}^{+0.36}$ | $1.00 \pm 0.26$ | $1.03 \pm 0.19$ |
| SCT layer 1 | $1.14 \pm 0.23$ | $1.80_{-0.59}^{+0.82}$ | $0.83_{-0.36}^{+0.85}$ | $1.00_{-0.30}^{+0.40}$ |

Figure 2: Distribution of photon conversion candidate radius $R$ integrated over all $\eta$ (top-left), $\eta$ integrated over all $R$ (top-right), and distribution of photon conversion candidate radius in $|\eta|<0.7$ (bottomleft) and $|\eta|>1.4$ (bottom-right). The points show the distribution for all photon conversion candidates in data; the open histograms, the corresponding distributions from the Monte Carlo simulation and the filled histograms show the contribution of true photon conversions as predicted from the Monte Carlo simulation. The contribution from the Dalitz decays of neutral mesons is shown in the radial distribution integrated over all $\eta$. The radial distributions for the separate $\eta$ regions are shown for $R>24 \mathrm{~mm}$, which corresponds to about six times the resolution of the vertex radial position, to ensure a good reconstruction of the $\eta$ of the vertex. The distributions are normalized to the same number of photon conversion candidates in data and Monte Carlo simulation.

Table 5: $N_{\text {reco }}$ is the number of reconstructed photon conversions. $F_{\text {comb }}, F_{\text {mis }}, \varepsilon$ are correction factors extracted from Monte Carlo simulation to quantify the purity of the converted photon sample, the misreconstruction of the vertex position (how often a photon conversion is assigned to the wrong volume) and the reconstruction and selection efficiencies. $\frac{X}{X_{0}}{ }_{\text {data }}, \frac{X}{X_{0}} \mathrm{MC}$ and $\frac{X}{X_{0}}$ data $/ \frac{X}{X_{0}} \mathrm{MC}$ represent the radiation length of the material in the different volumes estimated from data and Monte Carlo simulation and their ratios. The normalization to the number of reconstructed converted photons at the beam pipe introduces an additional uncertainty of $30 \%$ on $\frac{X}{X_{0}}$ data , which has been taken into account in the ratio of the radiation lengths in data and Monte Carlo simulation.

|  | $N_{\text {reco }}$ | $F_{\text {comb }}$ | $F_{\text {mis }}$ | $\varepsilon$ | $\frac{X}{X_{0}}$ data | $\frac{X}{X_{0}}$ MC | $\frac{X}{X_{0}}{ }_{\text {data }} / \frac{X}{X_{0}} \mathrm{MC}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Beam pipe | 9 | 0.91 | 0.99 | 0.033 | 0.00655 | 0.00655 |  |
| Pixel B-layer | 46 | 0.97 | 0.97 | 0.038 | $0.031 \pm 0.005$ | 0.032 | $0.98 \pm 0.36$ |
| Pixel layer 1 | 65 | 0.98 | 0.95 | 0.046 | $0.036 \pm 0.005$ | 0.027 | $1.34 \pm 0.48$ |
| Pixel layer 2 | 55 | 0.97 | 0.88 | 0.052 | $0.025 \pm 0.004$ | 0.023 | $1.12 \pm 0.41$ |
| SCT layer 1 | 25 | 0.99 | 0.97 | 0.034 | $0.021 \pm 0.004$ | 0.016 | $1.31 \pm 0.52$ |

down into the different reconstruction and selection steps: the single track reconstruction efficiency is about $65 \%$; the two-track efficiency is about $50 \%$; the conversion finding efficiency (i.e. after the constrained vertex fit) about $35 \%$ and the final selection to achieve the high purity photon conversion sample brings the efficiency to about $5 \%$. At each step the efficiency is calculated using as numerator the number of reconstructed tracks (photon conversions) and as denominator the number of truth tracks (photon conversions) within the fiducial volume defined by the acceptance of the tracker $(|\eta|<2.5$, conversion radius $R<800 \mathrm{~mm}$ ) or a given detector layer, and requiring the transverse momenta of the tracks above 500 MeV . To remove the dependence on the unknown number of photons produced at the primary vertex (mostly from the decay of neutral mesons), the reconstructed number of photon conversions in a given slice of the detector is normalized to the number of photon conversions in a reference volume. The beam pipe has been chosen as the reference because of its well-known material composition and because of its location upstream of the rest of the tracker. This method, which has been successfully tested on Monte Carlo simulation and demonstrated in the ATLAS Combined Test Beam [8], is applied here to collision data. The agreement between data and Monte Carlo simulation is presented in Tab. 5.
The tiny number of conversions on the beam pipe is presently the main limitation on the accuracy of this method. With larger data samples, the dominating systematic uncertainty on the material estimation will come from the determination of the photon conversion reconstruction efficiency.

## 5 Dalitz Decays

The neutral mesons produced at the primary vertex can decay to a pair of photons or through a Dalitz process, e.g. $\pi^{0} \rightarrow e^{+} e^{-} \gamma$. The branching ratios for the $\pi^{0}$, the neutral meson which is most abundantly produced in collisions, are very precisely measured: $\operatorname{BR}\left(\pi^{0} \rightarrow \gamma \gamma\right)=(98.798 \pm 0.032) \%$ and $\operatorname{BR}\left(\pi^{0} \rightarrow\right.$ $\left.e^{+} e^{-} \gamma\right)=(1.198 \pm 0.032) \%$. The ratio of photon conversions in a given volume to the number of Dalitz decays allows the setting of very stringent constraints on the amount of material in it. In particular, this can be used to constrain the amount of material in the beam pipe where the reconstruction efficiency is expected to be the same as at the primary vertex.

The reconstructed electron-positron pairs originating from the Dalitz decays of neutral mesons appear in Fig. 3 as conversion candidates occurring at the primary vertex. In the present data sample, nine photon

Figure 3: Distribution of $\pi^{0}$ Dalitz decays and photon conversion radius in Fig. 2, shown in more detail.
conversion candidates on the beam pipe and five Dalitz decays have been reconstructed. The two types of candidates are separated according to the reconstructed radial position of the vertex: Dalitz decay candidates are required to have a radial position of less than 20 mm from the beam spot, candidates for conversions on the beam pipe to have a radial position between 20 mm and 40 mm . The ratio of beam pipe photon conversions to Dalitz decays of $1.8 \pm 1$ is in agreement with the ratio expected from Monte Carlo simulation, $2.04 \pm 0.19$.

## 6 Reconstruction of $\pi^{0}$ Mesons Using Converted Photons

The reconstruction of $\pi^{0}$ mesons from two unconverted photons in the ATLAS detector has been extensively studied [10]. Here the study of $\pi^{0}$ reconstruction using one converted and one unconverted photon candidate is presented.

In addition to the converted photon candidates reconstructed in the tracker, unconverted photon candidates are reconstructed from clusters in the electromagnetic calorimeter. The clusters are built by a topological algorithm, which starts with a seed cell where the deposited energy is larger than four standard deviations above the expected noise and iteratively adds the neighboring cells passing certain threshold criteria. To suppress backgrounds from charged particles, clusters with a matching silicon or stand-alone TRT track are vetoed. In particular, this includes tracks that are used for the reconstruction of photon conversion candidates, which reduces the combinatorial background. The track-cluster matching is performed by extrapolating a given track from its last measurement in the tracker to the second layer of the electromagnetic calorimeter and by comparing the angular distance of the extrapolated track position to the angular position of the cluster. A wide window is used for the matching: $\Delta \phi<0.5(0.3)$ on the side where losses from bremsstrahlung are (are not) expected and for tracks with silicon hits $\Delta \eta<0.1$; for tracks without silicon hits, the matching in $\eta$ is relaxed, such that only matching of detector regions (barrel vs endcaps) is required. In addition, a transverse energy of the cluster greater than 300 MeV is required.

All reconstructed photon conversion candidates with at least four silicon hits per track are used in this analysis. To reduce combinatorial background, the two-photon candidates are required to be in the same hemisphere of the detector.

Figure 4: Invariant mass distribution of one converted and one unconverted photon as measured on data (points) and Monte Carlo simulation (histogram).

The $\gamma e^{+} e^{-}$-invariant-mass distribution for $p_{T}^{\gamma e^{+} e^{-}}>900 \mathrm{MeV}$ is shown in Fig. 4. The $\pi^{0}$ peak can be clearly observed. No energy corrections are applied to the reconstructed clusters, which accounts for the majority of the shift of the reconstructed $\pi^{0}$ mass compared to the true $\pi^{0}$ mass. This effect is well reproduced by the simulation, as is the width of the $\pi^{0}$ peak and the shape of the combinatorial background.

## 7 Conclusion

The analysis of the photon conversions reconstructed in the $\sqrt{s}=900 \mathrm{GeV}$ run in 2009 demonstrates the excellent performance of the conversion reconstruction algorithm. The spatial distributions of the photon conversion vertices show, albeit with low statistics, that the Monte Carlo model of the tracker represents the installed detector well. The number of reconstructed neutral meson Dalitz decays matches the one expected from Monte Carlo simulations. The $\pi^{0}$ reconstruction with one converted and one unconverted photon has been performed and agrees with expectations, demonstrating the ATLAS capability to combine both calorimeter and tracker information.

# Observation of $W \rightarrow \ell v$ and $Z \rightarrow \ell \ell$ production in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

The ATLAS Collaboration ${ }^{\text {a }}$

${ }^{a} C E R N$

#### Abstract

This note describes an observation by the ATLAS experiment of $57 W \rightarrow \ell v$ candidates and three $Z \rightarrow \ell \ell$ candidates, where $\ell=e, \mu$, produced in $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions at the LHC. These results correspond to total integrated luminosities of $6.7 \mathrm{nb}^{-1}$ for the $W \rightarrow e v$ and $Z \rightarrow e e$ channels, and $6.4 \mathrm{nb}^{-1}$ and $7.9 \mathrm{nb}^{-1}$ for the $W \rightarrow \mu \nu$ and $Z \rightarrow \mu \mu$ channels, respectively. The number of events observed is consistent with the expectations.

## 1 Introduction

The experimental study of the electroweak gauge bosons has a history of about thirty years. The $W$ and the $Z$ particles were initially discovered and measured at the CERN proton-antiproton collider in 1983 [1, 2, 3, 4]. During the early 1990's, the $Z$ properties were measured in great detail at the high energy $e^{+} e^{-}$colliders LEP and SLC [5]. In the second half of that decade, an energy increase of LEP allowed to measure $W$ bosons produced in pairs. The Tevatron proton-antiproton collider has been accumulating $W$ and $Z$ events over the last twenty years. The results of these programmes include highprecision measurements of the $W$ and $Z$ mass, width, and couplings, as well as detailed information on their production in proton-antiproton collisions and corresponding constraints on the proton parton density functions [6]. The current uncertainties on the intrinsic properties of the $W$ boson are about ten times larger than their $Z$ counterparts [7].

The $W$ and $Z$ bosons are expected to be produced abundantly at the Large Hadron Collider (LHC) [8], and for the first time in proton-proton collisions. This significant dataset and the high LHC energy will allow for detailed measurements of their production properties at a previously unexplored energy scale. These conditions, together with the particular nature of the collisions, will provide new insights on the proton properties, tests of perturbative QCD calculations, and ultimately a precise determination of the mass of the $W$ boson [9]. In this process, the well-known properties of the $Z$ boson will provide significant constraints on the determination of the performance of the collider experiments at the LHC; its known mass, width and leptonic decays can be exploited to measure precisely the detector energy and momentum scale, resolution, as well as lepton identification and trigger efficiencies.

The critical first step in making such precision measurements is an observation of $W$ and $Z$ production at the LHC. This note details an observation by the ATLAS [10] experiment of $17 \mathrm{~W} \rightarrow e v$ and 40 $W \rightarrow \mu \nu$ candidates produced from the $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions of the LHC, resulting from total integrated luminosities of $6.7 \mathrm{nb}^{-1}$ and $6.4 \mathrm{nb}^{-1}$ in the electron and muon channels, respectively. One $Z \rightarrow e e$ and two $Z \rightarrow \mu \mu$ candidates were also observed with data corresponding to integrated luminosities of $6.7 \mathrm{nb}^{-1}$ and $7.9 \mathrm{nb}^{-1}$, respectively. These data were collected over a seven-week period from March to May 2010. The uncertainty on the luminosity determination is on the order of $20 \%$.

In this note, the nominal interaction point is defined as the origin of the coordinate system, while the beam direction defines the $z$-axis and the $x-y$ plane is transverse to the beam direction. The positive $x$-axis is defined as pointing from the interaction point to the centre of the LHC ring and the positive $y$-axis is defined as pointing upwards. The azimuthal angle $\phi$ is measured around the beam axis and the polar angle $\theta$ is the angle from the beam axis. The pseudorapidity is defined as $\eta=-\ln \tan (\theta / 2)$. The transverse momentum $p_{\mathrm{T}}$, the transverse energy $E_{\mathrm{T}}$, and the transverse missing energy $E_{\mathrm{T}}^{\text {miss }}$ are defined in the $x-y$ plane. The distance $\Delta R$ in the $\eta-\phi$ space is defined as $\Delta R=\sqrt{\Delta \eta^{2}+\Delta \phi^{2}}$.

## 2 The ATLAS detector

The ATLAS detector [10] at the LHC comprises of a thin superconducting solenoid surrounding the inner-detector cavity and three large superconducting toroids arranged with an eight-fold azimuthal coil symmetry placed around the calorimeters, forming the basis of the muon spectrometer.

The Inner-Detector (ID) system is immersed in a 2 T axial field and provides tracking information on charged particles in a pseudorapidity range matched by the precision measurements of the electromagnetic calorimeter. The silicon tracking detectors, pixel and silicon microstrip (SCT), cover the pseudorapidity range $|\eta|<2.5$. The highest granularity is achieved around the vertex region using the pixel detectors. Typically three pixel layers are crossed by each track. For the SCT, eight strip layers (providing four space points) are crossed by each track in the barrel region. A large number of hits (typically 36 per track) is provided by the Transition Radiation Tracker (TRT), which enables track-following up
to $|\eta|=$ 2.0. The electron identification information is provided by the detection of transition radiation in the xenon-based gas mixture of the TRT straw tubes.

The calorimeter system covers the pseudorapidity range $|\eta|<4.9$, using a variety of detector technologies. The lead-liquid argon (LAr) electromagnetic (EM) calorimeter is divided into a barrel part ( $|\eta|<1.475$ ) and two end-cap components ( $1.375<|\eta|<3.2$ ). Over the region devoted to precision physics ( $|\eta|<2.5$ ), the EM calorimeter is segmented in three sections in depth. The remaining portion of the EM calorimeter, known as the end-cap inner wheel, is segmented in two sections in depth and has a coarser lateral granularity than for the rest of the acceptance. In the region of $|\eta|<1.8$, a thin LAr presampler detector is used to correct for the energy lost by electrons, positrons, and photons upstream of the calorimeter. The hadronic tile calorimeter is placed directly outside the EM calorimeter envelope. This steel/scintillating-tile detector consists of a barrel covering the region $|\eta|<1.0$, and two extended barrels in the range $0.8<|\eta|<1.7$. The copper-LAr Hadronic End-cap Calorimeter (HEC) consists of two independent wheels per end-cap $(1.5<|\eta|<3.2)$, located directly behind the end-cap electromagnetic calorimeter. The Forward Calorimeter ( FCal ) consists of three modules in each end-cap: the first, made of copper-LAr, is optimised for electromagnetic measurements, while the other two, made of tungsten-LAr, measure primarily the energy of hadronic interactions.

The muon spectrometer is based on the magnetic deflection of muon tracks in the large superconducting air-core toroid magnets, instrumented with separate trigger and high-precision tracking chambers. A system of three large air-core toroids, a barrel and two end-caps, generates the magnetic field for the muon spectrometer in the pseudorapidity range of $|\eta|<2.7$. In the barrel region, tracks are measured in chambers arranged in three cylindrical layers around the beam axis; in the transition and end-cap regions, the chambers are installed in planes perpendicular to the beam, also in three layers. Over most of the $\eta$-range, a precision measurement of the track coordinates in the principal bending direction of the magnetic field is provided by Monitored Drift Tubes (MDT's). At large pseudorapidities, Cathode Strip Chambers (CSC's) with higher granularity are used in the innermost plane over $2<|\eta|<2.7$, to withstand the demanding rate and background conditions expected with the LHC operation at the nominal luminosity and centre-of-mass energy. The trigger system which covers the pseudorapidity range $|\eta|<2.4$ consists of Resistive Plate Chambers (RPC's) in the barrel ( $|\eta|<1.05$ ) and Thin Gap Chambers (TGC's) in the end-cap regions.

The first-level (L1) trigger system uses a subset of the total detector information to make a decision on whether or not to process an event. Details about L1 calorimeter and muon trigger systems used in the analysis of the $W$ and $Z$ candidates are provided in Section 5.

## $3 W, Z$ processes and sources of background

The results presented in this note are compared to expectations based on Monte Carlo simulations. The signal and background samples used in this note were generated at $\sqrt{s}=7 \mathrm{TeV}$ with PYTHIA [11] using MRST LO [12] parton distribution functions (PDF), then simulated with GEANT4 [13] and fully reconstructed. These samples are summarised in Table 1.

The $W$ and $Z$ production cross sections times their respective $W \rightarrow \ell \nu$ and $Z / \gamma^{*} \rightarrow \ell \ell$ decay branching ratios used in this study are calculated at next-to-next-to-leading order (NNLO) in QCD corrections using the FEWZ program [14] with the MSTW2008 parton distribution function set [15]. The dilepton invariant mass of the $Z / \gamma^{*} \rightarrow \ell \ell$ process is chosen to be greater than 60 GeV . These values are:

$$
\begin{equation*}
\sigma_{W \rightarrow \ell v}^{N N L O}=10.45 \mathrm{nb} \text { and } \sigma_{Z / \gamma^{*} \rightarrow \ell \ell}^{N N L O}=0.989 \mathrm{nb} \tag{1}
\end{equation*}
$$

The estimated uncertainties for both cross sections coming from the factorization and renormalization scales as well as the parton distribution functions are expected to be approximately $3 \%[16,17,18]$.

| Physics process | Cross section (nb) $[\times \mathrm{BR}]$ | Luminosity $\left(\mathrm{nb}^{-1}\right)$ |
| :--- | :---: | :---: |
| $\mathrm{W} \rightarrow e v$ | 10.45 | $6.7 \times 10^{5}$ |
| $\mathrm{~W} \rightarrow \mu \nu$ | 10.45 | $6.7 \times 10^{5}$ |
| $\mathrm{~W} \rightarrow \tau \nu \rightarrow \ell \nu v(\ell=\mu, e)$ | 3.68 | $3.1 \times 10^{5}$ |
| $\mathrm{Z} \rightarrow e e\left(m_{\ell \ell}>60 \mathrm{GeV}\right)$ | 0.989 | $4.8 \times 10^{6}$ |

Table 1: Signal and background Monte Carlo samples used in the electron and muon channel analyses, including the production cross section (multiplied by the relevant branching ratios (BR)) and the integrated luminosity of the samples. The variable $\hat{p}_{T}$ is the transverse momentum of the partons involved in the hard scatter. $W$ and $Z$ cross sections are given at NNLO, the $t \bar{t}$ cross section is given at next-to-leading order (plus next-to-next-to-leading log), and the dijet cross sections are given at leading order.

The background contributions, expected primarily from jet production via QCD processes, have significant components from semi-leptonic decays of heavy quarks, hadrons misidentified as leptons, and in the case of the electron channel, electrons from conversions. For both the electron and muon channels, these sources of background have been obtained from dijet samples.

In the case of the $W$ analysis, $W$ events decaying into $\tau$-leptons with subsequent leptonic $\tau$ decays are also expected to contribute in both channels. Contributions from $Z \rightarrow \mu \mu$ decays are significant in the muon channel. Due to the $\eta$ coverage of the muon system, this type of decay is more likely to generate $E_{\mathrm{T}}^{\text {miss }}$ in the muon channel than $Z \rightarrow e e$ decays in the electron channel. The muon channel additionally takes into account contributions from $Z \rightarrow \tau \tau$ decays and from $t \bar{t}$ events involving at least one semi-leptonic decay, though these contributions are small.

## 4 Object reconstruction

### 4.1 Electrons

The ATLAS standard electron/photon reconstruction and identification algorithm [19] is designed to provide various levels of background rejection optimised for high identification efficiencies for transverse energy $E_{\mathrm{T}}>20 \mathrm{GeV}$, over the full acceptance of the inner-detector system. Electron reconstruction begins with a seed cluster of energy of $E_{\mathrm{T}}>2.5 \mathrm{GeV}$ in the second layer of the electromagnetic calorimeter. This cluster of size $\Delta \eta \times \Delta \phi=0.075 \times 0.125$ is selected by a sliding window algorithm. A matching track, extrapolated to the middle EM calorimeter layer, is searched for in a broad window of $\Delta \eta \times \Delta \phi=0.05 \times 0.1$ amongst all reconstructed tracks with $p_{\mathrm{T}}>0.5 \mathrm{GeV}$. The closest-matched track to this layer's cluster barycentre is kept as that belonging to the electron candidate. The final electron candidates have cluster sizes of $\Delta \eta \times \Delta \phi=0.075 \times 0.175$ in the barrel calorimeter and $0.125 \times 0.125$ in the end-cap. The total
transverse energy of these clusters is the $E_{\mathrm{T}}$ used in this analysis.
The baseline electron identification selections [19] are based on criteria using calorimeter and tracker information and have been optimised in 10 bins in $\eta$ and 11 bins in $E_{\mathrm{T}}$. Three reference sets of requirements (loose, medium, and tight) have been chosen, providing progressively stronger jet rejection at the expense of some identification efficiency loss. Each set adds additional constraints to the previous requirements:

- Loose: this basic selection uses EM shower shape information from the second layer of the EM calorimeter (lateral shower containment and shower width) and energy leakage into the hadronic calorimeters as discriminant variables. This set of requirements provides high and uniform identification efficiency but a low background rejection;
- Medium: this selection provides additional hadronic rejection by evaluating the energy deposit patterns in the first layer of the EM calorimeter (the shower width and the ratio of the energy difference associated with the largest and second largest energy deposit over the sum of these energies), track quality variables (number of hits in the pixel and silicon trackers, the transverse impact parameter) and a cluster-track matching variable ( $\eta$ between the cluster and the track extrapolated to the first layer of the EM calorimeter)
- Tight: this selection further rejects charged hadrons and secondary electrons from conversions by fully exploiting the electron identification potential of the ATLAS detector. It makes requirements on the ratio of cluster energy to track momentum, on the number of hits in the TRT, and on the ratio of high-threshold to the total number of hits in the TRT. Electrons from conversions are rejected by requiring at least one hit in the first layer of the pixel detector. A conversion-flagging algorithm is also used to further reduce this contribution. The impact-parameter requirement applied in the medium selection is further tightened at this level.

Using $Z \rightarrow e e$ signal and QCD dijet Monte Carlo samples for electrons with $E_{T}>20 \mathrm{GeV}$ within the range $|\eta|<2.47$ and excluding the transition region between the barrel and end-cap calorimeters ( $1.37<|\eta|<1.52$ ), the expected identification efficiencies are estimated to be $94 \%, 90 \%$, and $72 \%$ with respective rejection factors against background jets with true $E_{\mathrm{T}}>20 \mathrm{GeV}$ of 1100,6800 , and 92000 for loose, medium, and tight electron identification, respectively [19].

### 4.2 Muons

The ATLAS muon identification and reconstruction algorithms take advantage of the multiple subdetector technologies which provide complementary approaches and cover pseudorapidities up to 2.7 over a wide $p_{\mathrm{T}}$ range [9].

The stand-alone muon reconstruction is based entirely on muon-spectrometer information, independently of whether or not this track is also reconstructed in the inner detector. The muon reconstruction is initiated locally in a muon chamber by the search for straight line track segments in the bending plane. Hits in the precision chambers are used and the segment candidates are requested to point to the centre of ATLAS. The hit coordinate $\phi$ in the non-bending plane measured by the trigger detectors is associated to the segment when available. A minimum of two track segments in different muon stations are combined to form a muon track candidate using three-dimensional tracking in the magnetic field. The track parameters $\left(p_{\mathrm{T}}, \eta, \phi\right.$, distance of closest approach to the primary vertex along the beam axis and transverse to it) are obtained from the muon spectrometer track fit and are extrapolated to the interaction point taking into account both multiple scattering and energy loss in the calorimeters. For the latter, the reconstruction utilises either a parameterisation or actual measurements of calorimeter energy losses, together with parameterisation of energy loss in the inert material. The typical muon energy loss in the calorimeters is

3 GeV . The stand-alone muon reconstruction algorithms use the least-squares formalism to fit tracks in the muon spectrometer and most material effects are directly integrated into the $\chi^{2}$ function.

The combined muon reconstruction associates the stand-alone muon spectrometer tracks to an innerdetector track, that measures the bending of the muon within the solenoid, using the pixel, SCT and TRT detectors. The association between the stand-alone and inner-detector tracks is performed using a $\chi^{2}$, defined from the difference between the respective track parameters weighted by their combined covariance matrices. The parameters are evaluated at the point of minimum approach to the beam axis. The combined track parameters are derived either from a statistical combination of the two tracks or from a refit of the full track. To validate the results presented in this note, these two independent reconstruction chains were exercised, leading to a good agreement. The results presented here are based on the one which relies on the statistical combination of muon-spectrometer and inner-detector measurements.

The reconstruction and identification efficiencies for muons with $p_{\mathrm{T}}>10 \mathrm{GeV}$ as extracted from $W$ and $Z$ signal Monte Carlo samples is estimated to be $94 \%$ [9]. The availability of muons with energies up to 100 GeV energy in cosmic rays has enabled the commissioning of the muon identification system. Results from these studies indicate that the performance is in agreement with Monte Carlo expectation in this entire energy range. The tracking resolution has been measured to be better than $5 \%$ and the muon detection efficiency is in reasonable agreement with the values measured in simulated events. Detailed studies in collision data are underway but are currently limited by the number of high- $p_{\mathrm{T}}$ muons collected so far.

### 4.3 Transverse missing energy

The transverse missing energy ( $E_{\mathrm{T}}^{\text {miss }}$ ) reconstruction used in the electron channel is currently only based on calorimeter information. This relies on a cell-based algorithm which sums the electromagnetic-scale energy deposits of calorimeter cells inside three-dimensional topological clusters [20]. The EM scale is the energy deposited in the calorimeter calculated under the assumption that all processes are purely electromagnetic in nature. No corrections for the different calorimeter response to hadrons and electrons or photons nor for dead material losses are applied. These topological clusters are built around energy $E>4 \sigma_{\text {noise }}$ seeds, where $\sigma_{\text {noise }}$ is the Gaussian width of the cell energy distribution in randomly triggered events, by iteratively gathering neighbouring cells with $E>2 \sigma_{\text {noise }}$ and, in a final step, by adding all direct neighbours of these accumulated secondary cells. The $x$ - and $y$-components of the calorimeter $E_{\mathrm{T}}^{\text {miss }}$ term are calculated by summing over the transverse energies measured in these topological cluster cells $i$ :

$$
\begin{equation*}
E_{x, y}^{\text {Electron,miss }}=E_{x, y}^{\text {Calo,miss }}=-\sum_{i} E_{x, y} . \tag{2}
\end{equation*}
$$

The $E_{\mathrm{T}}^{\text {miss }}$ used in the muon channel is calculated from the reconstructed momenta of muons measured in the range of pseudorapidity $|\eta|<2.7$ and the calorimeter term as given in Eq. 2:

$$
\begin{equation*}
E_{x, y}^{\text {Muon,miss }}=-\left(\sum_{\text {Muons }} E_{x, y}+\sum_{i} E_{x, y}\right)=-\left(\sum_{\text {isolated }} p_{x, y}+\sum_{n o n-\text { isolated }} p_{x, y}\right)+E_{x, y}^{\text {Calo,miss }}, \tag{3}
\end{equation*}
$$

where non-isolated muons are those within a distance $\Delta R \leq 0.3$ of another jet in the event. The $p_{\mathrm{T}}$ of an isolated muon is determined from the combined measurement of the inner detector and muon spectrometer as explained in Section 4.2. The energy lost by an isolated muon in the calorimeters is not added to the calorimeter term. For a non-isolated muon, the energy lost in the calorimeter cannot be separated from the nearby jet energy. The muon spectrometer measurement of the muon momentum after energy loss in the calorimeter is therefore used unless there is a significant mis-match between the spectrometer and combined measurements, in which case the combined measurement minus the parameterised energy loss in the calorimeter is used. For higher values of the pseudorapidity outside the
fiducial volume of the inner detector $(2.5<|\eta|<2.7)$, there is no matched track requirement and the muon spectrometer stand-alone measurement is used instead.

In both the electron and muon cases, the $E_{T}^{m i s s}$ is defined as:

$$
\begin{equation*}
E_{\mathrm{T}}^{m i s s}=\sqrt{\left(E_{x}^{m i s s}\right)^{2}+\left(E_{y}^{m i s s}\right)^{2}} . \tag{4}
\end{equation*}
$$

The performance of the $E_{\mathrm{T}}^{\mathrm{miss}}$ reconstruction in minimum-bias data is described in Ref. [21].

## 5 Event selection and preparation

### 5.1 Event selection

The results presented in this note were collected over a seven-week period, from March to May 2010. From all data taken at a centre-of-mass energy of 7 TeV and for which the LHC declared stable beams, only those with the detector high voltage in nominal condition are selected. In addition, while the electron channel analysis requires the solenoid to be on, the muon channel analysis needs both solenoid and toroid at nominal field. Finally, both leptonic channels require that all of the sub-detectors are operational such that the response and main criteria needed for particle identification as well as energy and momentum computations do not deviate significantly from their expected behaviour. These basic dataquality requirements resulted in total integrated luminosities of $6.7 \mathrm{nb}^{-1}$ for the $W \rightarrow e v$ and $Z \rightarrow e e$ channels, and $6.4 \mathrm{nb}^{-1}$ and $7.9 \mathrm{nb}^{-1}$ for the $W \rightarrow \mu \nu$ and $Z \rightarrow \mu \mu$ channels, respectively. While the $W \rightarrow \mu \nu$ analysis requires calorimeter information to calculate the $E_{\mathrm{T}}^{\mathrm{miss}}$, no calorimeter information is required for the $Z \rightarrow \mu \mu$ channel. This is the reason why they do not have the same integrated luminosity. The uncertainty on the luminosity determination is on the order of $20 \%$, though the relative luminosity between the various channels is known to a much higher precision.

Events are selected with the hardware-based L1 trigger. The L1 calorimeter trigger selects photons and electrons within $|\eta|<2.5$ using calorimeter information with the reduced granularity of trigger towers of dimension $\Delta \eta \times \Delta \phi=0.1 \times 0.1$. The calorimeter trigger used in this analysis accepts electron and photon candidates if the signal from a cluster of trigger towers is above two trigger counts, where one count corresponds to approximately 1 GeV . The L1 muon trigger searches for patterns of hits within $|\eta|<2.4$ consistent with high- $p_{\mathrm{T}}$ muons originating from the interaction region. The trigger logic is based on three trigger stations. The algorithm requires a coincidence of hits in the different trigger stations within a road, which tracks the path of a muon from the interaction point through the detector. The width of the road is related to the $p_{\mathrm{T}}$ threshold to be applied. The muon trigger used in this analysis corresponds to the lowest $p_{\mathrm{T}}$ threshold trigger which has a fully-opened road with a two-station coincidence. As a result of these trigger decisions, $1.2 \times 10^{7}$ and $2.8 \times 10^{5}$ events are triggered in the electron and muon channels, respectively.

Collision candidates are selected by requiring a primary vertex with at least three tracks, consistent with the beam spot position. To reduce fake collision candidates from cosmic-ray or beam-halo events, the muon analysis requires the primary vertex position along the beam axis is required to be within 15 cm of the nominal position.

### 5.2 Event preparation

An analysis of a high statistics sample of minimum-bias events has shown that events can occasionally contain very localised high-energy calorimeter deposits not originating from the proton-proton collision, but e.g. from unexpected discharges in the hadronic end-cap calorimeter, and more rarely coherent noise in the electromagnetic calorimeter. Cosmic-ray muons undergoing a hard bremsstrahlung are also a potential source of localised energy deposits uncorrelated to the primary proton-proton collisions.

The occurrence of these events is very rare but can potentially impact significantly the $E_{\mathrm{T}}^{\text {miss }}$ measurement by creating high-energy tails [22]. To avoid spoiling the $E_{\mathrm{T}}^{\text {miss }}$ measurement, dedicated cleaning requirements using reconstructed jets (with the anti- $k_{t}$ algorithm [23]) in a narrow cone of size $\Delta R=0.4$ have been developed using a minimum-bias event sample. The jet properties are used as probes of the quality of the local calorimeter-energy deposit:
i) if more than $80 \%$ of the jet energy is deposited in the HEC calorimeter, $90 \%$ of the jet energy must be distributed over at least 6 calorimeter cells;
ii) if more than $95 \%$ of the jet energy is deposited in the EM calorimeter, less than $80 \%$ of the total jet energy must come from cells with an abnormal signal shape;
iii) the jet must primarily contain cells with energy deposited less than 50 ns before or after the nominal proton-proton collision time.

Events are kept only if all the jets reconstructed in the event with a transverse energy greater than 10 GeV at the EM scale fulfill the three requirements mentioned above. It was verified that these criteria remove less than one per mill of minimum-bias events and no $W \rightarrow \ell v$ events nor dijet events in Monte Carlo simulation.

For the electron channel only, the quality of the reconstruction of the energy deposited by the electron in the liquid argon calorimeter is assessed. The event is rejected if the candidate electromagnetic cluster is located in any problematic region of this detector: regions affected by major high-voltage problems, isolated cells producing a high noise signal or no signal at all, and electronic front-end boards not providing any output signal. These problems can cause extended dead regions in a given layer of the calorimeter, which may have an important impact on the energy reconstruction of the electron. To minimise the systematic uncertainty, an additional requirement is imposed such that a fiducial area around the energy clusters may not intersect that covered by a problematic front-end board if these are located in the first or second layers of the LAr EM calorimeter, where most of the electromagnetic shower energy is deposited. The loss in acceptance due to these requirements is $9 \%$ for the $W$ signal and the background.

## 6 Preselection of high transverse-energy leptons

A preselection of high transverse-energy electrons and muons is made. Electron candidates with the identification level "loose" according to the algorithm as described in Section 4.1 are required to have a cluster $E_{\mathrm{T}}>20 \mathrm{GeV}$ within the range $|\eta|<2.47$, excluding the transition region between the barrel and end-cap calorimeters ( $1.37<|\eta|<1.52$ ). Muon candidate events selected according to the algorithm described in Section 4.2 are required to have at least one combined muon with $p_{\mathrm{T}}>15 \mathrm{GeV}$ and a $p_{\mathrm{T}}$ as measured by the muon-spectrometer greater than 10 GeV , within the range $|\eta|<2.4$. The difference between the inner-detector and muon-spectrometer $p_{\mathrm{T}}$, corrected for the mean energy loss in upstream material, is required to be less than 15 GeV to increase the robustness against track reconstruction mismatches. The difference between the $z$ position of the muon track extrapolated to the beam line and the $z$ coordinate of the primary vertex is required to be less than 1 cm .

Figures 1 and 2 show the kinematic properties of these candidates and compare these to the signal and background Monte Carlo samples described in Section 3. At this stage of the selection, the candidate events are dominated by the QCD background. If these Monte Carlo distributions are normalised to the total integrated luminosity of the data, the dijet Monte Carlo cross section appears to be over-estimated by a factor of approximately 2.2 for the electron channel and a factor of 1.9 for the muon channel. This is one of the reasons why partially data-driven background estimates for the electron and muon channels are presented in Section 8. These estimates are a first attempt to measure the QCD background contribution to the $W$ channel and will greatly benefit from more statistics. The Monte Carlo distributions in Figures 1

Figure 1: Cluster $E_{T}(a)$, as well as $\eta(b)$ and $\phi(c)$ (measured in the second layer of the electromagnetic calorimeter) of electron candidates after preselection for data and Monte Carlo candidates broken down into the various signal and background components. The total number of Monte Carlo candidates is normalised to the number of observed data candidates. In Figure 1(a), the total QCD background is broken down into its constituents: hadrons misidentified as electrons, electrons from conversions, and electrons from semi-leptonic decays of heavy quarks.

Figure 2: Combined $p_{\mathrm{T}}(a), \eta(b)$, and $\phi(c)$ of muon candidates after preselection for data and Monte Carlo candidates broken down into the various signal and background components. The total number of Monte Carlo candidates is normalised to the number of observed data candidates.
and 2 have been normalised to the total number of data events, taking into account these scale factors for the QCD background. It is to be noted that all data distributions in this note are given with statistical error bars only, corresponding to $68.3 \%$ confidence intervals. These distributions show reasonable agreement in shape between data and Monte Carlo events. More details on the properties of inclusive muons are given in Ref. [24].

Figure 3 shows their transverse missing energy normalised in the same fashion as for Figures 1 and 2. Within the limited statistics afforded by the muon analysis, the $E_{\mathrm{T}}^{\text {miss }}$ distribution from the data is well reproduced by the Monte Carlo, and an excess of events around the expected signal peak region com-

Figure 3: $E_{\mathrm{T}}^{\text {miss }}$ of electron (a) and muon (b) candidates after preselection for data and Monte Carlo candidates broken down into the various signal and background components. The total number of Monte Carlo candidates is normalised to the number of observed data candidates. In Figure 3(a), the total QCD background is broken down into its constituents: hadrons misidentified as electrons, electrons from conversions, and electrons from semi-leptonic decays of heavy quarks.
pared to the background is already visible at this stage of the selection (and is the reason for the different histogramme-stacking order between the electron and the muon channel). The higher-statistics comparison of the electron analysis demonstrates that the $E_{\mathrm{T}}^{\text {miss }}$ rejection in the data for $E_{\mathrm{T}}^{\mathrm{miss}}>25 \mathrm{GeV}$ is worse than in the Monte Carlo. The source of this discrepancy is currently under investigation. It is strongly correlated to the presence of a jet faking the electron in the event and therefore not in disagreement with the conclusions of Ref. [21] which focuses on inclusive minimum-bias events.

## 7 Selection and observation of $W$ candidates

Additional requirements beyond those imposed in Section 6 are used to better discriminate potential $W \rightarrow \ell v$ events from background events. The electron identification level as described in Section 4.1 is increased to "tight" while the minimum muon combined $p_{\mathrm{T}}$ is increased to 20 GeV . Only the highest $p_{\mathrm{T}}$ lepton in the event is used.

Both the electron and muon analyses have considered the use of an isolation parameter to enhance the expected signal. However, the isolation requirements for the different channels should be considered separately, given that an electron is quite a complex object which can undergo bremsstrahlung while a muon is in some sense a simpler object primarily defined by its track. In addition, the EM calorimeter requirements for the electrons use variables which already provide some effective isolation.

A calorimeter-based isolation parameter for the electron channel defined as the total calorimeter energy within a cone of $\Delta R<0.3$ surrounding the candidate electron cluster which is then divided by the cluster $E_{\mathrm{T}}$ and a track-based isolation for the muon channel defined as the sum of inner-detector transverse momenta within a cone $\Delta R<0.4\left(\sum p_{T}^{I D}\right)$ which is then divided by the total combined muon

Figure 4: $E_{\mathrm{T}}^{\mathrm{miss}}$ versus calorimeter-isolation parameter for electron candidates (a) and track-isolation parameter for muon candidates (b) after preselection plus the "tight" requirement for electrons and muon combined $p_{\mathrm{T}}>20 \mathrm{GeV}$.
$p_{\mathrm{T}}$ are shown in Figure 4 and are plotted against the $E_{\mathrm{T}}^{\text {miss }}$ of the event. The isolation variable will be used in the electron analysis to make a data-driven estimate of the background contributions to the $W \rightarrow e v$ candidates; therefore, no form of isolation is explicitly applied in the electron-channel selection. An isolation requirement of $\sum p_{T}^{I D} / p_{T}<0.2$ is used in the muon analysis given that, after all other selections are made to identify $W$ candidates, this requirement rejects over $87 \%$ of the expected QCD background while keeping $99 \%$ of signal events. All further results shown in this section have passed the preselection requirements of Section 6, the "tight" requirement for electrons, the muon combined $p_{\mathrm{T}}>20 \mathrm{GeV}$, and this muon isolation requirement.

Additional kinematic requirements are explored in the last step of the signal selection: the $E_{\mathrm{T}}^{\text {miss }}$ of the event and the transverse mass $m_{\mathrm{T}}$ of the lepton $-E_{\mathrm{T}}^{\text {miss }}$ system defined as

$$
\begin{equation*}
m_{\mathrm{T}}=\sqrt{2 p_{\mathrm{T}}^{\ell} p_{\mathrm{T}}^{v}\left(1-\cos \left(\phi^{\ell}-\phi^{v}\right)\right)} \tag{5}
\end{equation*}
$$

where the measured $E_{\mathrm{T}}^{\text {miss }}$ components in $(x, y)$ provide the neutrino information. All Monte Carlo one-dimensional distributions shown in this section have been normalised to integrated luminosities of $6.7 \mathrm{nb}^{-1}$ and $6.4 \mathrm{nb}^{-1}$, in the electron and muon channels, respectively, using the cross sections as given in Table 1. In addition, the QCD background contributions have been scaled by factors of $1 / 2.2$ and $1 / 1.9$ in the electron and muon channels, respectively, to account for the over-estimation of the the dijet Monte Carlo cross section described in Section 6.

Figure 5 shows the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution of all electron and muon candidates passing the requirements listed above. Both distributions indicate that applying a requirement of $E_{\mathrm{T}}^{\mathrm{miss}}>25 \mathrm{GeV}$ would greatly enhance the $W$ signal over the expected background. This observation is also evident from the twodimensional plot of $E_{\mathrm{T}}^{\mathrm{miss}}$ versus electron cluster $E_{\mathrm{T}}$ and muon combined $p_{\mathrm{T}}$ shown in Figure 6. True $W \rightarrow \ell v$ events in the Monte Carlo are predominantly at high $E_{\mathrm{T}}^{\text {miss }}$ due to the escaping neutrino in the event. Although some of the QCD background may also have neutrinos in their final state, these events

Figure 5: $E_{\mathrm{T}}^{\mathrm{miss}}$ of selected electron (a) and muon (b) candidates.

Figure 6: $E_{\mathrm{T}}^{\text {miss }}$ versus the electron cluster $E_{\mathrm{T}}(a)$ and the muon combined $p_{\mathrm{T}}(b)$. For the purpose of this figure, the requirement of the muon combined $p_{\mathrm{T}}$ is lowered to 15 GeV .
mostly populate the regions of small $E_{\mathrm{T}}^{\mathrm{miss}}$.
The transverse mass of the lepton $-E_{\mathrm{T}}^{\mathrm{miss}}$ system is highly correlated to the $E_{\mathrm{T}}^{\mathrm{miss}}$ of the event as is demonstrated in Figure 7 which shows a two-dimensional plot of the $E_{\mathrm{T}}^{\mathrm{miss}}-m_{\mathrm{T}}$ plane. Figures 8 and 9 show projections of Figure 7 where the $m_{\mathrm{T}}$ of the event is shown without and with a requirement of

Figure 7: $E_{\mathrm{T}}^{\text {miss }}$ versus $m_{\mathrm{T}}$ of the lepton- $E_{\mathrm{T}}^{\text {miss }}$ system for electrons (a) and muons (b).

| Requirement | Number of <br> candidates |
| :--- | :---: |
| Triggered (Section 5) | $1.2 \times 10^{7}$ |
| Preselection (Section 6) | $2.2 \times 10^{3}$ |
| Tight electron (Section 4.1) | 77 |
| $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ | 17 |
| $m_{\mathrm{T}}>40 \mathrm{GeV}$ | 17 |

Table 2: Number of $W \rightarrow e v$ candidates remaining after each major requirement is applied.

| Requirement | Number of <br> candidates |
| :--- | :---: |
| Triggered (Section 5) | $2.8 \times 10^{5}$ |
| Preselection (Section 6) | 534 |
| $p_{\mathrm{T}}>20 \mathrm{GeV}$ | 166 |
| $\sum p_{T}^{I D} / p_{T}<0.2$ | 76 |
| $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ | 42 |
| $m_{\mathrm{T}}>40 \mathrm{GeV}$ | 40 |

Table 3: Number of $W \rightarrow \mu \nu$ candidates remaining after each major requirement is applied.
$E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$.
Tables 2 and 3 summarise the number of $W \rightarrow \ell v$ candidates remaining after each major requirement in the respective analyses described in this note. A total of 17 candidates ( $11 e^{+}$and $6 e^{-}$) pass all requirements in the electron channel and 40 candidates ( $25 \mu^{+}$and $15 \mu^{-}$) in the muon channel in the $m_{\mathrm{T}}$ region above 40 GeV . It is to be noted that the pseudorapidity dependence of the acceptance of $W^{+}$

Figure 8: $m_{\mathrm{T}}$ of the electron- $E_{\mathrm{T}}^{\text {miss }}$ system without (a) and with (b) a requirement of $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$. In Figure $8(a)$, the total QCD background is broken down into its constituents: hadrons misidentified as electrons, electrons from conversions, and electrons from semi-leptonic decays of heavy quarks.

Figure 9: $m_{\mathrm{T}}$ of the muon- $E_{\mathrm{T}}^{\text {miss }}$ system without (a) and with (b) a requirement of $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$.
and $W^{-}$production is not same and so the relative amount of positively-charged to negatively-charged $W$ bosons does not translate trivially into a cross-section ratio. Additional studies are still required (and are currently underway) before these observations can be converted into a cross section measurement.

Figure 10: Electron cluster $E_{T}(a)$ and muon combined $p_{T}(b)$ of the $W$ candidates after final selection. $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ and $m_{\mathrm{T}}>40 \mathrm{GeV}$ are required in both channels.

Figure 11: $p_{\mathrm{T}}$ of the $W$ candidates in the electron-channel (a) and muon-channel (b) after final selection. $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ and $m_{\mathrm{T}}>40 \mathrm{GeV}$ are required in both channels.

The properties of the final $W \rightarrow \ell v$ candidates are presented here. For the final selection, leptonic channels use the preselection requirements of Section 6, the "tight" requirement for electrons, the muon combined $p_{\mathrm{T}}>20 \mathrm{GeV}$ and muon isolation requirements, $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ and $m_{\mathrm{T}}>40 \mathrm{GeV}$. Figure 10
shows the electron cluster $E_{T}$ and muon combined $p_{\mathrm{T}}$ of the lepton candidates while Figure 11 shows the $p_{\mathrm{T}}$ spectrum of the $W \rightarrow \ell v$ candidates. Both channels demonstrate a clear $W$ signal over an almost negligible background. No attempt is made in this analysis to specifically identify and remove $Z$ bosons from the $W$ channel.

A few outlier events, with respect to the expected signal region, are observed in the muon channel and correspond to the events with large $W$ boson transverse momentum in Figure 11. These candidates have been inspected in detail and are consistent with the presence of a $W$ boson with a well isolated muon. Different missing energy calibrations and muon-momentum measurements have been attempted and no evident pathologies have been found.

## 8 Signal and background expectations for the $W \rightarrow \ell v$ candidates

The Monte Carlo samples discussed in Section 3 are used to provide an expectation for signal events and, in some cases for the background events. These results are summarised in Table 4. A total of 20.7 events are predicted to come from the $W \rightarrow e v$ process and 25.9 events from the $W \rightarrow \mu \nu$ process, with negligible statistical uncertainties. The difference between these two expectations stems primarily from the lower reconstruction efficiency of "tight" electrons compared to that of combined muons.

For the electron channel, the contribution from the $W \rightarrow \tau \nu$ process is expected to be small ( 0.4 events). Instead, a predominantly QCD background is expected (based on the dijet Monte Carlo, the expectation is evenly divided between heavy-quark decays, conversions, and hadrons faking electrons). $Z$ bosons decaying to electrons are expected to contribute at the $10 \%$ level of the QCD background. A partially data-driven estimate of the QCD background to the observed $W$ candidate events is made. The calorimeter isolation in a cone of $\Delta R=0.3$ divided by the electron $E_{\mathrm{T}}$ (as described in Section 7) is used as a discriminating variable in a binned maximum likelihood fit which uses Poisson statistics as described in Ref. [25]. This technique uses the prediction for the shape of the signal and the QCD background for this variable in the form of histogram templates taken from Monte Carlo samples. The distribution of this variable after the preselection is shown in Figure 12(a).

Due to the limited statistics and the very few background events, the fit cannot be performed after the final selection. Therefore only the "medium" instead of the "tight" electron identification requirement as described in Section 4.1 is applied, while the requirements on $E_{\mathrm{T}}^{\mathrm{miss}}$ and $m_{\mathrm{T}}$ are kept. Also for this reason, the signal and background templates are obtained from PYTHIA Monte Carlo samples. The fit result is shown in Fig. 12(b) and provides a background estimate of $N_{\mathrm{QCD}}$, medium $=9.8 \pm 5.7$ events, where the uncertainty contains the statistical uncertainty of the data and of the templates. The number of QCD background events after the final selection is estimated by scaling this number with the jet rejection factor for the "tight" requirement, with respect to the "medium" requirement extracted from the data for $E_{\mathrm{T}}^{\text {miss }}<20 \mathrm{GeV}$. This number is found to be $4.9 \pm 1.0$, thus giving a total QCD background of $N_{\mathrm{QCD}}$, tight $=2.0 \pm 1.2($ stat $)$. The total background in the $W$ channel is estimated to be this QCD contribution plus that coming from the $W \rightarrow \tau v$ process ( 0.4 events).

Different sources of systematic uncertainties were investigated. The QCD PYTHIA template was replaced by one obtained from the HERWIG [26] Monte Carlo. In addition, instead of dropping the "tight" requirement, the fit was performed on a sample where the "tight" requirement was applied but the $E_{\mathrm{T}}^{\mathrm{miss}}$ and $m_{\mathrm{T}}$ requirements were dropped. Finally, the number of bins used in the fit was varied in a large range. The observed variations are all small compared to the uncertainty of the fit which is to a large extent statistical. Therefore, the number of QCD background events as estimated by this template method is $N_{\mathrm{QCD}}=2.0 \pm 1.2(\mathrm{stat}) \pm 0.4$ (syst). The predicted number of QCD background events based on the dijet Monte Carlo given in Table 1 scaled by the factor of $1 / 2.2$ (as described in Section 6) is 0.8 events and so is in good agreement with this measurement.

An alternative estimate of the QCD background has been derived with the following data-driven

Figure 12: (a) Calorimeter isolation/ $E_{\mathrm{T}}$ (as described in Section 7) after preselection. The total number of Monte Carlo candidates is normalised to the number of observed data candidates. (b) Result of the template fit where the event selection contains all requirements but that of the "tight" electron (these are "medium" electrons). The Monte Carlo distributions are scaled to the result of the fit.
method. The ratio between the number of electrons passing the "tight" selection and the number of electrons passing the "loose" but failing the "medium" selection (as described in Section 4.1) is measured in data for events with $E_{\mathrm{T}}^{\mathrm{miss}}<10 \mathrm{GeV}$. The estimated number of QCD events after the signal selection is then obtained as the number of observed events with one "loose" electron failing "medium" requirements, which pass the signal selection requirements on $E_{\mathrm{T}}^{\text {miss }}$ and transverse mass. Several sources of systematic uncertainties have been considered such as the limited statistics of the Monte Carlo samples, the expected contamination of $W$ and $Z$ events in the control regions, and the stability of the accuracy of the estimate varying each individual component (hadron, conversion, and heavy flavour) in the Monte Carlo sample by a factor of two. The size of QCD background in the signal candidates selection is estimated to be $1.2 \pm 0.5$ events and is in agreement with the result of the template method quoted above.

For the muon channel, the total background estimate is 2.8 events, primarily coming from multijets and $Z \rightarrow \mu \mu$ decays ( $36 \%$ each of all the background). Other sources of backgrounds are $24 \%$ from $W \rightarrow \tau v$ decays, $3 \%$ from top production and $1 \%$ from $Z \rightarrow \tau \tau$ decays. Given the high uncertainty in the Monte Carlo dijet cross section, this source of background has been also measured in data using the distribution of missing energy versus isolation prior to the transverse mass requirement, as described below. The isolation distribution for preselected events is shown in Figure 13.

The primary assumption of this method to extract the multijet component of the total background is that the $E_{\mathrm{T}}^{\text {miss }}$ and the lepton isolation are uncorrelated. The $E_{\mathrm{T}}^{\text {miss }}$ versus track-isolation plane is divided into four separate regions defined by the same $E_{\mathrm{T}}^{\mathrm{miss}}$ and isolation requirements as for the $W$ selection (Figure 4(b)). The background contribution to the $W$ signal region is obtained from a similarity relationship between the contents in the four regions of the $E_{\mathrm{T}}^{\text {miss }}$-isolation space. The calculation is corrected for the contributions from the signal and the electroweak backgrounds described above.

This method yields a jet background estimate of $1.3 \pm 1.2$ events if no $m_{\mathrm{T}}$ requirement is imposed or $1.0 \pm 0.5$ (stat) $\pm 0.7$ (syst) events if $m_{\mathrm{T}}>40 \mathrm{GeV}$. The systematic uncertainty in this method is due to

Figure 13: Track-isolation variable $\sum p_{T}^{I D} / p_{T}(a)$ and $E_{T}^{\text {miss }}$ distribution of non-isolated events (b) after muon preselection. The total number of Monte Carlo candidates is normalised to the number of observed data candidates.
the correlation between the two variables used and has been estimated from the difference between the number of predicted and observed events in the signal region in a consistency check with Monte Carlo QCD sample. Since this technique is also sensitive to poorly reconstructed events faking muons as well as pion and kaon decays, this estimation is used for the final number of expected events.

An alternative estimation of the multijet background has been made by measuring the QCD background normalisation in data. The control sample used is obtained by reversing the isolation requirement after preselection. The assumption is that these events are dominated by muons from QCD background events. The background normalisation is taken from the comparison of the distributions of $E_{\mathrm{T}}^{\mathrm{miss}}$, in both data and jet background Monte Carlo samples. These are shown in Figure 13(b), where the QCD distribution has been normalised to the numbers of event in the control sample. The data and Monte Carlo shapes appear to agree well and an overall scale factor of Monte Carlo QCD cross section to data of 0.54 is measured. This method derives a background estimate of $0.2 \pm 0.1$. A value in agreement with this estimate is found when increasing the muon transverse momentum requirement to 20 GeV . An independent study using dijet Monte Carlo predicts that the background contamination from pion and kaon decays is $0.15 \pm 0.15$, which is well within the direct estimation from data.

All muon candidate events were inspected individually, verifying the main reconstruction parameters. Distributions of hit multiplicities in inner-detector and muon-spectrometer tracks, their track-matching $\chi^{2}$, and the difference in the transverse momentum measurement between the two sub-detectors were compared in data and Monte Carlo. A good agreement was found for all of these items. The hypothesis that a cosmic ray overlays with the collision was carefully verified by looking at the timing properties of muon tracks. TRT, tile calorimeter and MDT time measurements where analysed and no clear indication of cosmic contamination was found.

A fair degree of uncertainty still exits in these background estimates due to the statistically limited control samples and Monte Carlo simulations, and also from leading-order jet cross sections and fragmentation functions.

|  | $W \rightarrow e v$ channel | $W \rightarrow \mu \nu$ channel |
| :--- | :--- | :--- |
| Observed | 17 | 40 |
| Expected | $23.1 \pm 1.2($ stat $) \pm 1.7($ syst $) \pm 4.6($ lumi $)$ | $28.7 \pm 0.5($ stat $) \pm 3.9($ syst $) \pm 5.7(\mathrm{lumi})$ |
| Signal | $20.7 \pm 1.7($ syst $) \pm 4.1($ lumi $)$ | $25.9 \pm 3.6($ syst $) \pm 5.2($ lumi $)$ |
| Bkg | $2.4 \pm 1.2($ stat $) \pm 0.4($ syst $) \pm 0.5($ lumi $)$ | $2.8 \pm 0.5($ stat $) \pm 0.8($ syst $) \pm 0.6(\mathrm{lumi})$ |

Table 4: Numbers of observed and expected events from the $W \rightarrow \ell v$ channel. The statistical uncertainty is represented by "stat". The "syst" uncertainty is given for both the measured background and the signal prediction as described in the text. The "lumi" uncertainty refers to the contribution due to the luminosity determination.

The systematic uncertainties for the electron and muon channels on the number of expected events come from a number of sources. The dominant one is the luminosity determination for which a $20 \%$ scale uncertainty is used for both channels. Other sources of inefficiencies contributing to the total systematic error are analysis dependent. For the electron channel, data-Monte Carlo comparisons estimate the lepton identification uncertainties at $5 \%$ and the choice of $E_{\mathrm{T}}^{\mathrm{miss}}$ requirement at $5 \%$. In addition, an uncertainty of $4 \%$ is attributed to the theoretical cross section and on the acceptance from the parton distribution functions. Trigger inefficiencies are considered to be negligible in comparison. For the muon channel, several sources of uncertainties were considered and added in quadrature resulting in an overall $14 \%$ systematic uncertainty. The following contributions are included. The uncertainty on muon reconstruction efficiency is estimated to be $10 \%$. The single-muon trigger efficiency as measured in data is calculated as an average of the values measured in RPC and TGC detectors, weighted by the relative number of events in their acceptance. The ratio of trigger efficiency as measured in data and in Monte Carlo samples is 0.92 . This scale factor has been used to correct the Monte Carlo predictions in this note. A $7 \%$ uncerainty is attributed to this muon trigger scale factor. A $5 \%$ uncertainty is assigned to the muon resolution. Finally, a $4 \%$ uncertainty is assigned to the theoretical cross section and on the acceptance from the parton distribution functions.

The total number of events expected to pass all selection requirements in the $W \rightarrow e v$ channel is $23.1 \pm 1.2($ stat $) \pm 1.7($ syst $) \pm 4.6($ lumi $)$ and is $28.7 \pm 0.5($ stat $) \pm 3.9$ (syst) $\pm 5.7$ (lumi) in the $W \rightarrow \mu v$ channel. The numbers of observed and expected events in both channels are summarised in Table 4.

## 9 Observation of $Z$ candidates

A search for $Z$ candidates was also performed in both the electron and muon channels. The preselection specifications listed in Section 6 are first applied. Subsequent requirements are made to specifically search for lepton pairs consistent with being produced from the decay of a $Z$ boson. For the electron channel, leptons are required to be of opposite charge and each lepton must pass at least the "medium" requirements as presented in Section 4.1. For the muon channel, the selection is loosened compared to the $W$ search: only one of the muon candidates is required to have a minimum muon combined $p_{\mathrm{T}}$ above 20 GeV . The other muon minimum $p_{\mathrm{T}}$ threshold remains at 15 GeV and the pseudorapidity requirement of this second muon is relaxed to $|\eta|<2.5$. Muon candidates must have opposite charge and a muon isolation parameter $\sum p_{T}^{I D} / p_{T}<0.2$. Within the invariant mass window $m_{\ell \ell}=80-100 \mathrm{GeV}$, one candidate with an invariant mass of 91.4 GeV passes these requirements in the electron channel and two candidates with invariant masses of 80.2 GeV and 87.6 GeV in the muon channel. No events were found in the electron selection outside this mass window and only one event at lower mass in the muon selection.

The $Z \rightarrow \ell \ell$ Monte Carlo samples discussed in Section 3 are used to provide an expectation for signal events. For the electron channel, a total of $1.6 \pm 0.1$ (syst) $\pm 0.3$ (lumi) signal events with a negligible statistical uncertainty are expected for an integrated luminosity of $6.7 \mathrm{nb}^{-1}$. This estimate includes a $20 \%$ uncertainty on the luminosity, a $5 \%$ systematic uncertainty on the acceptance and efficiency, and a $4 \%$ contribution for the theoretical cross section uncertainty and on the acceptance from the parton distribution functions. For the muon channel, a total of $3.2 \pm 0.7$ (syst) $\pm 0.6$ (lumi) signal events with a negligible statistical uncertainty are expected for an integrated luminosity of $7.9 \mathrm{nb}^{-1}$. Apart from the $20 \%$ uncertainty in luminosity determination, the primary source of systematic uncertainty in this prediction is the reconstruction efficiency. Since the final state in $Z \rightarrow \mu \mu$-like events contains two muons, the uncertainties in their reconstruction efficiencies are added linearly, yielding an uncertainty on the event reconstruction efficiency of $20 \%$. This number assumes that the uncertainties are fully correlated between the two muons. The uncertainty in the trigger efficiency scaling factor is $4 \%$. The other sources of systematics are the same as for the $W$ channel. These contributions are added in quadrature resulting in the final number given above.

The background Monte Carlo samples in Section 3 as such have insufficient statistics to provide a direct estimate of the expected background events in the $Z \rightarrow e e$ channel within the mass window $80<$ $m_{e e}<100 \mathrm{GeV}$. A partially data-derived estimate is made. For the electron channel, the QCD background Monte Carlo sample may be used to estimate the number of pairs of leptons that both pass the "loose" electron requirement, in the appropriate mass range. A data-derived "loose" to "medium" rejection factor is then used to estimate the expected number of lepton pairs which both pass the nominal $Z \rightarrow e e$ requirements. The ratio of "medium" to "loose" electrons with $p_{\mathrm{T}}>20 \mathrm{GeV}$, reconstructed using the standard electron algorithm of Section 4.1 and within the $\eta$ acceptance of the detector is measured in data to be $0.40 \pm 0.16$. This rejection, quoted here as its reciprocal, is consistent with the rejection measured from electrons in the QCD background Monte Carlo. In the Z mass window $80<m_{e e}<100 \mathrm{GeV}$, the Monte Carlo predicts there to be $0.14 \pm 0.01$ QCD background events in the opposite-charge invariant mass distribution for "loose" lepton pairs. By applying the data-derived rejections to each electron in these pairs, a background estimate of 0.01 "medium" pairs in the opposite-charge distribution in the $Z$ mass window is derived.

The total number of expected background events within the mass window $80<m_{\mu \mu}<100 \mathrm{GeV}$ in the muon channel after all requirements as estimated from Monte Carlo samples described in Table 1 is $(2.1 \pm 0.8$ (syst) $\pm 0.4$ (lumi) $) \times 10^{-4}$, where the dominant source is top-pair production $(52 \%)$. The QCD contribution is $38 \%$ and other sources are negligible.

## 10 Summary

This note presents an observation by the ATLAS experiment of $57 \mathrm{~W} \rightarrow \ell v$ candidates produced from $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions at the LHC. These results, collected over a seven-week period from March to May 2010, correspond to a total integrated luminosity of $6.7 \mathrm{nb}^{-1}$ for the $W \rightarrow e v$ channel, and $6.4 \mathrm{nb}^{-1}$ for the $W \rightarrow \mu \nu$ channel. These results are in agreement with the expectation of 51.8 events. Three $Z \rightarrow \ell \ell$ candidates were observed with an expectation of 4.8 given the integrated luminosities of $6.7 \mathrm{nb}^{-1}$ for the $Z \rightarrow e e$ channel and $7.9 \mathrm{nb}^{-1}$ for the $Z \rightarrow \mu \mu$ channel. The number of events observed is consistent with the expectation.

# Measurement of the $W \rightarrow \ell v$ production cross-section and observation of $Z \rightarrow \ell \ell$ production in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

The ATLAS Collaboration ${ }^{\text {a }}$

${ }^{a}$ CERN

#### Abstract

This note describes the first measurement of the $W \rightarrow \ell v$ production cross section and an observation of $Z \rightarrow \ell \ell$ production, where $\ell=e, \mu$, by the ATLAS experiment. These results are based on $118 \mathrm{~W} \rightarrow \ell v$ candidates and $14 Z \rightarrow \ell \ell$ candidates, produced in $\sqrt{s}=$ 7 TeV proton-proton collisions at the LHC and correspond to a total integrated luminosity of approximately $17 \mathrm{nb}^{-1}$. The total inclusive $W$-boson production cross section times the leptonic branching ratio is measured to be ( $8.5 \pm 1.3$ (stat) $\pm 0.7$ (syst) $\pm 0.9$ (lumi)) nb for the $W \rightarrow e v$ channel and $(10.3 \pm 1.3$ (stat) $\pm 0.8$ (syst) $\pm 1.1$ (lumi)) nb for the $W \rightarrow \mu \nu$ channel. This constitutes the first $W$ cross-section measurement by ATLAS in proton-proton collisions and the result obtained is in agreement with theoretical calculations based on NNLO QCD. In addition the expected charge asymmetry between the cross sections for $W^{+}$and $W^{-}$production is experimentally confirmed.

## 1 Introduction

The experimental study of the electroweak gauge bosons has a history of about thirty years. The $W$ and the $Z$ particles were initially discovered and measured at the CERN proton-antiproton collider in 1983 [1, 2, 3, 4]. During the early 1990's, the $Z$ properties were measured in great detail at the high energy $e^{+} e^{-}$colliders LEP and SLC [5]. In the second half of that decade, an energy increase of LEP enabled the study of $W$ bosons produced in pairs. The Tevatron proton-antiproton collider has been accumulating $W$ and $Z$ events over the last twenty years [6, 7]. The results of these programmes include high-precision measurements of the $W$ and $Z$ mass, width, and couplings, as well as detailed information on their production in proton-antiproton collisions. The current uncertainties on the intrinsic properties of the $W$ boson are about ten times larger than on their $Z$ counterparts [8].

The $W$ and $Z$ bosons are expected to be produced abundantly at the Large Hadron Collider (LHC) [9], and for the first time in proton-proton collisions. This eventual large dataset and the high LHC energy will allow for detailed measurements of their production properties at a previously unexplored kinematic domain of low parton momentum fraction at a high energy scale. These conditions, together with the particular nature of the collisions, will provide new insights on the proton properties, tests of perturbative QCD calculations, and ultimately a precise determination of the mass of the $W$ boson [10, 11]. In this process, the well-known properties of the $Z$ boson will provide significant constraints in the determination of the performance of the collider experiments at the LHC; its known mass, width and leptonic decays can be exploited to measure precisely the detector energy and momentum scale, resolution, as well as lepton identification and trigger efficiencies.

This note details an observation by the ATLAS [12] experiment of $46 \mathrm{~W} \rightarrow e v$ and $72 \mathrm{~W} \rightarrow \mu \nu$ candidates produced from the $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions of the LHC, resulting from a total integrated luminosity of approximately $17 \mathrm{nb}^{-1}$. A total of five $Z \rightarrow e e$ and nine $Z \rightarrow \mu \mu$ candidates were also observed. These data were collected over a ten-week period from March to June 2010. The uncertainty on the luminosity determination is estimated to be $11 \%$ [13]. The results presented in this note supersede those of Ref. [14].

## 2 The ATLAS detector

The ATLAS detector [12] at the LHC comprises a thin superconducting solenoid surrounding the innerdetector cavity and three large superconducting toroids arranged with an eight-fold azimuthal coil symmetry placed around the calorimeters, forming the basis of the muon spectrometer.

In this note, the nominal interaction point is defined as the origin of the coordinate system, while the anti-clockwise beam direction defines the $z$-axis and the $x-y$ plane is transverse to the beam direction. The positive $x$-axis is defined as pointing from the interaction point to the centre of the LHC ring and the positive $y$-axis is defined as pointing upwards. The azimuthal angle $\phi$ is measured around the beam axis and the polar angle $\theta$ is the angle from the beam axis. The pseudorapidity is defined as $\eta=-\ln \tan (\theta / 2)$. The transverse momentum $p_{\mathrm{T}}$, the transverse energy $E_{\mathrm{T}}$, and the transverse missing energy $E_{\mathrm{T}}^{\mathrm{miss}}$ are defined in the $x-y$ plane. The distance $\Delta R$ in the $\eta-\phi$ space is defined as $\Delta R=\sqrt{\Delta \eta^{2}+\Delta \phi^{2}}$.

The Inner-Detector (ID) system is immersed in a 2 T axial field and provides tracking information on charged particles in a pseudorapidity range matched by the precision measurements of the electromagnetic calorimeter. The silicon tracking detectors, pixel and silicon microstrip (SCT), cover the pseudorapidity range $|\eta|<2.5$. The highest granularity is achieved around the vertex region using the pixel detectors. Typically three pixel layers are crossed by each track. For the SCT, eight strip layers (providing four space points) are crossed by each track in the barrel region. A large number of hits (typically 36 per track) is provided by the Transition Radiation Tracker (TRT), which enables track-following up to $|\eta|=2.0$. The electron identification information is provided by the detection of transition radiation in
the xenon-based gas mixture of the TRT straw tubes.
The calorimeter system covers the pseudorapidity range $|\eta|<4.9$, using a variety of detector technologies. The lead/liquid-argon (LAr) electromagnetic (EM) calorimeter is divided into a barrel part $(|\eta|<1.475)$ and two end-cap components $(1.375<|\eta|<3.2)$. The pseudorapidity range $1.37<|\eta|<$ 1.52 is considered as the transition region between the barrel and end-cap and is omitted in this analyses. Over the region devoted to precision physics ( $|\eta|<2.5$ ), the EM calorimeter is segmented in three sections in depth. The remaining portion of the EM calorimeter, known as the end-cap inner wheel, is segmented in two sections in depth and has a coarser lateral granularity than for the rest of the acceptance. In the region of $|\eta|<1.8$, a thin LAr presampler detector is used to correct for the energy lost by electrons, positrons, and photons upstream of the calorimeter. The hadronic tile calorimeter is placed directly outside the EM calorimeter envelope. This steel/scintillating-tile detector consists of a barrel covering the region $|\eta|<1.0$, and two extended barrels in the range $0.8<|\eta|<1.7$. The copper-LAr Hadronic End-cap Calorimeter (HEC) consists of two independent wheels per end-cap ( $1.5<|\eta|<3.2$ ), located directly behind the end-cap electromagnetic calorimeter. The Forward Calorimeter (FCal) consists of three modules in each end-cap: the first, made of copper-LAr, is optimised for electromagnetic measurements, while the other two, made of tungsten-LAr, measure primarily the energy of hadronic interactions.

The muon spectrometer is based on the magnetic deflection of muon tracks in the large superconducting air-core toroid magnets, instrumented with separate trigger and high-precision tracking chambers. A system of three large air-core toroids, a barrel and two end-caps, generates the magnetic field for the muon spectrometer in the pseudorapidity range of $|\eta|<2.7$. In the barrel region, tracks are measured in chambers arranged in three cylindrical layers around the beam axis; in the transition and end-cap regions, the chambers are installed in planes perpendicular to the beam, also in three layers. Over most of the $\eta$-range, a precision measurement of the track coordinates in the principal bending direction of the magnetic field is provided by Monitored Drift Tubes (MDT's). At large pseudorapidities, Cathode Strip Chambers (CSC's) with higher granularity are used in the innermost plane over $2.0<|\eta|<2.7$, to withstand the demanding rate and background conditions expected with the LHC operation at the nominal luminosity and centre-of-mass energy. The muon trigger system, which covers the pseudorapidity range $|\eta|<2.4$, consists of Resistive Plate Chambers (RPC's) in the barrel $(|\eta|<1.05)$ and Thin Gap Chambers (TGC's) in the end-cap regions ( $1.05<|\eta|<2.4$ ), with a small overlap in the $|\eta|=1.05$ region.

The first-level (L1) trigger system uses a subset of the total detector information to make a decision on whether or not to process an event. Details about the L1 calorimeter and muon trigger systems used in the analysis of the $W$ and $Z$ candidates are provided in Section 5.

## $3 W, Z$ processes and sources of background

The results presented in this note are compared to expectations based on Monte Carlo simulations. The signal and background samples used in this note were generated at $\sqrt{s}=7 \mathrm{TeV}$ with PYTHIA [15] using MRSTLO* [16] parton distribution functions (PDF), then simulated with GEANT4 [17] and fully reconstructed. Details of these samples are summarised in Table 1.

The $W$ and $Z$ production cross sections times their respective $W \rightarrow \ell \nu$ and $Z / \gamma^{*} \rightarrow \ell \ell$ decay branching ratios used in this study are calculated to next-to-next-to-leading order (NNLO) in QCD using the FEWZ program [18] with the MSTW2008 set of parton distribution functions [19]. The dilepton invariant mass of the $Z / \gamma^{*} \rightarrow \ell \ell$ process is required to be greater than 60 GeV . In contrast to proton-antiproton collisions, the cross sections for $W^{+}$and $W^{-}$production measured with proton-proton collisions are asymmetric due to the absence of valence anti-quarks in the proton. These values are:

$$
\begin{equation*}
\sigma_{W \rightarrow \ell v}^{N N L O}=10.46 \mathrm{nb} \quad\left(\sigma_{W^{+} \rightarrow \ell^{+} v}^{N N L O}=6.16 \mathrm{nb} \text { and } \sigma_{W^{-} \rightarrow \ell^{-} v}^{N N L O}=4.30 \mathrm{nb}\right) \text { and } \sigma_{Z / \gamma^{*} \rightarrow \ell \ell}^{N N L O}=0.99 \mathrm{nb} \tag{1}
\end{equation*}
$$

An overall uncertainty of the NNLO $Z$ and $W$ cross sections of $4 \%$ has been estimated using the MSTW2008NNLO PDF error eigenvectors at the $90 \%$ C.L. limit, the NNLO HERAPDF1.0 $\alpha_{s}$ variations [20], and normalisation and scale variations. The obtained uncertainty covers the NNLO crosssection predictions using the ABKM09 fits [21].

The background contributions expected from jet production via QCD processes (referred to as "QCD background" in this note) have significant components from semi-leptonic decays of heavy quarks, hadrons misidentified as leptons, and in the case of the electron channel, electrons from conversions. For both the electron and muon channels, these sources of background have been obtained from dijet samples.

In the case of the $W$ analysis, $W$ events decaying into $\tau$-leptons with subsequent leptonic $\tau$ decays are also expected to contribute in both channels. Contributions from $Z \rightarrow \mu \mu$ decays are significant in the muon channel but less so for the corresponding $Z \rightarrow e e$ decays in the electron channel. The large $\eta$ coverage of the calorimeter system is less likely to generate $E_{\mathrm{T}}^{\text {miss }}$ in the electron channel than $Z \rightarrow \mu \mu$ decays in the muon channel. The muon channel additionally takes into account contributions from $Z \rightarrow$ $\tau \tau$ decays and from $t \bar{t}$ events involving at least one semi-leptonic decay, though these contributions are small. The $t \bar{t}$ contribution in the electron channel is estimated to be $0.4 \%$ of the total electroweak signal. The cosmic ray contribution to the overall background in the muon channel is estimated to be very small ( $0.10 \pm 0.04$ ) and is neglected in this analysis.

## 4 Object reconstruction

### 4.1 Electrons

### 4.1.1 Standard electrons

The ATLAS standard electron/photon reconstruction and identification algorithm [22] is designed to provide various levels of background rejection optimised for high identification efficiencies for calorimeter transverse energy $E_{\mathrm{T}}>20 \mathrm{GeV}$, over the full acceptance of the inner-detector system. Electron reconstruction begins with a seed cluster of energy of $E_{\mathrm{T}}>2.5 \mathrm{GeV}$ in the second layer of the electromagnetic calorimeter. This cluster of size $\Delta \eta \times \Delta \phi=0.075 \times 0.125$ is selected by a sliding window algorithm. A matching track, extrapolated to the middle EM calorimeter layer, is searched for in a broad window of $\Delta \eta \times \Delta \phi=0.05 \times 0.1$ amongst all reconstructed tracks with $p_{\mathrm{T}}>0.5 \mathrm{GeV}$. The closest-matched track to this layer's cluster barycentre is kept as that belonging to the electron candidate. The final electron candidates have cluster sizes of $\Delta \eta \times \Delta \phi=0.075 \times 0.175$ in the barrel calorimeter and $0.125 \times 0.125$ in the end-cap. The total transverse energy of these clusters is the $E_{\mathrm{T}}$ used in this analysis.

The baseline electron identification selections [22] are based on criteria using calorimeter and tracker information and have been optimised in 10 bins in $\eta$ and 11 bins in $E_{\mathrm{T}}$. Three reference sets of requirements ("loose", "medium", and "tight") have been chosen, providing progressively stronger jet rejection at the expense of some identification efficiency loss. Each set adds additional constraints to the previous requirements:

- "Loose": this basic selection uses EM shower shape information from the second layer of the EM calorimeter (lateral shower containment and shower width) and energy leakage into the hadronic calorimeters as discriminant variables. This set of requirements provides high and uniform identification efficiency but a low background rejection;

| Physics process | Cross section (nb) [ $\times$ BR] | Luminosity ( $\mathrm{nb}^{-1}$ ) |
| :---: | :---: | :---: |
| $\mathrm{W} \rightarrow e v$ | 10.46 | $6.7 \times 10^{5}$ |
| $\mathrm{W} \rightarrow \mu \nu$ | 10.46 | $6.7 \times 10^{5}$ |
| $\mathrm{W} \rightarrow \tau \nu$ (electron channel analysis) | 10.46 | $1.9 \times 10^{5}$ |
| $\mathrm{W} \rightarrow \tau \nu \rightarrow \mu \nu \nu$ | 3.68 | $3.1 \times 10^{5}$ |
| $\mathrm{Z} \rightarrow e e\left(m_{\ell \ell}>60 \mathrm{GeV}\right)$ | 0.99 | $4.8 \times 10^{6}$ |
| $\mathrm{Z} \rightarrow \mu \mu\left(m_{\ell \ell}>60 \mathrm{GeV}\right)$ | 0.99 | $5.1 \times 10^{6}$ |
| $\mathrm{Z} \rightarrow \tau \tau\left(m_{\ell \ell}>60 \mathrm{GeV}\right)$ | 0.99 | $2.0 \times 10^{6}$ |
| $t \bar{t}$ | 0.16 | $2.5 \times 10^{6}$ |
| Dijet (electron channel, $\hat{p}_{\mathrm{T}}>15 \mathrm{GeV}$ ) | $1.15 \times 10^{6}$ | 100 |
| Dijet (muon channel, $8<\hat{p}_{\mathrm{T}}<17 \mathrm{GeV}$ ) | $9.86 \times 10^{6}$ | 0.05 |
| Dijet (muon channel, $17<\hat{p}_{\mathrm{T}}<35 \mathrm{GeV}$ ) | $6.78 \times 10^{5}$ | 0.74 |
| Dijet (muon channel, $35<\hat{p}_{\text {T }}<70 \mathrm{GeV}$ ) | $4.10 \times 10^{4}$ | 12.20 |
| Dijet (muon channel, $70<\hat{p}_{\mathrm{T}}<140 \mathrm{GeV}$ ) | $2.20 \times 10^{3}$ | 227.74 |
| Dijet (muon channel, $140<\hat{p}_{\text {T }}<280 \mathrm{GeV}$ ) | $0.88 \times 10^{2}$ | $5.70 \times 10^{3}$ |
| Dijet (muon channel, $280<\hat{p}_{\mathrm{T}}<1120 \mathrm{GeV}$ ) | 2.35 | $2.13 \times 10^{5}$ |
| $b \bar{b}$ (muon channel, $\hat{p}_{T}>15 \mathrm{GeV}$ ) | $7.39 \times 10^{4}$ | $59 \times 10^{3}$ |
| $c \bar{c}$ (muon channel, $\hat{p}_{\mathrm{T}}>15 \mathrm{GeV}$ ) | $2.84 \times 10^{4}$ | $53 \times 10^{3}$ |

Table 1: Signal and background Monte Carlo samples used in the electron and muon channel analyses, including the production cross section (multiplied by the relevant branching ratios (BR)) and the integrated luminosity of the samples. The variable $\hat{p}_{T}$ is the transverse momentum of the partons involved in the hard scatter. $W$ and $Z$ cross sections are given at NNLO, the $t \bar{t}$ cross section is given at next-toleading order (plus next-to-next-to-leading log), and the dijet and heavy quark cross sections are given at leading order (LO).

- "Medium": this selection provides additional hadronic rejection by evaluating the energy deposit patterns in the first layer of the EM calorimeter (the shower width and the ratio of the energy difference associated with the largest and second largest energy deposit over the sum of these energies), track quality variables (number of hits in the pixel and silicon trackers, the transverse impact parameter) and a cluster-track matching variable ( $\Delta \eta$ between the cluster and the track extrapolated to the first layer of the EM calorimeter);
- "Tight": this selection further rejects charged hadrons and secondary electrons from conversions by fully exploiting the electron identification potential of the ATLAS detector. It makes requirements on the ratio of cluster energy to track momentum, on the number of hits in the TRT, and on the ratio of high-threshold to the total number of hits in the TRT. Electrons from conversions are rejected by requiring at least one hit in the first layer of the pixel detector. A conversion-flagging algorithm is also used to further reduce this contribution. The impact-parameter requirement applied in the medium selection is further tightened at this level.

Using $Z \rightarrow e e$ signal and QCD dijet Monte Carlo samples for electrons with $E_{T}>20 \mathrm{GeV}$ within the range $|\eta|<2.47$ and excluding the transition region between the barrel and end-cap calorimeters ( $1.37<|\eta|<1.52$ ), the expected identification efficiencies are estimated to be $94 \%, 90 \%$, and $72 \%$ with rejection factors against background jets with true $E_{\mathrm{T}}>20 \mathrm{GeV}$ of 1100,6800 , and 92000 for "loose", "medium", and "tight" electron identification, respectively [22].

### 4.1.2 Forward electrons

In contrast to the standard electron selection discussed above, forward electrons are reconstructed outside the range of the ATLAS inner-detector system where no tracking is available and so an alternative topological clustering algorithm (discussed in Section 4.3) is used. The electron candidates with $|\eta|>2.5$ are reconstructed if a cluster with $E_{\mathrm{T}}>5 \mathrm{GeV}$ is present in the calorimeter. The direction of the electron candidate cluster is defined by the barycenter of the cells belonging to the calorimeter cluster. The total energy deposited in the calorimeter is taken to be the energy of the electron candidate. Two classes of forward electrons are defined: "loose-forward" electrons with longitudinal and transverse shower profile consistent with an electron shower and "tight-forward" electrons that have further requirements based on shower shape variables. This "tight-forward" electron identification uses six discriminating variables defined using cluster moments or a combination of them as discussed in Ref [22].

### 4.2 Muons

The ATLAS muon identification and reconstruction algorithms take advantage of the multiple subdetector technologies which provide complementary approaches and cover pseudorapidities up to 2.7 over a wide $p_{\mathrm{T}}$ range [10].

The stand-alone muon reconstruction is based entirely on muon-spectrometer information, independently of whether or not this muon-spectrometer track is also reconstructed in the inner detector. The muon reconstruction is initiated locally in a muon chamber by a search for straight line track segments in the bending plane. Hits in the precision chambers are used and the segment candidates are requested to point to the centre of ATLAS. The hit coordinate $\phi$ in the non-bending plane measured by the trigger detectors is associated to the segment when available. A minimum of two track segments in different muon stations are combined to form a muon track candidate using three-dimensional tracking in the magnetic field. The track parameters $\left(p_{\mathrm{T}}, \eta, \phi\right.$, distance of closest approach to the primary vertex along the beam axis and transverse to it) are obtained from the muon spectrometer track fit and are extrapolated to the interaction point taking into account both multiple scattering and energy loss in the calorimeters. For the latter, the reconstruction utilises either a parameterisation or actual measurements of calorimeter energy losses, together with a parameterisation of energy loss in the inert material. The typical muon energy loss in the calorimeters is 3 GeV . The stand-alone muon reconstruction algorithms use the least-squares formalism to fit tracks in the muon spectrometer and most material effects are directly integrated into the $\chi^{2}$ function.

The combined muon reconstruction associates a stand-alone muon spectrometer track to an innerdetector track, that measures the bending of the muon within the solenoid, using the pixel, SCT and TRT detectors. The association between the stand-alone and inner-detector tracks is performed using a $\chi^{2}$-test, defined from the difference between the respective track parameters weighted by their combined covariance matrices. The parameters are evaluated at the point of closest approach to the beam axis. The combined track parameters are derived either from a statistical combination of the two tracks or from a refit of the full track. To validate the results presented in this note, these two independent reconstruction chains were exercised, leading to a good agreement. The results presented here are based on the one which relies on the statistical combination of muon-spectrometer and inner-detector measurements.

Detailed studies of the muon performance in collision data have been done. They are limited to the momentum region below about 20 GeV due to the small size of the data samples available in the higher $p_{\mathrm{T}}$ domain. The studies are based on relative measurements of the muon track properties taking the inner detector as a reference. In the region of $p_{\mathrm{T}}$ between 10 GeV and 20 GeV , the relative momentum scale difference is found to be below $2 \%$ in both barrel and endcap regions, while the relative momentum resolution is measured to be $5 \%$ in the barrel and $8.5 \%$ in the endcap regions [23]. This value in the end-cap region may be explained by alignment issues. In the barrel region, chambers have been better
aligned with cosmic rays [24]; however, additional inert material is possibly needed to account for the observed sagitta and resolution dependence on momentum. Different complementary approaches have been inspected to measure the relative muon reconstruction efficiency in data. Results are in agreement with Monte Carlo expected values within 2-3\%. The results based on these analyses have been used in the systematic uncertainty evaluation reported in Section 10.2.2. Studies with collision data are underway but are currently limited by the number of high- $p_{\mathrm{T}}$ muons collected so far [23].

### 4.3 Transverse missing energy

The transverse missing energy ( $E_{\mathrm{T}}^{\text {miss }}$ ) reconstruction used in the electron channel is based on calorimeter information. This relies on a cell-based algorithm which sums the electromagnetic-scale energy deposits of calorimeter cells inside three-dimensional topological clusters [25]. The EM scale is the energy deposited in the calorimeter calculated under the assumption that all processes are purely electromagnetic in nature. These clusters are then corrected to take into account the different response to hadrons than to electrons or photons, dead material losses and out of cluster energy losses [26]. These topological clusters are built around energy $E>4 \sigma_{\text {noise }}$ seeds, where $\sigma_{\text {noise }}$ is the Gaussian width of the cell energy distribution in randomly triggered events, by iteratively gathering neighbouring cells with $E>2 \sigma_{\text {noise }}$ and, in a final step, by adding all direct neighbours of these accumulated secondary cells. The $x$ - and $y$-components of the calorimeter $E_{\mathrm{T}}^{\mathrm{miss}}$ term are calculated by summing over the transverse energies measured in these topological cluster cells $i$ :

$$
\begin{equation*}
E_{x, y}^{\text {Electron,miss }}=E_{x, y}^{\text {Calo,miss }}=-\sum_{i} E_{x, y} \tag{2}
\end{equation*}
$$

The $E_{\mathrm{T}}^{\text {miss }}$ used in the muon channel is calculated from the reconstructed momenta of muons measured in the range of pseudorapidity $|\eta|<2.7$ and the calorimeter term as given in Eq. 2:

$$
\begin{equation*}
E_{x, y}^{\text {Muon,miss }}=-\left(\sum_{\text {Muons }} E_{x, y}+\sum_{i} E_{x, y}\right)=-\left(\sum_{\text {isolated }} p_{x, y}+\sum_{n o n-i s o l a t e d} p_{x, y}\right)+E_{x, y}^{\text {Calo,miss }}, \tag{3}
\end{equation*}
$$

where non-isolated muons are those within a distance $\Delta R \leq 0.3$ of a jet in the event. The $p_{\mathrm{T}}$ of an isolated muon is determined from the combined measurement of the inner detector and muon spectrometer as explained in Section 4.2. The energy lost by an isolated muon in the calorimeters is not added to the calorimeter term. For a non-isolated muon, the energy lost in the calorimeter cannot be separated from the nearby jet energy. The muon spectrometer measurement of the muon momentum after energy loss in the calorimeter is therefore used unless there is a significant mis-match between the spectrometer and combined measurements, in which case the combined measurement minus the parameterised energy loss in the calorimeter is used. For higher values of the pseudorapidity outside the fiducial volume of the inner detector ( $2.5<|\eta|<2.7$ ), there is no matched track requirement and the muon spectrometer stand-alone measurement is used instead.

In both the electron and muon cases, the $E_{T}^{\text {miss }}$ is defined as:

$$
\begin{equation*}
E_{\mathrm{T}}^{m i s s}=\sqrt{\left(E_{x}^{m i s s}\right)^{2}+\left(E_{y}^{m i s s}\right)^{2}} \tag{4}
\end{equation*}
$$

The performance of the $E_{\mathrm{T}}^{\mathrm{miss}}$ reconstruction in minimum-bias data is described in Ref. [27].

## 5 Event selection and preparation

### 5.1 Event selection

The data presented in this note were collected over a ten-week period, from March to June 2010. From all data taken at a centre-of-mass energy of 7 TeV and for which the LHC declared stable beams, only
those with the detector high voltage in nominal condition are selected. Both the electron and muon channels require that all of the essential sub-detectors are operational such that the response and main criteria needed for particle identification as well as energy and momentum computations do not deviate significantly from their expected behaviour. In addition, while the electron channel analysis requires the solenoid to be on, the muon channel analysis needs both solenoid and toroid at nominal field. These basic data-quality requirements resulted in total integrated luminosities of $16.9 \mathrm{nb}^{-1}$ and $17.0 \mathrm{nb}^{-1}$ for the $W \rightarrow e v$ and $Z \rightarrow e e$ channels, respectively, and $16.6 \mathrm{nb}^{-1}$ and $17.7 \mathrm{nb}^{-1}$ for the $W \rightarrow \mu \nu$ and $Z \rightarrow \mu \mu$ channels, respectively. While the $W \rightarrow \mu \nu$ analysis requires calorimeter information to calculate the $E_{\mathrm{T}}^{\text {miss }}$, no calorimeter information used for the $Z \rightarrow \mu \mu$ channel. This is the reason why this channel does not have the same integrated luminosity as the electron channel. The uncertainty on the luminosity determination is estimated to be $11 \%$ [13].

Events are selected with the hardware-based L1 trigger. The L1 calorimeter trigger selects photons and electrons within $|\eta|<2.5$ using calorimeter information with the reduced granularity of trigger towers of dimension $\Delta \eta \times \Delta \phi=0.1 \times 0.1$. The calorimeter trigger used in this analysis accepts electron and photon candidates if the signal from a cluster of trigger towers is above five trigger counts, where one count corresponds to approximately 1 GeV . The L1 muon trigger searches for patterns of hits within $|\eta|<2.4$ consistent with high $-p_{\mathrm{T}}$ muons originating from the interaction region. The trigger logic is based on three trigger stations. The algorithm requires a coincidence of hits in the different trigger stations within a road, which tracks the path of a muon from the interaction point through the detector. The width of the road is related to the $p_{\mathrm{T}}$ threshold to be applied. The muon trigger used in this analysis corresponds to the lowest $p_{\mathrm{T}}$ threshold trigger which has a fully-opened road with a two-station time coincidence. As a result of these trigger decisions, $2.4 \times 10^{6}$ and $2.0 \times 10^{6}$ events are triggered in the electron and muon channels, respectively.

Collision candidates are selected by requiring a primary vertex with at least three tracks, consistent with the beam spot position. To reduce fake collision candidates from cosmic-ray or beam-halo events, the muon analysis requires the primary vertex position along the beam axis to be within 15 cm of the nominal position.

### 5.2 Event preparation

An analysis of a high statistics sample of minimum-bias events has shown that events can occasionally contain very localised high-energy calorimeter deposits not originating from the proton-proton collision, but e.g. from sporadic discharges in the hadronic end-cap calorimeter, and more rarely coherent noise in the electromagnetic calorimeter. Cosmic-ray muons undergoing a hard bremsstrahlung are also a potential source of localised energy deposits uncorrelated to the primary proton-proton collisions.

The occurrence of these events is very rare but can potentially impact significantly the $E_{\mathrm{T}}^{\text {miss }}$ measurement by creating high-energy tails [28]. To remove such events, dedicated cleaning requirements using reconstructed jets (with the anti- $k_{t}$ algorithm [29]) in a narrow cone of size $\Delta R=0.4$ have been developed using a minimum-bias event sample. It was verified that these criteria remove less than $0.1 \%$ of minimum-bias events, $0.004 \%$ of $W \rightarrow \ell v$, and $0.01 \%$ dijet events in Monte Carlo simulation.

For the electron channel only, the quality of the reconstruction of the energy deposited by the electron in the liquid argon calorimeter is assessed. The event is rejected if the candidate electromagnetic cluster is located in any problematic region of this detector: regions affected by major high-voltage problems, isolated cells producing a high noise signal or no signal at all, and electronic front-end boards not providing any output signal. These problems can cause extended dead regions in a given layer of the calorimeter, which may have an important impact on the energy reconstruction of the electron. The loss in acceptance due to these requirements is $4.8 \%$ for the $W$ channel and $10.5 \%$ for the $Z$ channel.

Figure 1: Calorimeter $E_{T}$ of the cluster (a), as well as $\eta(b)$ and $\phi(c)$ of electron candidates after preselection for data and Monte Carlo candidates broken down into the various signal and background components. The total number of Monte Carlo candidates is normalised to the number of observed data candidates. In Figure 1(a), the total QCD background is broken down into its constituents: hadrons misidentified as electrons, electrons from conversions, and electrons from semi-leptonic decays of heavy quarks.

Figure 2: Combined $p_{\mathrm{T}}(a), \eta(b)$, and $\phi(c)$ of muon candidates after preselection for data and Monte Carlo candidates broken down into the various signal and background components. The total number of Monte Carlo candidates is normalised to the number of observed data candidates.

## 6 Preselection of high transverse-energy leptons

A preselection of high transverse-energy electrons and muons is made. Electron candidates with the identification level "loose" according to the algorithm as described in Section 4.1 are required to have a cluster $E_{\mathrm{T}}>20 \mathrm{GeV}$ within the range $|\eta|<2.47$, excluding the transition region between the barrel and end-cap calorimeters $(1.37<|\eta|<1.52)$. Muon candidate events selected according to the algorithm described in Section 4.2 are required to have at least one combined muon with $p_{\mathrm{T}}>15 \mathrm{GeV}$ and a $p_{\mathrm{T}}$ as measured by the muon spectrometer greater than 10 GeV , within the range $|\eta|<2.4$. The difference between the inner-detector and muon-spectrometer $p_{\mathrm{T}}$, corrected for the mean energy loss in upstream material, is required to be less than 15 GeV to increase the robustness against track reconstruction mismatches. The difference between the $z$ position of the muon track extrapolated to the beam line and the $z$ coordinate of the primary vertex is required to be less than 1 cm .

Figures 1 and 2 show the kinematic properties of these electron and muon candidates, respectively,

Figure 3: $E_{\mathrm{T}}^{\mathrm{miss}}$ of electron (a) and muon (b) candidates after preselection for data and Monte Carlo candidates broken down into the various signal and background components. The total number of Monte Carlo candidates is normalised to the number of observed data candidates. In Figure 3(a), the total QCD background is broken down into its constituents: hadrons misidentified as electrons, electrons from conversions, and electrons from semi-leptonic decays of heavy quarks.
and compare these to the signal and background Monte Carlo samples described in Section 3. At this stage of the selection, the candidate events are dominated by QCD background. For the electron channel, Figure 1(a) shows this background consists mainly of conversion events and hadrons faking electrons. If these QCD Monte Carlo distributions are normalised to the total integrated luminosity of the data, the dijet Monte Carlo over-estimates the amount of background by a factor of approximately 2.6 for the electron channel and a factor of 1.7 for the muon channel. The Monte Carlo distributions in Figures 1 and 2 have been normalised to the total number of data events, taking into account these scale factors for the QCD background. It is to be noted that all data distributions in this note are given with statistical error bars only, corresponding to $68.3 \%$ confidence intervals unless otherwise stated. These distributions show reasonable agreement in shape between data and Monte Carlo simulation. More details on the properties of inclusive electrons and muons are given in Refs. [30] and [31].

Figure 3 shows the transverse missing energy normalised in the same fashion as for Figures 1 and 2. An excess of events around the expected signal region ( $E_{\mathrm{T}}^{\text {miss }} \sim 40 \mathrm{GeV}$ and above) compared to the background is already visible at this stage of the selection. The four highest- $E_{\mathrm{T}}^{\text {miss }}$ candidates in the muon channel are all events with jets.

## 7 Selection and observation of $W$ candidates

Additional requirements beyond those imposed in Section 6 are used to better discriminate $W \rightarrow \ell v$ events from background events. The electron identification level as described in Section 4.1 is increased to "tight" while the minimum muon combined $p_{\mathrm{T}}$ is increased to 20 GeV . Only the highest $p_{\mathrm{T}}$ lepton in the event is used. In the electron channel, events that would pass the $Z \rightarrow e e$ selection as given in Section 11 are vetoed. In the muon channel, $Z \rightarrow \mu \mu$ events, where one muon is outside the acceptance of the detector, fake a large $E_{T}^{\text {miss }}$ signature and hence can mimic a $W$-boson signal. Since those events have only one reconstructed muon track by construction, a veto for these events cannot be applied. It

Figure 4: $E_{\mathrm{T}}^{\mathrm{miss}}$ versus calorimeter-isolation parameter for electron candidates (a) and track-isolation parameter for muon candidates (b) after preselection plus the "tight" requirement for electrons and muon combined $p_{\mathrm{T}}>20 \mathrm{GeV}$.

Figure 5: $E_{\mathrm{T}}^{\text {miss }}$ of selected electron (a) and muon (b) candidates.
should be noted that the acceptance of the electromagnetic calorimeter goes up to $|\eta|=4.9$ in contrast to the muon spectrometer acceptance which is limited to $|\eta|=2.7$.

The use of an isolation parameter to enhance the expected signal has been considered in the muon and electron channels. However, separate isolation requirements must be considered for the electron and muon channels since the electron can undergo bremsstrahlung while a muon is primarily defined by its track. In addition, the EM calorimeter requirements for the electrons use variables which already provide some effective isolation.

A calorimeter-based isolation parameter defined as the total calorimeter transverse energy in a cone

Figure 6: $E_{\mathrm{T}}^{\text {miss }}$ versus the electron cluster $E_{\mathrm{T}}(a)$ and the muon $p_{\mathrm{T}}(b)$. For the purpose of this figure, the requirement of the muon $p_{T}$ is lowered to 15 GeV .

Figure 7: $E_{\mathrm{T}}^{\text {miss }}$ versus $m_{\mathrm{T}}$ of the lepton- $E_{\mathrm{T}}^{\text {miss }}$ system for the electron (a) and muon (b) channels.
of $\Delta R<0.3$ surrounding the candidate electron cluster which is then divided by the cluster $E_{\mathrm{T}}$ is considered for the electron channel. A track-based isolation for the muon channel defined as the sum of inner-detector transverse momenta within a cone $\Delta R<0.4\left(\sum p_{T}^{I D}\right)$ which is then divided by the total combined muon $p_{\mathrm{T}}$ is considered in the muon channel. The minimum- $p_{\mathrm{T}}$ used in the isolation requirement is 1 GeV . These isolation parameters are shown in Figure 4 and are plotted against the $E_{\mathrm{T}}^{\text {miss }}$ of the event. The isolation variable will be used in the electron analysis to make a data-driven estimate of the background contributions to the $W \rightarrow e v$ candidates; therefore, no form of isolation is explicitly applied in the electron-channel selection. An isolation requirement of $\sum p_{T}^{I D} / p_{T}<0.2$ is used in the

Figure 8: $m_{\mathrm{T}}$ of the electron- $E_{\mathrm{T}}^{\text {miss }}$ system without (a) and with (b) a requirement of $E_{\mathrm{T}}^{\mathrm{miss}}>25 \mathrm{GeV}$. In Figure 8(a), the total QCD background is broken down into its constituents: hadrons misidentified as electrons, electrons from conversions, and electrons from semi-leptonic decays of heavy quarks.

Figure 9: $m_{\mathrm{T}}$ of the muon- $E_{\mathrm{T}}^{\text {miss }}$ system without (a) and with (b) a requirement of $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$.
muon analysis given that, after all other selections are made to identify $W$ candidates, this requirement rejects over $84 \%$ of the expected QCD background while keeping $99 \%$ of signal events.

All further results shown in this section have passed the preselection requirements of Section 6, the "tight" requirement for electrons, the muon combined $p_{\mathrm{T}}>20 \mathrm{GeV}$, and the muon isolation requirement.

The last step of the signal selection is additional kinematic requirements applied to the $E_{\mathrm{T}}^{\text {miss }}$ of the

| Requirement | Number of <br> candidates |
| :--- | :---: |
| Triggered (Section 5) | $2.4 \times 10^{6}$ |
| Preselection (Section 6) | $5.1 \times 10^{3}$ |
| Tight electron (Section 4.1) | 177 |
| $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ | 49 |
| $m_{\mathrm{T}}>40 \mathrm{GeV}$ | 46 |

Table 2: Number of $W \rightarrow e v$ candidates in data remaining after each major requirement is applied.

| Requirement | Number of <br> candidates |
| :--- | :---: |
| Triggered (Section 5) | $2.0 \times 10^{6}$ |
| Preselection (Section 6) | 1155 |
| $p_{\mathrm{T}}>20 \mathrm{GeV}$ | 420 |
| $\sum p_{T}^{I D} / p_{T}<0.2$ | 186 |
| $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ | 77 |
| $m_{\mathrm{T}}>40 \mathrm{GeV}$ | 72 |

Table 3: Number of $W \rightarrow \mu \nu$ candidates in data remaining after each major requirement is applied.
event and the transverse mass $m_{\mathrm{T}}$ of the lepton- $E_{\mathrm{T}}^{\text {miss }}$ system defined as

$$
\begin{equation*}
m_{\mathrm{T}}=\sqrt{2 p_{\mathrm{T}}^{\ell} p_{\mathrm{T}}^{v}\left(1-\cos \left(\phi^{\ell}-\phi^{v}\right)\right)} \tag{5}
\end{equation*}
$$

where the measured $E_{\mathrm{T}}^{\mathrm{miss}}$ components in $(x, y)$ provide the neutrino information. All Monte Carlo distributions shown in this section have been normalised to integrated luminosities of $16.9 \mathrm{nb}^{-1}$ and $16.6 \mathrm{nb}^{-1}$, in the electron and muon channels, respectively, using the cross sections as given in Table 1. In addition, the QCD background contributions have been scaled by factors of $1 / 2.6$ and $1 / 1.7$ in the electron and muon channels, respectively, to account for the over-estimation of the dijet Monte Carlo sample described in Section 6.

Figure 5 shows the $E_{\mathrm{T}}^{\text {miss }}$ distribution of all electron and muon candidates passing the requirements described above. Both distributions indicate that applying a minimum requirement on $E_{\mathrm{T}}^{\text {miss }}$ would greatly enhance the $W$ signal over the expected background. This observation is also evident from the two-dimensional plot of $E_{\mathrm{T}}^{\text {miss }}$ versus electron cluster $E_{\mathrm{T}}$ and muon combined $p_{\mathrm{T}}$ shown in Figure 6. True $W \rightarrow \ell v$ events in the Monte Carlo are predominantly at high $E_{\mathrm{T}}^{\mathrm{miss}}$ due to the escaping neutrino in the event. Although some of the QCD background may also have neutrinos in their final state, these events mostly populate the regions of small $E_{\mathrm{T}}^{\mathrm{miss}}$.

The transverse mass of the lepton- $E_{\mathrm{T}}^{\mathrm{miss}}$ system is highly correlated to the $E_{\mathrm{T}}^{\mathrm{miss}}$ of the event as is demonstrated in Figure 7 which shows a two-dimensional plot of the $E_{\mathrm{T}}^{\text {miss }}-m_{\mathrm{T}}$ plane. Figures 8 and 9 show projections of Figure 7 where the $m_{\mathrm{T}}$ of the event is shown without and with a requirement of $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$. In the muon channel, the events at very low- $m_{\mathrm{T}}$ have, in the transverse plane, their $E_{\mathrm{T}}^{\mathrm{miss}}$ direction aligned with that of the muon candidate.

Tables 2 and 3 summarise the number of $W \rightarrow \ell v$ candidates remaining after each major requirement in the respective analyses described in this note. A total of 46 candidates ( $27 e^{+}$and $19 e^{-}$) pass all requirements in the electron channel and 72 candidates ( $47 \mu^{+}$and $25 \mu^{-}$) in the muon channel in the $m_{\mathrm{T}}$ region above 40 GeV .

Figure 10: Pseudorapidity distributions of $e^{+}(a), e^{-}(b), \mu^{+}(c)$, and $\mu^{-}(d)$ candidates satisfying all $W$ requirements. The data describe well the larger expected fraction of $\ell^{+}$candidates at high pseudorapidity compared to $\ell^{-}$ due to the larger average rapidity of $W^{+}$bosons expected in proton-proton collisions.

Figure 11: Electron cluster $E_{T}(a)$ and muon $p_{T}(b)$ of the $W$ candidates after final selection. $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ and $m_{\mathrm{T}}>40 \mathrm{GeV}$ are required in both channels.

Figure 12: $\quad p_{\mathrm{T}}$ of the $W$ candidates in the electron-channel (a) and muon-channel (b) after final selection. $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ and $m_{\mathrm{T}}>40 \mathrm{GeV}$ are required in both channels.

## 8 Properties of $W \rightarrow \ell v$ candidates

For the final selection, the preselection requirements of Section 6, the "tight" requirement for electrons, the muon $p_{\mathrm{T}}>20 \mathrm{GeV}$ and muon isolation requirements, $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$ and $m_{\mathrm{T}}>40 \mathrm{GeV}$ are used. Figure 10 shows the pseudorapidity distributions of the $\ell^{+}$and $\ell^{-}$candidate events that pass the final selection requirements. The larger expected fraction of $\ell^{+}$candidates at high pseudorapidity compared to $\ell^{-}$reflects the larger average rapidity of $W^{+}$bosons expected in proton-proton collisions. This is the motivation of the asymmetry measurement presented in Section 10.6 and so Figure 10 uses the $\eta$

Figure 13: (a) Calorimeter isolation variable divided by $E_{\mathrm{T}}$ (as described in Section 7) after preselection. The total number of Monte Carlo candidates is normalised to the number of observed data candidates. (b) Result of the template fit used to obtain an estimate of the QCD background, where the "tight" electron identification requirement has been substituted by "loose" to increase statistics (see text for details). The Monte Carlo distributions are scaled to the result of the fit.
binning of this measurement. Figure 11 shows the electron cluster $E_{T}$ and muon combined $p_{\mathrm{T}}$ of the lepton candidates while Figure 12 shows the $p_{\mathrm{T}}$ spectrum of the $W \rightarrow \ell v$ candidates. Both channels demonstrate a clear $W$ signal over an almost negligible background.

## 9 Background expectations for the $W \rightarrow \ell v$ candidates

The Monte Carlo samples discussed in Section 3 are used to provide an expectation for signal events and, in some cases, for the background events. The QCD component of the background is estimated from the data (as discussed below) while the electroweak component of the background is obtained from the appropriate Monte Carlo samples. The numbers of observed candidates and expected background events in both channels are summarised in Table 4. The difference between the expectations for the electron and muon channels stem primarily from the lower reconstruction efficiency of "tight" electrons compared to that of combined muons.

### 9.1 Background estimation for the electron channel

For the electron channel, the contribution from the $W \rightarrow \tau \nu$ process is expected to be small (1.4 events) and the contribution from $Z \rightarrow e e$ decays even smaller ( 0.1 events). The QCD background expectation is divided between heavy-quark decays, conversions, and hadrons faking electrons. A partially data-driven estimate of the QCD background to the observed $W$ candidate events is made. The calorimeter isolation in a cone of $\Delta R=0.3$ divided by the electron $E_{\mathrm{T}}$ (as described in Section 7) is used as a discriminating variable in a binned maximum likelihood fit. This technique uses the prediction for the shape of the signal and the QCD background for this variable in the form of histogram templates taken from Monte Carlo samples. The distribution of this variable after the preselection is shown in Figure 13(a).

Due to the limited statistics and the very few background events, the fit cannot be performed after

Figure 14: Track-isolation variable $\sum p_{T}^{I D} / p_{T}$ (a) and $E_{\mathrm{T}}^{\text {miss }}$ distribution of events in the control region (see text) (b) after muon preselection (only QCD background is shown). The total number of Monte Carlo candidates is normalised to the number of observed data candidates.
the final selection. Therefore only the "loose" instead of the "tight" electron identification requirement as described in Section 4.1 is applied, while the requirements on $E_{\mathrm{T}}^{\text {miss }}$ and $m_{\mathrm{T}}$ are kept. Also for this reason, the signal and background templates are obtained from Monte Carlo samples. The fit result is shown in Figure 13(b) and provides a background estimate of $N_{\mathrm{QCD}}$ loose $=40.6 \pm 8.0$ events, where the uncertainty contains the statistical uncertainty of the data and of the templates. The number of QCD background events after the final selection is estimated by scaling this number with the jet rejection factor for the "tight" requirement, with respect to the "loose" requirement. The central value of the rejection factor is extracted from Monte Carlo, while its systematic uncertainty is estimated by comparing Monte Carlo and data rejection factors, obtained in five low $E_{\mathrm{T}}^{\text {miss }}$ bins of 5 GeV between $0-25 \mathrm{GeV}$ with small signal contribution. The rejection factor, quoted here as its reciprocal, is found to be $0.03 \pm 0.01$, giving a total QCD background of $N_{\mathrm{QCD}}$, tight $=1.1 \pm 0.2$ (stat). The total background in the electron channel is estimated to be this QCD contribution plus that coming from the $W \rightarrow \tau v$ (1.4 events) and $Z \rightarrow e e$ ( 0.1 events) processes.

Various sources of systematic uncertainties were investigated. The QCD PYTHIA template was replaced by one obtained from data using the "loose" selection without $E_{\mathrm{T}}^{\text {miss }}$ and $m_{\mathrm{T}}$ cut. In addition, instead of dropping the "tight" requirement, the fit was performed on a sample where the "tight" requirement was applied but the $E_{\mathrm{T}}^{\text {miss }}$ and $m_{\mathrm{T}}$ requirements were dropped. The observed variations are all small compared to the uncertainty due to the tight-to-loose rejection factor. Therefore, the number of QCD background events as estimated by this template method is $N_{\mathrm{QCD}}=1.1 \pm 0.2$ (stat) $\pm 0.4$ (syst). The predicted number of QCD background events based on the dijet Monte Carlo and scaled by the factor of $1 / 2.6$ (as described in Section 6) is $0.7 \pm 0.2$ (stat) events and so is in agreement with this measurement. These estimates for the QCD background contribution to the $W$ channel will greatly benefit from more statistics.

### 9.2 Background estimation for the muon channel

For the muon channel, the total background estimate is 5.3 events, primarily coming from $Z \rightarrow \mu \mu$ and $W \rightarrow \tau \nu$ decays, respectively $42 \%$ ( $2.23 \pm 0.16$ events) and $36 \%$ ( $1.90 \pm 0.13$ events) of all the background. Background from multijets is $16 \%$ and the remaining $6 \%$ comes from top production ( $4.5 \%$ ) and from $Z \rightarrow \tau \tau$ decay ( $1.5 \%$ ). Given the high uncertainty in the Monte Carlo dijet cross section, this source of background has been measured in data using the distribution of transverse missing energy versus isolation prior to the transverse mass requirement, as described below. The isolation distribution for preselected events is shown in Figure 14(a).

The primary assumption of this method to extract the multijet component of the total background is that the $E_{\mathrm{T}}^{\text {miss }}$ and the lepton isolation are uncorrelated. The $E_{\mathrm{T}}^{\text {miss }}$ versus track-isolation plane is divided into four separate regions defined by the $E_{\mathrm{T}}^{\text {miss }}$ and isolation requirements as for the $W$ selection (Figure 4(b)). The background contribution to the $W$ signal region is obtained from a similarity relationship between the contents in the four regions of the $E_{\mathrm{T}}^{\text {miss }}$-isolation space [32]. The calculation is corrected for the contributions from the signal and the electroweak backgrounds outlined above.

The background estimation method described above yields a jet background estimate of $3.8 \pm 1.3$ events if no $m_{\mathrm{T}}$ requirement is imposed, which corresponds to $0.9 \pm 0.3$ (stat) $\pm 0.6$ (syst) events if $m_{\mathrm{T}}>40 \mathrm{GeV}$. The systematic uncertainty in this method is due to the correlation between the two variables used and it has been estimated in a consistency check applying the same technique on a Monte Carlo QCD sample. A 70\% systematic uncertainty is estimated from the difference between the number of predicted events from Monte Carlo and the number of observed events in the signal region in data. This technique provides the better estimation of the background in multijet events because it is also sensitive to poorly reconstructed events faking muons as well as pion and kaon decays and so is used as the default for this analysis, rather than the alternate method discussed immediately below.

An alternative estimation of the multijet background has been made by measuring the QCD background normalisation in data. The control sample used is obtained by reversing the isolation requirement after preselection. The assumption is that these events are dominated by muons from QCD background events. The background normalisation is taken from the comparison of the distributions of $E_{\mathrm{T}}^{\text {miss }}$, in both data and jet background Monte Carlo samples. These are shown in Figure 14(b), where the QCD background distribution has been normalised to the numbers of events in the control sample. The data and Monte Carlo shapes agree well and an overall scale factor of Monte Carlo QCD cross section to data of $0.58 \pm 0.05$ (stat) is measured as described in Section 3. This method derives a QCD background estimate of $0.28 \pm 0.05$ (stat). A value in agreement with this estimate is found when decreasing the muon transverse momentum requirement to 15 GeV (in order to get more statistics). A study using dijet Monte Carlo predicts that the background contamination from pion and kaon decays is $0.45 \pm 0.45$ (tot), which is within the direct estimation from data.

All muon candidate events were inspected individually, verifying the main reconstruction parameters. Distributions of hit multiplicities in inner-detector and muon-spectrometer tracks, their track-matching $\chi^{2}$, and the difference in the transverse momentum measurement between the two sub-detectors were compared in data and Monte Carlo. Good agreement was found for all of these items. The hypothesis that a cosmic ray overlays with the collision was carefully examined by looking at the timing properties of muon tracks. TRT, tile calorimeter and MDT time measurements were analysed and no indication of cosmic contamination was found.

Detailed estimates of uncertainties in these backgrounds due to the statistically limited control samples and Monte Carlo simulations, and also from leading-order jet cross sections and fragmentation functions will be evaluated in future studies with higher data statistics.

| $\ell$ | Observed <br> candidates | Background <br> $(\mathrm{EW})$ | Background <br> $(\mathrm{QCD})$ | Background-subtracted <br> signal $N_{W}^{\text {sig }}$ |
| :---: | :---: | :---: | :---: | :---: |
| $e^{+}$ | 27 | $0.9 \pm 0.0 \pm 0.1$ | $0.6 \pm 0.1 \pm 0.3$ | $25.6 \pm 5.2 \pm 0.3$ |
| $e^{-}$ | 19 | $0.6 \pm 0.0 \pm 0.1$ | $0.6 \pm 0.1 \pm 0.3$ | $17.8 \pm 4.4 \pm 0.3$ |
| $e^{ \pm}$ | 46 | $1.5 \pm 0.0 \pm 0.1$ | $1.1 \pm 0.2 \pm 0.4$ | $43.4 \pm 6.8 \pm 0.4$ |
| $\mu^{+}$ | 47 | $2.4 \pm 0.0 \pm 0.2$ | $0.7 \pm 0.3 \pm 0.5$ | $43.8 \pm 6.9 \pm 0.6$ |
| $\mu^{-}$ | 25 | $2.0 \pm 0.0 \pm 0.2$ | $0.2 \pm 0.1 \pm 0.2$ | $22.8 \pm 5.0 \pm 0.3$ |
| $\mu^{ \pm}$ | 72 | $4.4 \pm 0.0 \pm 0.3$ | $0.9 \pm 0.3 \pm 0.6$ | $66.7 \pm 8.5 \pm 0.7$ |

Table 4: Numbers of observed candidate events for the $W \rightarrow \ell v$ channel, electroweak (EW) and dataderived QCD background events, and background-subtracted signal events. The first uncertainty is statistical (signal statistical uncertainties are described in Section 10 while Monte Carlo statistical errors are negligible). The second uncertainty represents the systematics (as described in the text). In addition to what is quoted in this table, an $11 \%$ uncertainty on the luminosity determination is applicable to the electroweak background.

### 9.3 Observed candidate events

Table 4 summarises the numbers of observed candidate events for the $W \rightarrow \ell v$ channel, the number of background events from both the QCD and electroweak processes, and the number of backgroundsubtracted signal events. The first uncertainty is due to statistics and is described in Section 10. Monte Carlo statistical uncertainties are considered to be negligible in comparison to the statistical uncertainties associated to the data and to the estimation of the QCD background. The second uncertainty is a systematic one. For the electron (muon) electroweak background, this amounts to the $5 \%$ ( $7 \%$ ) experimental systematic uncertainty (Section 10.2.1), $4 \%$ systematic uncertainty on the predicted cross section (Section 3), and $3 \%$ on the parton distribution function acceptance (Section 10.3) resulting in a total systematic uncertainty of $7 \%$ ( $8 \%$ ) for the electron (muon) channel. The QCD background systematic uncertainties are explained in this section. The luminosity determination uncertainty of $11 \%$ is used in both channels but is only applicable to the electroweak background. The numbers in Table 4 form the basis of the cross section measurements and the $W$ asymmetry measurements presented in Section 10.

## 10 Cross-section measurements for $W$-boson decays to electrons and muons

### 10.1 Introduction

The $W$-boson cross-section measurement is given by:

$$
\begin{equation*}
\sigma_{t o t}=\sigma_{W} \times B R(W \rightarrow \ell v)=\frac{N_{W}^{s i g}}{A_{W} C_{W} L_{i n t}} \tag{6}
\end{equation*}
$$

where

- $N_{W}^{s i g}$ denotes the number of background-subtracted signal events in the channel of interest, as summarised in Table 4;
- $A_{W}$ denotes the so-called geometrical acceptance for the $W$-boson decays under consideration, defined as the fraction of decays satisfying the geometrical and kinematical (fiducial) constraints at
the generator level. These include the $\eta$ requirements as given in Section 6, as well as requirements on $p_{\mathrm{T}}{ }^{\ell}>20 \mathrm{GeV}, p_{\mathrm{T}}{ }^{\nu}>25 \mathrm{GeV}$, and $m_{\mathrm{T}}>40 \mathrm{GeV}$ at the generator level. This quantity can only be determined from $W \rightarrow \ell v$ Monte Carlo simulation at generator level;
- $C_{W}$ denotes the ratio between number of signal events which pass the final selection requirements after reconstruction and the total number of generated events within the fiducial volume. In this note, $C_{W}$ is estimated using Monte Carlo signal simulation, but this correction factor includes the efficiency for triggering on lepton candidates as well as reconstructing/identifying $W$-boson decays falling within the geometrical acceptance. The different components of $C_{W}$ can be estimated using Monte Carlo simulation but most of these will eventually be determined from data-driven measurements. In this note, the correction factors $C_{W}$ are fully taken from simulation for the electron channel, but some data-driven corrections are used for the muon channel, as described in Section 10.2.2;
- and $L_{i n t}$ denotes the integrated luminosity for the channel of interest.

The geometrical acceptance $A_{W}$, as well as the denominator of $C_{W}$, are computed at the Born level, i.e. from lepton kinematics before QED radiation. The factor $C_{W}$ thus includes the corrections for the QED final state radiation.

Equation 6 defines the measured total inclusive cross sections for each channel, $\sigma_{t o t}$. Equation 6 with the geometrical acceptance $A_{W}$ set to unity defines the measured fiducial inclusive cross sections $\sigma_{\text {fid }}$ for each channel. These fiducial cross sections do not rely strongly on any theoretical prediction for the geometrical acceptance and therefore do not contain significant theoretical uncertainties related to it. Cross-section results in this note will be presented for both the electron and muon channels, separated by and averaged over charges.

The Eq. 6 above assumes that only one correction factor $C_{W}$ is needed for the fiducial cross-section calculation. This specific case can be interpreted as a cross-section measurement in phase space defined by the fiducial requirements at Monte Carlo truth level. This simplified approach is biased where the predicted kinematical distributions of the $W$-bosons entering $C_{W}$ via the signal simulation differ from reality. This bias has been checked to be negligible compared to the statistical uncertainties of the measurements presented here (see Figures 11 and 12 which demonstrate the agreement between data and Monte Carlo simulation for various kinematic distributions). For the electron channel, a large number of pseudo-experiments binned, in $E_{\mathrm{T}}$ and $\eta$, corresponding to the statistics observed in the electron channel has been performed to verify that the biases of the single bin approach are negligible (below the percent level).

In the following, the efficiencies and correction factors with their associated experimental systematic uncertainties are discussed separately for the electrons and muons. The fiducial and total cross sections are derived next with their associated statistical, experimental systematic, and luminosity uncertainties. These results are compared to the most recent theoretical calculations. In the final part of this section, the measured lepton asymmetry in the fiducial acceptance is also presented.

### 10.2 Detector-related efficiencies/scale factors and the uncertainty on $C_{W}$

The primary components of the correction factor $C_{W}$ shown in Eq. 6 come from the detector-related efficiencies such as triggering and reconstruction/identification of leptons. These values and their uncertainties feed directly into the determination of the cross section. These efficiencies are summarised in Table 5 for the electron channel and in Table 6 for the muon channel and are further described below. The final values for $C_{W}$ will later be presented in Table 8.

For the case of the muon channel, differences were observed between data and Monte Carlo for some of these efficiency values. For this reason, additional data-derived scale factors are applied to the

| Electron channel |  |
| :--- | :---: |
| Trigger efficiency | $0.999 \pm 0.001$ (tot) |
| Reconstruction/identification efficiency | $0.78 \pm 0.05$ (syst) |

Table 5: Detector-related efficiencies used in the extraction of the measured cross sections for the electron channel. No scale factor to correct the Monte Carlo sample are used in this channel.

| Muon channel |  |
| :--- | :---: |
| Trigger efficiency | $0.88 \pm 0.01 \pm 0.03$ |
| Reconstruction/identification efficiency | $0.97 \pm 0.01 \pm 0.04$ |
| Trigger scale factor | $0.97 \pm 0.01 \pm 0.04$ |
| Reconstruction scale factor | $0.99 \pm 0.01 \pm 0.04$ |

Table 6: Detector-related efficiencies after all corrections used in the extraction of the measured cross sections for the muon channel. The data-derived scale factors were used to correct the Monte Carlo sample to the data value. The first uncertainty is statistical and the second is systematic.

Monte Carlo sample. These scale factors are also presented in Table 6 and described below. No such correction factors are applied to the electron channel, where the trigger efficiency agrees between data and Monte Carlo, and reconstruction/identification of leptons cannot yet be measured from data due to lack of high- $E_{\mathrm{T}}$-electron statistics.

### 10.2.1 Electron efficiencies and systematic uncertainty on $C_{W}$

The most important efficiency component for the electron channel is the tight electron reconstruction and identification efficiency measured with respect to all reconstructed electron candidates. Its average value is $78 \%$. This efficiency depends strongly on both $E_{\mathrm{T}}$ and $\eta$ of the electron. Most of this dependence arises from material interactions in the inner detector and is a significant source of systematic uncertainty as discussed below. A total systematic uncertainty of $\pm 6 \%$ is assigned to the tight electron identification efficiency and comes from these material effects as well as observed discrepancies in the electron identification variables, as mentioned below.

It should be noted that the performance-based efficiency definition discussed in Section 4.1 leads to a tight electron efficiency which is $6 \%$ lower than the one determined by truth-matching the reconstructed electron to the $W$, as used in this cross-section determination ( $78 \%$ ). This change of definition for efficiency is consistently taken into account in the calculation of $C_{W}$, which is derived for the $W$-matched tight electrons. This choice of definition for the tight electron identification efficiency is one of the largest contributors to the difference between the electron efficiency value of $78 \%$ and the final value for $C_{W}$ value quoted below.

The correction factor $C_{W}$ that feeds directly into the cross-section Eq. 6 includes as a primary component the efficiency for reconstructing and identifying $W$-boson decays falling within the geometrical acceptance. The tight electron identification efficiency mentioned above is calculated with respect to all reconstructed candidate electrons and so additional factors must be taken into account for electrons that are in the acceptance but, due to various effects, fail to even be reconstructed as candidate electrons. An important source of loss is the fiducial selection of the approximately $5 \%$ problematic regions of the calorimeter as specified in Section 5.2 and an additional $5 \%$ loss due to the kinematic and $E_{\mathrm{T}}$ requirements. The correction factor $C_{W}$ in addition accounts for inefficiencies for selecting collisions with a reconstructed vertex (a minor contribution), and also includes contributions from trigger effects as well
as electron energy and $E_{\mathrm{T}}^{\text {miss }}$ scale and resolutions, as explained below. The total systematic uncertainty on $C_{W}$ is then the quadratic sum of the following contributions:

- Trigger efficiency: The trigger efficiency has been measured in data to be better than $99.9 \%$, and carries a negligible statistical and systematic uncertainty;
- Discrepancies in electron identification variables: Such discrepancies in electron identification variables have been observed for both electron and photon candidates in samples, however, contaminated by significant background [22]. A systematic uncertainty was obtained by varying the observed shapes for the Monte Carlo signal electrons from $W$-boson decay to match those observed for electron candidates in the same kinematic range in data. A systematic uncertainty of $\pm 6 \%$ is assigned to $C_{W}$.
- Material effects and problematic regions in the calorimeter: The impact of possible extra material in the inner detector and in front of the active EM calorimeter has been evaluated with a dedicated simulation. There are two components that contribute to the overall systematic uncertainty due to this effect: impact on the reconstruction of candidate electrons and on the tight electron identification efficiency. An additional smaller uncertainty is attributed to electrons that fail to be reconstructed due to problematic regions in the liquid argon calorimeter. A total systematic uncertainty of $\pm 4 \%$ is assigned to $C_{W}$;
- Energy scale and resolution: The impact of the electron scale and resolution is dominated by the estimated uncertainty on the EM calorimeter energy scale of $\pm 3 \%$ based on test-beam measurements and first in-situ measurements of $\pi^{0} \rightarrow \gamma \gamma$ [33]. Varying the energy scale by this factor (which includes the proper recalculation of $E_{\mathrm{T}}^{\text {miss }}$ ) provides an uncertainty of $\pm 3 \%$ on $C_{W}$;
- $E_{\mathrm{T}}^{\text {miss }}$ scale and resolution: Several possible sources of uncertainty on the $E_{\mathrm{T}}^{\text {miss }}$ scale and resolution have been considered such as the energy scale of the clustering algorithm used in the construction of $E_{\mathrm{T}}^{\text {miss }}$ variable [34], the impact of pile-up in the data sample, and the problematic regions in the calorimeter, resulting in an estimated uncertainty of $\pm 2 \%$ on $C_{W}$.

In summary, the final $C_{W}$, averaged over all bins in electron $\eta$ and $E_{\mathrm{T}}$, is 0.656 with a total systematic uncertainty of $\pm 8 \%$.

### 10.2.2 Muon efficiencies, scale factors, and uncertainty on $C_{W}$

Several important components such as muon reconstruction and trigger efficiencies feed into the evaluation of $C_{W}$ and its systematic uncertainty. These efficiencies have been measured in Monte Carlo and corrected by data-driven scale factors to take into account differences between data and simulation. The numbers used in the cross section calculation and the measured scale factors are presented in Table 6.

The muon reconstruction efficiency as determined from the Monte Carlo and corrected by the scale factor is $0.97 \pm 0.01$ (stat) $\pm 0.04$ (syst). The scale factor of $0.99 \pm 0.01$ (stat) $\pm 0.04$ (syst) was obtained from efficiency studies of isolated combined muon tracks relative to inner detector tracks matched to muon hits in the muon spectrometer which reduce the contribution of fake muons. The inner-detector track efficiency and the muon hit efficiency are considered well modelled in the Monte Carlo, and a systematic is assigned to the level of agreement of this assumption.

The trigger efficiency of $0.88 \pm 0.01$ (stat) $\pm 0.03$ (syst) was obtained by correcting the value obtianed in Monte Carlo with the correction factor of $0.97 \pm 0.01$ (stat) $\pm 0.04$ (syst) measured from data. This has been derived by comparing the relative trigger efficiency for reconstructed muons above 15 GeV in data and simulations for both barrel and end-cap trigger systems.

The systematic uncertainty on $C_{W}$ comes in part from the uncertainties on the reconstruction and trigger efficiencies mentioned above. Other effects are due to inefficiencies for selecting collisions with a reconstructed vertex (a minor contribution), as well as the muon and $E_{\mathrm{T}}^{\mathrm{miss}}$ energy scale and resolutions. The total systematic uncertainty on $C_{W}$ is then the quadratic sum of the following contributions:

- Muon reconstruction: This systematic uncertainty of $\pm 4 \%$ is dominated by the dependence of the efficiency on the transverse momenta and the uncertainty on the remaining $\pi / \mathrm{K}$ contamination in the data sample where the efficiency is measured;
- Trigger efficiency: This uncertainty of $\pm 4 \%$ is derived by changing the tolerance on the matching between tracks and trigger signals and comparing measurements obtained in different trigger data streams. This number is a weighted average of the RPC and TGC trigger efficiency uncertainties (respectively $\pm 5 \%$ and $\pm 3 \%$ );
- Energy scale and resolution: This uncertainty estimation is obtained by applying a smearing of Monte Carlo muon momentum resolution and scale using parameters in agreement with the data ( $5 \%$ in the barrel and $8.5 \%$ in the endcap for the resolution and $2 \%$ for the scale) [23]. A systematic uncertainty of $\pm 4 \%$ is assigned to $C_{W}$.
- $E_{\mathrm{T}}^{\text {miss }}$ scale and resolution: Several possible sources of uncertainty on the $E_{\mathrm{T}}^{\text {miss }}$ scale and resolution have been considered as discussed Section 10.2.1, resulting in an estimated uncertainty of $\pm 2 \%$ on $C_{W}$.

The final $C_{W}$ is 0.814 with a total systematic uncertainty of $\pm 7 \%$.

### 10.3 Geometrical acceptance and uncertainty

The calculation of the total cross section takes into account the phase-space requirements applied in the fiducial cross-section measurement and is entirely based on Monte-Carlo simulations. This geometrical acceptance factor, $A_{W}$, is defined as

$$
\begin{equation*}
A_{W}=\left(\frac{N^{a c c}}{N^{a l l}}\right)_{g e n} \tag{7}
\end{equation*}
$$

where $N^{a c c}$ is the number of generated events that pass the fiducial requirements (accepted events as defined in Sections 6 and 7) and $N^{\text {all }}$ is the total number of generated events at truth level. The quantity $A_{W}$ is determined at Born level, i.e. before the decay lepton may emit photons (QED final-state radiation) and the losses due to this effect become a component of the $C_{W}$, evaluated with the full simulation of the detector response.

The acceptance is calculated using the PYTHIA $W$ samples generated with the modified LO parton distribution function (PDF) MRSTLO* [16] and the corresponding ATLAS MC09 tune [35]. The central values of the acceptances are provided in Table 7. The statistical uncertainty resulting from the Monte Carlo sample is negligible.

The systematic uncertainties on the acceptance are dominated by the limited knowledge of the proton PDFs and the modelling of the $W$-production at the LHC. These uncertainties are evaluated using dedicated MC@NLO [36] samples generated with two different NLO PDFs: the CTEQ6.6 PDF [37] and HERAPDF1.0 [38]. The latter predicts a noticably higher $W^{+}\left(W^{-}\right)$cross section by $1.7 \%$ ( $4.4 \%$ ) and, for this reason, is a good choice to use as one of the alternative samples for the evaluation of the systematic uncertainty. The acceptance results determined with these alternate PDFs are presented in Table 7.

The systematic uncertainty on the acceptance is derived from the following two sources:

| MC | $A_{W}$ <br> $W^{+} \rightarrow e^{+} v$ | $A_{W}$ <br> $W^{+} \rightarrow \mu^{+} v$ | $A_{W}$ <br> $W^{-} \rightarrow e^{-} v$ | $A_{W}$ <br> $W^{-} \rightarrow \mu^{-} v$ | $A_{W}$ <br> $W \rightarrow e v$ | $A_{W}$ <br> $W$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| PYTHIA MRSTLO* | 0.466 | 0.484 | 0.457 | 0.475 | 0.462 | 0.480 |
| MC@NLO HERAPDF1.0 | 0.475 | 0.494 | 0.454 | 0.472 | 0.465 | 0.483 |
| MC@NLO CTEQ6.6 | 0.478 | 0.496 | 0.452 | 0.470 | 0.465 | 0.483 |

Table 7: Summary of geometrical acceptance values $A_{W}$ for $W \rightarrow e v$ and $W \rightarrow \mu \nu$ using various MonteCarlo simulations.

- The difference for the MC@NLO geometrical acceptances using the two PDFs is at most $\pm 0.6 \%$ while the statistical precision per sample is negligible. The relative uncertainties, estimated by using the CTEQ6.6 PDF error eigenvector sets at the $90 \%$ C.L. limit, in combination with the MC@NLO acceptance calculation, are $\pm 1.0 \%$ for the $W^{+}$and $\pm 1.8 \%$ for the $W^{-}$production.
- The geometrical acceptances obtained with MC@NLO are larger by $2.6 \%(2.1 \%)$ and smaller by $1.1 \%(1.1 \%)$ for $W^{+}$and $W^{-}$production in the electron channel (muon channel), respectively, when compared to the PYTHIA values.

These two components added in quadrature result in systematic uncertainties on the acceptance values for $W^{+}$and $W^{-}$production of approximately $\pm 3 \%$ and $\pm 2 \%$, respectively. Given that only two alternate PDFs were used to illustrate the possible range of this uncertainty, the more conservative of these two values, $\pm 3 \%$, is used as the overall relative systematic uncertainty for the PYTHIA acceptance values. This value is dominated by the large difference to the MC@NLO values.

### 10.4 Measured cross sections

All of the elements necessary to calculate the fiducial and total cross sections for $W^{+}, W^{-}$, and $W^{ \pm}$production and decay in the electron and muon channels are summarised in Table 8. The derived fiducial and total cross sections are also presented in this table, along with their statistical, systematic and luminosity uncertainties. The total cross section values for the combined electron-muon channels, when taking into account the correlated and uncorrelated sources of uncertainty, are $\sigma_{\text {tot }}\left(W^{+}\right)=$ $[5.7 \pm 0.7$ (stat) $\pm 0.4($ syst $) \pm 0.6($ lumi $)] \mathrm{nb}, \sigma_{\text {tot }}\left(W^{-}\right)=[3.5 \pm 0.5$ (stat) $\pm 0.2($ syst $) \pm 0.4$ (lumi) nb , and $\sigma_{\text {tot }}\left(W^{ \pm}\right)=[9.3 \pm 0.9($ stat $) \pm 0.6($ syst $) \pm 1.0($ lumi $)] \mathrm{nb}$.

### 10.5 Comparison to theoretical calculations

A comparison of the measured cross-section values to theoretical predictions including next-to-next-toleading order QCD corrections is shown in Figure 15 (where the electron and muon channels are shown separately) and Figure 16 (where the electron and muon channels are combined). The calculations were performed with the program FEWZ [18] using the MSTW2008 NNLO structure function parameterisation [19]. The renormalisation scale $\mu_{R}$ and factorisation scale $\mu_{F}$ were chosen to be $\mu_{F}=\mu_{R}=m_{W}$. Within the experimental uncertainties, the measured cross sections agree well with the calculations for both $W^{+}$and $W^{-}$production and the expected asymmetry between these cross sections is confirmed experimentally. It should be noted that the theoretical uncertainties resulting from variations of the renormalisation and factorisation scales as well as uncertainties resulting from structure-function parameterisations are not shown. As discussed in Section 3, these uncertainties are expected to be of the order of $\pm 4 \%$ at 7 TeV . Figure 15 also displays the results of previous measurements of the total $W$ production cross section by the CDF [7] and D0 [6] experiments at $\sqrt{s}=1.96 \mathrm{TeV}$ at the Fermilab Tevatron collider and by the UA1 [39] and UA2 [40] experiments at $\sqrt{s}=0.63 \mathrm{TeV}$ at the CERN Sp $\overline{\mathrm{p} S}$ protonantiproton collider. All measurements are in good agreement with the theoretical prediction. The energy dependence of the total $W$-production cross section is well described.

Table 8: Results for the fiducial cross sections $\sigma_{\text {fid }}$ and total cross section $\sigma_{\text {tot }}$ for $W^{+}, W^{-}$, and $W^{ \pm}$in the electron and muon channels. Shown are the observed numbers of signal events after background subtraction for each channel, the average correction factors $C_{W}$, the fiducial cross sections, the geometrical acceptance correction factors, and the total cross sections with their statistical, systematic, and luminosity uncertainties quoted in that order.

### 10.6 Lepton asymmetries

The measurement of the charge asymmetry of the decay leptons from $W$ bosons at hadron colliders provides important information about parton distribution functions. Inclusive measurements have been performed at the Tevatron [41, 42, 43, 44], for both $W \rightarrow e v$ and $W \rightarrow \mu \nu$ events and the data have been included in global fits of parton distributions [19, 45]. The lepton asymmetry is defined as:

$$
\begin{equation*}
A=\frac{\sigma^{\varepsilon^{+}}-\sigma^{\ell^{-}}}{\sigma^{\ell^{+}}+\sigma^{\ell^{-}}} \tag{8}
\end{equation*}
$$

where in the analysis presented in this note, the fiducial cross section is used to calculate the asymmetry.
At proton-proton colliders, the overall asymmetry is predicted to be significantly different from zero as discussed in Section 3. The asymmetry varies as a function of lepton pseudorapidity since it is highly correlated with the kinematic phase space of the incoming partons and hence each $\eta$-bin probes partons with different average values of the momentum fraction.

The asymmetry $A$ is sensitive to valence quark distributions [46]. It provides complementary information to that obtained from measurements of structure functions in deep-inelastic scattering [47, $48,49,50]$, which do not strongly constrain the ratio between $u$ and $d$ quarks in the kinematic region probed at the LHC (parton momentum fraction between 0.001 and 0.1 ). In fact, the PDF parameterisations of CTEQ [37] and MSTW [19] have been shown to disagree even outside their respective errors bands [32, 51].

(a)

Figure 15: The measured values of $\sigma_{W} \cdot \mathrm{BR}(W \rightarrow \ell v)$ for $W^{+}, W^{-}$and for their sum compared to the theoretical predictions based on NNLO QCD calculations. Results are shown separately for the electron and muon channels. The predictions are shown for both proton-proton ( $W^{+}, W^{-}$and their sum) and proton-antiproton colliders $(W)$ as a function of $\sqrt{s}$. The calculations are based on the FEWZ program with the MSTW2008 NNLO structure function parameterisations (see text). In addition, measurements at previous proton-antiproton colliders are shown. The data points at the various energies are staggered to improved readability. The data points are plotted with their total uncertainty.

The $\eta$ distributions of reconstructed electrons and muons are shown to be in good agreement with the expectation (see Figure 10). The charge misidentification (the assignment of an incorrect charge to the measured lepton) is found to be negligible for muons. For electrons, it is of order of $0.1 \%$ for the barrel and $1.0 \%$ for the end-cap regions. It is implicitly taken into account in the efficiency corrections applied for the cross section.

To extract the asymmetry, QCD and $W \rightarrow \tau v$ backgrounds are subtracted from the number of observed candidates. The remaining events are corrected by the same factors as those used in the fiducial cross-section measurement. As the last step, the asymmetry is calculated for $|\eta|$ in central and end-cap bins and as well as integrated over the entire pseudorapidity range. The systematic uncertainties as discussed in the previous sections were applied to obtain the final asymmetry results. This includes the variation of the backgrounds within their associated uncertainties. However, the statistical uncertainties dominate by far the total uncertainties.

The measured lepton asymmetries as a function of $|\eta|$ are tabulated in Table 9 and shown in Figure 17. In this table, the asymmetry integrated over the full pseudorapidity range has the region $1.37<|\eta|<1.52$ excluded in both the electron and muon channels to make this number more comparable between the two channels. The statistical uncertainty on the asymmetry is determined using Gaussian error propagation from the errors on the number of observed signal events in the individual $|\eta|$ regions. If the number of events is larger than 25 , the square-root of the number of events is used for the error. If it is smaller,

(a)

Figure 16: The measured values of $\sigma_{W} \cdot \mathrm{BR}(W \rightarrow \ell v)$ for $W^{+}, W^{-}$and for their sum compared to the theoretical predictions based on NNLO QCD calculations. Results are shown for the combined electron-muon results. The predictions are shown for both proton-proton ( $W^{+}, W^{-}$and their sum) and proton-antiproton colliders $(W)$ as a function of $\sqrt{s}$. The calculations are based on the FEWZ program with the MSTW2008 NNLO structure function parameterisations (see text). In addition, measurements at previous proton-antiproton colliders are shown. The data points at the various energies are staggered to improved readability. The data points are plotted with their total uncertainty.

Poissonian confidence levels are used. These give asymmetric uncertainties on the observed number of events. As an approximation, the larger of these asymmetric uncertaintied is used in the error propagation. The asymmetry values are compared to theoretical predictions obtained with NLO calculations, namely MC@NLO [36] and DYNNLO [52] which have been interfaced to various PDF parameterisations of the respective order. The parton distribution functions MSTW08 [19], CTEQ6.6 [37] and HERAPDF 1.0 [50] were used.

## 11 Observation of $Z$ candidates

A search for $Z$ candidates was also performed in both the electron and muon channels. The preselection specifications listed in Section 6 are first applied. Subsequent requirements are made to specifically search for lepton pairs consistent with being produced from the decay of a $Z$ boson. For the electron channel, leptons pairs within $|\eta|<2.47$ are required to be of opposite charge and each lepton must pass at least the "medium" requirements as presented in Section 4.1. Events with at least one "medium" lepton in the central region of $|\eta|<2.47$ and one "forward-tight" lepton in the forward region of $2.47<|\eta|<4.9$ are also accepted. For the muon channel, the selection is loosened compared to the $W$ search: only one of the muon candidates is required to have a minimum muon combined $p_{\mathrm{T}}$ above 20 GeV . The other muon

Figure 17: Lepton charge asymmetries for the electron (a) and muon (b) channels. Superposed are several theoretical predictions (see text).

| Electron channel |  |  |  |
| :---: | :---: | :---: | :---: |
|  | $A$ | $A(\|\eta\|<1.37)$ | $A(1.52<\|\eta\|<2.47)$ |
| Measured | $0.21 \pm 0.18 \pm 0.01$ | $0.06 \pm 0.22 \pm 0.01$ | $0.54 \pm 0.40 \pm 0.01$ |
| Predicted | 0.20 | 0.16 | 0.25 |
| Muon channel |  |  |  |
|  | $A$ | $A(\|\eta\|<1.05)$ | $A(1.05<\|\eta\|<2.4)$ |
| Measured | $0.33 \pm 0.12 \pm 0.01$ | $0.32 \pm 0.18 \pm 0.01$ | $0.32 \pm 0.15 \pm 0.01$ |
| Predicted | 0.20 | 0.15 | 0.23 |

Table 9: The measured lepton asymmetries integrated over the full pseudorapidity range, as well as separately for the barrel and end-cap regions. For the electron channel: the full range represents $|\eta|<2.47$ but excludes $1.37<|\eta|<1.52$, the barrel region is $|\eta|<1.37$, and end-cap region is $1.52<|\eta|<2.47$. For the muon channel: the full range represents $|\eta|<2.4$ but excludes $1.37<|\eta|<1.52$, the barrel region is $|\eta|<1.05$, and end-cap region is $1.05<|\eta|<2.4$. The quoted uncertainties are statistical and systematic, in that order. Also quoted are the DYNNLO [52] predictions.
minimum $p_{\text {T }}$ threshold remains at 15 GeV and the pseudorapidity requirement of this second muon is relaxed to $|\eta|<2.5$. Muon candidates must have opposite charge and a muon isolation parameter $\sum p_{T}^{I D} / p_{T}<0.2$. Within the invariant mass window $m_{\ell \ell}=66-116 \mathrm{GeV}$, five candidates pass these requirements (including one candidate in the forward region) in the electron channel and nine candidates in the muon channel. Figure 18 shows the invariant masses of these candidates.

The $Z \rightarrow \ell \ell$ Monte Carlo samples discussed in Section 3 are used to estimate the number of signal events. For the electron channel, a total of $6.3 \pm 0.6$ (syst) $\pm 0.7$ (lumi) signal events with a negligible statistical uncertainty are expected for an integrated luminosity of $17.0 \mathrm{nb}^{-1}$. This estimate includes a $11 \%$ uncertainty on the luminosity and a $10 \%$ systematic uncertainty due to electron identification, energy scale, theoretical cross section uncertainty, and on the acceptance from the parton distribution functions. For the muon channel, a total of $7.9 \pm 0.8$ (syst) $\pm 0.9$ (lumi) signal events with a negligible

Figure 18: Invariant mass $m_{\ell \ell}$ of $Z$ candidates in the electron (a) and muon (b) channels. All backgrounds are too small to be shown in these figures.
statistical uncertainty are expected for an integrated luminosity of $17.7 \mathrm{nb}^{-1}$. Apart from the $11 \%$ uncertainty in luminosity determination, the primary source of systematic uncertainty in this prediction for the muon channel is the reconstruction efficiency. Since the final state in $Z \rightarrow \mu \mu$-like events contains two muons, the uncertainties in their reconstruction efficiencies are added linearly, yielding an uncertainty on the event reconstruction efficiency of $8 \%$. This number assumes that the uncertainties are fully correlated between the two muons. The uncertainty in the trigger efficiency scaling factor is $2.4 \%$. The other sources of systematic uncertainty are the same as for the $W$ channel. These contributions are added in quadrature resulting in the final number given above.

The background Monte Carlo samples in Section 3 have insufficient statistics to provide a direct estimate of the expected background events in the $Z \rightarrow e e$ channel within the mass window $66<m_{e e}<$ 116 GeV . A partially data-derived estimate is made. For the electron channel, the QCD background Monte Carlo sample may be used to estimate the number of pairs of leptons that both pass the "loose" electron requirement (either central or forward) in the appropriate mass range. A data-derived "loose" to "medium" rejection factor for the central leptons and "forward-loose" to "forward-tight" rejection factor for forward leptons are then used to estimate the expected number of lepton pairs which both pass the nominal $Z \rightarrow e e$ requirements. The ratio of "medium" to "loose" electrons with $E_{\mathrm{T}}>20 \mathrm{GeV}$, reconstructed using the standard electron algorithm of Section 4.1 and within the $\eta$ acceptance of the detector is measured in data to be $0.14 \pm 0.01$. The equivalent number for the forward region is $0.18 \pm$ 0.03 for the ratio of "forward-tight" to "forward-loose" electrons. In the $Z$ mass window $66<m_{e e}<$ 116 GeV , the Monte Carlo predicts there to be $6.9 \pm 0.7 \mathrm{QCD}$ background events in the opposite-charge invariant mass distribution for "loose" lepton pairs. By applying the data-derived rejection factors to each electron in these pairs, separating appropriately central leptons and forward leptons, a background estimate totalling $0.2 \pm 0.1$ events in the opposite-charge distribution in the $Z$ mass window is derived. The primary electroweak background directly under the mass peak $(W \rightarrow e v)$ is flat as a function of the invariant mass and expected to appear in Figure 18(a) at the $3 \times 10^{-3}$ level. $\mathrm{Z} \rightarrow \tau \tau$ background also appears at the same level but drops off sharply as a function of the invariant mass.

The total number of expected background events within the mass window $66<m_{\mu \mu}<116 \mathrm{GeV}$ in the muon channel after all requirements as estimated from Monte Carlo samples described in Table 1
is $0.04 \pm 0.01$ (syst) $\pm 0.01$ (lumi) The dominant source of background is $Z \rightarrow \tau \tau$ ( $52 \%$ ), followed by top-pair production ( $27 \%$ ). The QCD contribution ( $b \bar{b}$ events) is $17 \%$ and other sources are negligible.

## 12 Summary

This note presents a measurement by the ATLAS experiment of the $W \rightarrow \ell v$ production cross section based on $118 W \rightarrow \ell v$ candidates produced from $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions at the LHC. These results correspond to a total integrated luminosity of $16.9 \mathrm{nb}^{-1}$ for the $W \rightarrow e v$ channel, and $16.6 \mathrm{nb}^{-1}$ for the $W \rightarrow \mu \nu$ channel. The total inclusive $W$-boson production cross section times the leptonic branching ratio in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ was measured to be $(8.5 \pm 1.3($ stat $) \pm$ 0.7 (syst) $\pm 0.9$ (lumi)) nb for the $W \rightarrow e v$ channel and ( $10.3 \pm 1.3$ (stat) $\pm 0.8$ (syst) $\pm 1.1$ (lumi)) nb for the $W \rightarrow \mu \nu$ channel. This constitutes the first $W$ cross-section measurement by ATLAS in protonproton collisions and the result obtained is in agreement with theoretical calculations based on NNLO QCD. In addition the expected charge asymmetry between the cross section for $W^{+}$and $W^{-}$production is experimentally confirmed.

A total of $14 Z \rightarrow \ell \ell$ candidates was observed with an expectation of 14.2 given the integrated luminosities of $17.0 \mathrm{nb}^{-1}$ for the $Z \rightarrow e e$ channel and $17.7 \mathrm{nb}^{-1}$ for the $Z \rightarrow \mu \mu$ channel.

# Measurement of the $Z \rightarrow \ell \ell$ production cross section in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

The ATLAS Collaboration ${ }^{\text {a }}$

${ }^{a}$ CERN

#### Abstract

This note describes the first measurement of the $Z \rightarrow \ell \ell$ production cross section, where $\ell=e, \mu$, by the ATLAS experiment. These results are based on $125 Z \rightarrow \ell \ell$ candidates, produced in $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions at the LHC and correspond to a total integrated luminosity of approximately $225 \mathrm{nb}^{-1}$. The total inclusive $Z$-boson production cross section times the charged leptonic branching ratio within the invariant mass window $66<m_{e e}<116 \mathrm{GeV}$ was measured to be $[0.72 \pm 0.11$ (stat) $\pm 0.10$ (syst) $\pm 0.08$ (lumi)] nb for the $Z \rightarrow e e$ channel and $[0.89 \pm 0.10$ (stat) $\pm 0.07$ (syst) $\pm 0.10$ (lumi) $] \mathrm{nb}$ for the $Z \rightarrow \mu \mu$ channel, resulting in a combined value of $[0.83 \pm 0.07$ (stat) $\pm 0.06$ (syst) $\pm 0.09$ (lumi)] nb. This constitutes the first $Z$ cross-section measurement by ATLAS in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ and the results obtained are in agreement with theoretical calculations based on NNLO QCD.

## 1 Introduction

The $W$ and $Z$ bosons are expected to be produced abundantly at the Large Hadron Collider (LHC) [1], and for the first time in proton-proton collisions. The well-known properties of the $Z$ boson will provide significant constraints in the determination of the performance of the collider experiments at the LHC; its known mass, width and leptonic decays can be exploited to determine the detector energy and momentum scale and resolution, as well as lepton identification and trigger efficiencies.

A first measurement of the $W \rightarrow \ell v$ cross section from the $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions of the LHC was presented recently [2] by the ATLAS experiment [3]. This note details a measurement of the $Z \rightarrow \ell \ell$ cross section by ATLAS. This result is based on $46 Z \rightarrow e e$ and $79 Z \rightarrow \mu \mu$ candidates resulting from a total integrated luminosity of approximately $225 \mathrm{nb}^{-1}$.

## 2 The $Z$ process and sources of background

The results presented in this note are compared to expectations based on Monte Carlo simulations. The signal and background samples used in this note were generated at $\sqrt{s}=7 \mathrm{TeV}$ with PYTHIA [4] using MRSTLO* [5] parton distribution functions (PDF), then simulated with GEANT4 [6] and fully reconstructed. Details of these samples are summarised in Table 1. For the $t \bar{t}$ samples, both MC@NLO [7, 8] and POWHEG [9] were used.

The $Z$ production cross section times its respective $Z / \gamma^{*} \rightarrow \ell \ell$ decay branching ratio used in this study is calculated to next-to-next-to-leading order (NNLO) in QCD using the FEWZ program [10] with the MSTW2008 set of parton distribution functions [11]. The invariant mass of the charged leptons from the process $Z / \gamma^{*} \rightarrow \ell \ell$ is required to be greater than 60 GeV . This value is:

$$
\begin{equation*}
\sigma_{Z / \gamma^{*} \rightarrow \ell \ell}^{N N L O}=0.99 \mathrm{nb} \tag{1}
\end{equation*}
$$

An overall uncertainty of this $Z$ cross section of $4 \%$ has been estimated using the MSTW2008NNLO PDF error eigenvectors at the $90 \%$ C.L. limit, the NNLO HERAPDF1.0 $\alpha_{s}$ variations [12], and normalisation and scale variations. In this note, the term " $Z$ cross section" will generically refer to the $Z / \gamma^{*}$ cross section.

For the electron channel, the primary backgrounds are expected to be from QCD processes, $Z \rightarrow$ $\tau \tau, W \rightarrow e v$, and $t \bar{t}$ production. These background estimates are partially derived from data and by the Monte Carlo samples described in Table 1. For the muon channel, the primary backgrounds are expected to be $Z \rightarrow \tau \tau, W \rightarrow \mu \nu, \bar{t}$, and $b \bar{b}$ production. These background estimates are derived from the Monte Carlo samples described in Table 1.

### 2.1 Event selection

The data presented in this note were collected over a four-month period, from March to July 2010. The basic beam and data-quality requirements as described in Ref. [2] resulted in total integrated luminosities of $219 \mathrm{nb}^{-1}$ for the $Z \rightarrow e e$ channel and $229 \mathrm{nb}^{-1}$ for the $Z \rightarrow \mu \mu$ channel. The uncertainty on the luminosity determination is estimated to be $11 \%$ [13].

Events are selected with the hardware-based L1 trigger as described in Ref. [2] with the following exceptions. The threshold above which the calorimeter trigger accepts electron and photon candidates increased from five to ten trigger counts, where one count corresponds to approximately 1 GeV . The muon trigger, which had no $p_{\mathrm{T}}$ threshold requirement, was changed to one whose $p_{\mathrm{T}}$ threshold is at 6 GeV , as estimated from the hit pattern of multiple chamber layers. As a result of these trigger decisions, a total of $4.4 \times 10^{6}$ and $3.8 \times 10^{6}$ events are triggered in the electron and muon channels, respectively.

| Physics process | Cross section $(\mathrm{nb})[\times \mathrm{BR}]$ | Luminosity $\left(\mathrm{nb}{ }^{-1}\right)$ |
| :--- | :---: | :---: |
| $\mathrm{Z} \rightarrow e e\left(m_{\ell \ell}>60 \mathrm{GeV}\right)$ | 0.99 | $4.8 \times 10^{6}$ |
| $\mathrm{Z} \rightarrow \mu \mu\left(m_{\ell \ell}>60 \mathrm{GeV}\right)$ | 0.99 | $5.1 \times 10^{6}$ |
| $\mathrm{Z} \rightarrow \tau \tau\left(m_{\ell \ell}>60 \mathrm{GeV}\right)$ | 0.99 | $2.0 \times 10^{6}$ |
| $\mathrm{~W} \rightarrow e \nu$ | 10.46 | $6.7 \times 10^{5}$ |
| $\mathrm{~W} \rightarrow \mu \nu$ | 10.46 | $6.7 \times 10^{5}$ |
| Dijet $\left(\right.$ electron channel, $\left.\hat{p}_{\mathrm{T}}>15 \mathrm{GeV}\right)$ | $1.15 \times 10^{6}$ | 100 |
| $b \bar{b}$ (muon channel, $\left.\hat{p}_{\mathrm{T}}>15 \mathrm{GeV}\right)$ | $7.39 \times 10^{4}$ | $59 \times 10^{3}$ |
| $c \bar{c}\left(\right.$ muon channel, $\left.\hat{p}_{\mathrm{T}}>15 \mathrm{GeV}\right)$ | $2.84 \times 10^{4}$ | $53 \times 10^{3}$ |
| $t \bar{t}($ electron channel, MC@ NLO) | 0.16 | $11 \times 10^{6}$ |
| $t \bar{t}$ (muon channel, POWHEG) | 0.16 | $2.5 \times 10^{6}$ |

Table 1: Signal and background Monte Carlo samples used in the electron and muon channel analyses, including the production cross section (multiplied by the relevant branching ratios (BR)) and the integrated luminosity of the samples. The variable $\hat{p}_{T}$ is the transverse momentum of the partons involved in the hard-scattering process. The $Z$ cross section is given at NNLO, the inclusive QCD jet and heavy quark cross sections are given at leading order (LO), and the $t \bar{t}$ cross section at NLO.

Collision candidates are selected by requiring a primary vertex with at least three tracks, consistent with the beam spot position. To reduce fake collision candidates from cosmic-ray or beam-halo events, the muon analysis requires the primary vertex position along the beam axis to be within 15 cm of the nominal position.

For the electron channel, the quality of the reconstruction of the energy deposited by the electron in the liquid argon calorimeter is assessed. The event is rejected if the candidate electromagnetic cluster is located in any problematic region of this detector [2]. These problems can cause extended dead regions in a given layer of the calorimeter, which may have an important impact on the energy reconstruction of the electron. The loss in acceptance due to this requirement is approximately $13 \%$.

## 3 Selection of $Z$ candidates

In the electron channel, pairs are formed from oppositely-charged electron-positron candidates. These lepton candidates are selected with the identification level "medium" as decribed in Ref. [2] and are required to have a cluster transverse energy $E_{\mathrm{T}}>20 \mathrm{GeV}$ within the pseudorapidity range $|\eta|<2.47$, excluding the transition region between the barrel and end-cap calorimeters ( $1.37<|\eta|<1.52$ ).

In the muon channel, pairs are formed from oppositely-charged muon candidates. These lepton candidates are required to be combined muons (stand-alone muon spectrometer tracks associated to an inner-detector (ID) tracks) with transverse momentum $p_{\mathrm{T}}>20 \mathrm{GeV}$ as well as have their $p_{\mathrm{T}}$ as measured by the muon spectrometer greater than 10 GeV , within the range $|\eta|<2.4$. The difference between the inner-detector and muon-spectrometer $p_{\mathrm{T}}$, corrected for the mean energy loss in upstream material, is required to be less than 15 GeV to increase the robustness against track reconstruction mismatches. All muon candidates must satisfy the muon isolation parameter requirement $\sum p_{T}^{I D} / p_{T}<0.2$ in a narrow cone of size 0.4 in pseudorapidity-azimuthal angle space. The minimum $-p_{\mathrm{T}}$ used in the isolation requirement is 1 GeV . The difference between the $z$ position of the muon spectrometer tracks extrapolated to the beam line and the $z$ coordinate of the primary vertex is required to be less than 1 cm .

Table 2 summarises the number of $Z \rightarrow \ell \ell$ candidates remaining in data after all requirements have been imposed. A total of 46 candidates pass all requirements in the electron channel and 79 candidates in the muon channel within the invariant mass window $m_{\ell \ell}=66-116 \mathrm{GeV}$. Figure 1 shows the electron

|  | Electron channel | Muon channel |
| :--- | :---: | :---: |
| Requirement | Number of <br> candidates | Number of <br> candidates |
| Triggered | $4.4 \times 10^{6}$ | $3.8 \times 10^{6}$ |
| $\ell^{+} \ell^{-}$pairs | 51 | 85 |
| $66<m_{\ell^{+}+\ell^{-}}<116 \mathrm{GeV}$ | 46 | 79 |

Table 2: Number of $Z \rightarrow \ell \ell$ candidates in data.

Figure 1: Electron cluster $E_{\mathrm{T}}(a)$ and muon $p_{\mathrm{T}}$ (b) of the $Z$ candidate leptons after final selection.
cluster $E_{\mathrm{T}}$ and muon combined $p_{\mathrm{T}}$ of the lepton candidates. The breakdown of the various background contributions are also shown in this figure. Only the electroweak and $\bar{t}$ backgrounds are shown in the electron channel due to the lack QCD Monte-Carlo samples with sufficient statistics. Instead, this component will be measured from the data, as described in Section 4. Due to the small size of the backgrounds in both the electron and muon channels, backgrounds are not shown in subsequent plots. Figure 2 shows the $p_{\mathrm{T}}$ spectrum of the $Z \rightarrow \ell \ell$ candidates. It is to be noted that all data distributions in this note are given with statistical error bars only, corresponding to $68.3 \%$ confidence intervals unless otherwise specified and that the Monte-Carlo distributions are normalised to the total luminosity.

The invariant mass distribution of these opposite-charged candidate leptons is presented in Figure 3. In Figure 4, a fit is superposed to these data. The data are modelled using the theoretical lineshape, including photon and $Z$ contributions, convolved with a gaussian resolution function. The fitted peak of the distribution is found to be $[88.7 \pm 0.8$ (stat) $] \mathrm{GeV}$ in the electron channel, and $[89.3 \pm 0.8$ (stat) $] \mathrm{GeV}$ in the muon channel (with values of 90.6 GeV and 91.2 GeV , respectively, from the Monte Carlo). The experimental resolution is found to be $[3.6 \pm 0.8$ (stat) $] \mathrm{GeV}$ and $[4.2 \pm 0.8$ (stat) $] \mathrm{GeV}$ (with values of 1.7 GeV and 1.8 GeV from the Monte Carlo), respectively. These results are within the electromagnetic calorimeter expected energy scale and resolution based on test-beam measurements and first in-situ measurements of $\pi^{0} \rightarrow \gamma \gamma$ [14]. The increase of the $Z$ width in the muon channel is due mostly to inner-detector alignment modes affecting high $-p_{\mathrm{T}}$ tracks and misalignments in the forward region of the muon spectrometer.

Figure 2: $p_{\mathrm{T}}$ of the $Z$ candidates in the electron channel (a) and muon channel (b) after final selection.

## 4 Background expectations for the $Z \rightarrow \ell \ell$ candidates

A partially data-derived estimate of the QCD background is made for the electron channel using the same procedure as described in Ref [2] and using the same QCD scale factor as observed in that measurement. A QCD background Monte Carlo sample is used to estimate the number of pairs of charged leptons that both pass the "loose" electron requirement ( as decribed in Ref. [2]) within the mass window $66<m_{e e}<$ 116 GeV . A data-derived "loose" to "medium" rejection factor for the leptons is then used to estimate the expected number of lepton pairs which both pass the nominal $Z \rightarrow e e$ requirements. The ratio of "medium" to "loose" electrons with $E_{\mathrm{T}}>20 \mathrm{GeV}$ within the $\eta$ acceptance of the detector is measured in data to be $0.15 \pm 0.01$ (stat). This result is consistent with the equivalent number derived from the QCD background Monte Carlo. In the $Z$ mass window $66<m_{e e}<116 \mathrm{GeV}$, the Monte Carlo predicts $14.2 \pm 3.4$ (stat) QCD background events in the opposite-charge invariant mass distribution for "loose" lepton pairs. By applying the data-derived rejection factors to each electron in these pairs, a background estimate totalling $0.31 \pm 0.07$ (stat) $\pm 0.05$ (syst) events in the opposite-charge distribution in the $Z$ mass window is derived. Within the mass window $66<m_{e e}<116 \mathrm{GeV}$, the remaining sources of backgrounds ( $W \rightarrow e v: 0.06$ events and $\bar{t}: 0.08$ events) are expected to be flat as a function of the invariant mass while $\mathrm{Z} \rightarrow \tau \tau$ background ( 0.04 events) is expected to drop off sharply. The total expected background within the invariant mass window $66<m_{e e}<116 \mathrm{GeV}$ is then $0.49 \pm 0.07$ (stat) $\pm 0.05$ (syst) events.

The total number of expected background events in the muon channel within the mass window $66<$ $m_{\mu \mu}<116 \mathrm{GeV}$ after all requirements as estimated from Monte Carlo samples described in Table 1 is $0.17 \pm 0.01$ (stat) $\pm 0.01$ (syst) and consists of $\bar{t}$ ( 0.08 events), $Z \rightarrow \tau \tau$ ( 0.06 events), $b \bar{b}$ ( 0.02 events), and $W \rightarrow \mu \nu$ ( 0.01 events). All other sources of background are negligible in comparison.

The number of same-charge lepton pairs that otherwise satisfy all other requirements is a good indicator of the level of background in the selection. In the electron channel, only one same-charge lepton pair (at $m_{e e}=82.8 \mathrm{GeV}$ ) satisfies all $Z$ selection requirements within the invariant mass window while there are none in the muon channel.

Figure 3: Invariant mass $m_{\ell \ell}$ of $Z$ candidates in the electron (a) and muon $(b)$ channels.

## 5 Cross-section measurements for Z-boson decays to electrons and muons

### 5.1 Introduction

The Z-boson cross-section measurement is given by:

$$
\begin{equation*}
\sigma_{t o t}=\sigma_{Z / \gamma^{*}} \times B R\left(Z / \gamma^{*} \rightarrow \ell \ell\right)=\frac{N_{Z}^{s i g}}{A_{Z} C_{Z} L_{i n t}} \tag{2}
\end{equation*}
$$

where $\sigma_{\text {tot }}$ is measured within the invariant mass window $m_{\ell \ell}=66-116 \mathrm{GeV}$ and

- $N_{Z}^{s i g}$ denotes the number of background-subtracted signal events in the channel of interest, as summarised in Table 4;
- $A_{Z}$ denotes the so-called geometrical acceptance for the $Z$-boson decays under consideration, defined as the fraction of decays satisfying the geometrical and kinematical (fiducial) constraints at the generator level. These include the $\eta$ requirements as given in Section 3, as well as requirements on $p_{\mathrm{T}}{ }^{\ell}>20 \mathrm{GeV}$ for the electron and muon channels. These acceptance values are calculated within the invariant mass window $m_{\ell \ell}=66-116 \mathrm{GeV}$ and can only be determined from $Z \rightarrow \ell \ell$ Monte Carlo simulation at generator level;
- $C_{Z}$ denotes the ratio between number of signal events which pass the final selection requirements after reconstruction and the total number of generated events within the geometrical acceptance. In this note, $C_{Z}$ is estimated using Monte Carlo signal simulation, but this correction factor includes the efficiency for triggering on lepton candidates as well as reconstructing/identifying $Z$-boson decays falling within the geometrical acceptance. In this note, the correction factors $C_{Z}$ are taken from simulation for the electron channel, but some data-derived corrections are used for the muon channel, as described in Section 5.3. The effect of final state radiation (QED) and event migration from outside the mass window, evaluated with the full simulation of the detector, is also absorbed into this factor;
- and $L_{i n t}$ denotes the integrated luminosity for the channel of interest.

Figure 4: Invariant mass $m_{\ell \ell}$ of $Z$ candidates in the electron $(a)$ and muon $(b)$ channels. The data are modelled using the theoretical lineshape, including photon and $Z$ contributions, convolved with a gaussian resolution function.

The geometrical acceptance $A_{Z}$, as well as the denominator of $C_{Z}$, are computed at the Born level, i.e. from lepton kinematics before QED corrections. The factor $C_{Z}$ thus includes the corrections for the final state radiation.

Equation 2 defines the measured total inclusive cross sections for each channel, $\sigma_{t o t}$, measured within the invariant mass window $m_{\ell \ell}=66-116 \mathrm{GeV}$ and. Equation 2 with the geometrical acceptance $A_{Z}$ set to unity defines the measured fiducial inclusive cross sections $\sigma_{\text {fid }}$ for each channel. These fiducial cross sections do not rely strongly on any theoretical prediction for the geometrical acceptance and therefore do not contain significant theoretical uncertainties related to it. Cross-section results in this note will be presented for both the electron and muon channels.

### 5.2 Electron efficiencies and systematic uncertainty on $C_{Z}$

The correction factor $C_{Z}$ includes as a primary component the efficiency for reconstructing and identifying $Z$-boson decays falling within the geometrical acceptance. An important efficiency component for the electron channel is the "medium" electron reconstruction/identification efficiency measured with respect to all reconstructed electron candidates. Its average value is 0.863 . A total systematic uncertainty of $\pm 11 \%$ is assigned to the "medium" electron identification efficiency and comes from material interaction effects upstream of the calorimeter, the impact of event pile-up in the detector, as well as observed discrepancies in the electron identification variables, as mentioned below. This "medium" electron identification efficiency is calculated with respect to all reconstructed candidate electrons and so additional factors must be taken into account for electrons that are in the acceptance but, due to various effects, fail to be reconstructed as candidate electrons. Important sources of loss of approximately $17 \%$ are due to problematic regions of the calorimeter as specified in Section 2.1 as well as kinematic and $E_{\mathrm{T}}$ requirements. Other sources of loss are due to the mass window and opposite-charge requirements. The correction factor $C_{Z}$ in addition accounts for the very small inefficiencies for selecting collisions with a reconstructed primary vertex and also includes contributions from trigger effects. The total systematic uncertainty on $C_{Z}$ is then the sum in quadrature of the following contributions:

- Trigger efficiency: The trigger efficiency has been measured in data to be $(99.8 \pm 0.2) \%$;
- Discrepancies in electron identification variables: Some discrepancies in electron identification variables have been observed for both electron and photon candidates. A systematic uncertainty was obtained by shifting the observed shapes for the Monte Carlo signal electrons from Z-boson decay to match those observed for electron candidates in the same kinematic range in data. A systematic uncertainty of $\pm 10 \%$ is assigned to $C_{Z}$;
- Pile-up: The impact of pile-up on the "medium" electron identification efficiency is evaluated with dedicated pile-up Monte-Carlo samples. A total systematic uncertainty of $\pm 2 \%$ is assigned to $C_{Z}$;
- Material effects: The impact of possible extra material in the inner detector and in front of the active EM calorimeter has been evaluated with a dedicated simulation as described in Ref. [2]. There are two components that contribute to the overall systematic uncertainty due to this effect: impact on the reconstruction of candidate electrons and on the "medium" electron identification efficiency. A total systematic uncertainty of $\pm 8 \%$ is assigned to $C_{Z}$;
- Problematic regions in the calorimeter: An additional uncertainty is attributed to electrons that fail to be reconstructed due to problematic regions in the liquid argon calorimeter. A total systematic uncertainty of $\pm 4 \%$ is assigned to $C_{Z}$;
- Energy scale and resolution: The impact of the electron scale and resolution is dominated by the estimated uncertainty on the EM calorimeter energy scale of $\pm 3 \%$ based on test-beam measurements and first in-situ measurements of $\pi^{0} \rightarrow \gamma \gamma$ [14]. Varying the energy scale by this factor provides an uncertainty of $\pm 2 \%$ on $C_{Z}$.

In summary, the final correction $C_{Z}$ is 0.645 with a total systematic uncertainty of $\pm 14 \%$.

### 5.3 Muon efficiencies, scale factors, and uncertainty on $C_{Z}$

Several important components such as muon reconstruction and trigger efficiencies feed into the evaluation of $C_{Z}$ and its systematic uncertainty. These efficiencies have been determined in Monte Carlo and corrected by data-driven scale factors to take into account differences between data and simulation. The muon reconstruction efficiency as determined from the Monte Carlo and corrected by the scale factor is $0.98 \pm 0.01$ (stat) $\pm 0.03$ (syst). This scale factor of $1.00 \pm 0.01$ (stat) $\pm 0.03$ (syst) was obtained from efficiency studies of isolated combined muon tracks relative to inner detector tracks matched to muon hits in the muon spectrometer which reduce the contribution of fake muons. The inner-detector track efficiency and the muon hit efficiency are considered well modelled in the Monte Carlo, and a systematic is assigned to the level of agreement of this assumption.

The trigger efficiency of $0.84 \pm 0.01$ (stat) $\pm 0.02$ (syst) was obtained by correcting the value obtained in Monte Carlo with the correction factors $0.98 \pm 0.01$ (stat) $\pm 0.02$ (syst) measured from data. These results have been derived by comparing the relative trigger efficiency for reconstructed muons above 15 GeV in data and simulations for both barrel and end-cap trigger systems.

The systematic uncertainty on $C_{Z}$ comes in part from the uncertainties on the reconstruction and trigger efficiencies mentioned above. Other effects are due to inefficiencies for selecting collisions with a reconstructed primary vertex, as well as the muon scale and resolutions. The total systematic uncertainty on $C_{Z}$ is then the sum in quadrature of the following contributions:

- Muon reconstruction: This systematic uncertainty of $\pm 7 \%$ is dominated by the dependence of the efficiency on the transverse momenta and the uncertainty on the remaining $\pi / \mathrm{K}$ contamination in the data sample where the efficiency is measured;

| MC | $A_{Z}$ | $A_{Z}$ |
| :--- | :--- | :--- |
|  | $Z \rightarrow e e$ | $Z \rightarrow \mu \mu$ |
| PYTHIA MRSTLO* | 0.446 | 0.486 |
| MC@NLO HERAPDF1.0 | 0.440 | 0.479 |
| MC@NLO CTEQ6.6 | 0.445 | 0.485 |

Table 3: Summary of geometrical acceptance values $A_{Z}$ for $Z \rightarrow e e$ and $Z \rightarrow \mu \mu$ using various MonteCarlo simulations.

- Trigger efficiency: This uncertainty of $\pm 2 \%$ is derived by changing the tolerance on the matching between tracks and trigger signals and comparing measurements obtained in different trigger data streams. This number is a weighted average of the barrel and end-cap trigger efficiency uncertainties, taking into account that there are two muons that can pass the trigger requriements;
- Energy scale and resolution: This uncertainty estimation is obtained by applying a smearing of Monte Carlo muon momentum resolution and scale using parameters in agreement with the data (energy scale uncertainty of $2 \%$ and a resolution uncertainty of $5 \%$ in the barrel and $8.5 \%$ in the end-cap [15]) A systematic uncertainty of $\pm 1 \%$ is assigned to $C_{Z}$.

The final $C_{Z}$ is 0.797 with a total systematic uncertainty of $\pm 7 \%$.

### 5.4 Geometrical acceptance and uncertainty

The calculation of the total cross section takes into account the phase-space requirements applied in the fiducial cross-section measurement and is entirely based on Monte-Carlo simulations. This geometrical acceptance factor, $A_{Z}$, is defined as

$$
\begin{equation*}
A_{Z}=\left(\frac{N^{a c c}}{N^{\text {all }}}\right)_{\text {gen }}, \tag{3}
\end{equation*}
$$

where $N^{a c c}$ is the number of generated events that pass the fiducial requirements (accepted events as defined in Section 3) and $N^{\text {all }}$ is the total number of generated events (both values are calculated within the mass window $66<m_{\ell \ell}<116 \mathrm{GeV}$ ). The effect of event migration from below and above the mass window is taken into account in $C_{Z}$, which has been evaluated using events generated with $\sqrt{\hat{s}}>60 \mathrm{GeV}$. The quantity $A_{Z}$ is determined before the final-state radiation and the losses due to this effect become a component of the $C_{Z}$, evaluated with the full simulation of the detector response [16].

The acceptance is calculated using the PYTHIA $Z$ samples generated with the modified LO parton distribution function (PDF) MRSTLO* [5] and the corresponding ATLAS MC09 tune [17]. The central values of the acceptances are provided in Table 3. The statistical uncertainty resulting from the Monte Carlo sample is negligible.

The systematic uncertainties on the acceptance are dominated by the limited knowledge of the proton PDFs and the modelling of the Z-production at the LHC. These uncertainties are evaluated using dedicated MC@NLO [18] samples generated with two different NLO PDFs: the CTEQ6.6 PDF [19] and HERAPDF1.0 [20]. The acceptance results determined with these alternate PDFs are presented in Table 3.

The systematic uncertainty on the acceptance is derived from the following sources:

- The difference for the MC@NLO acceptances using the two PDFs is $1.3 \%$;
- The uncertainty due to the CTEQ6.6 PDF error eigenvector sets on $A_{Z}$ is evaluated using a PDF reweighting technique and is estimated to be $\pm 1.6 \%$;
- The MC@NLO HERAPDF1.0 acceptance values are smaller than PYTHIA values by $1.5 \%$.

|  | Z |  |  |  |  |  |  |  |

Table 4: Results for the fiducial cross sections $\sigma_{\text {fid }}$ and total cross section $\sigma_{\text {tot }}$ for $Z$ in the electron and muon channels. Shown are the observed numbers of signal events after background subtraction for each channel, the average correction factors $C_{Z}$, the fiducial cross sections, the geometrical acceptance correction factors, and the total cross sections with their statistical, systematic, and luminosity uncertainties quoted in that order.

These components added in quadrature result in systematic uncertainties on the acceptance values of $2.5 \%$. Due to the limited choice of samples and knowledge about correlations between the contributions, the acceptance-related uncertainty on the $Z$ cross-section measurement is taken to be $3 \%$, motivated by studies from Ref. [2].

### 5.5 Measured cross sections

All of the elements necessary to calculate the fiducial and total cross sections for $Z$ production and decay in the electron and muon channels are summarised in Table 4. The background-subtracted number of signal events consists of the 46 (79) observed candidates events in the electron (muon) channel as given in Table 2 minus the 0.49 ( 0.17 ) background events in the electron (muon) channel as described in Section 4.

The derived fiducial and total cross sections for both the electron and muon channels within the invariant mass window $66<m_{e e}<116 \mathrm{GeV}$ are also presented in this table, along with their statistical , systematic, and luminosity uncertainties. The total cross section value for the combined electronmuon channels, when taking into account the correlated and uncorrelated sources of uncertainty, is $\sigma_{\text {tot }}=[0.83 \pm 0.07$ (stat) $\pm 0.06$ (syst) $\pm 0.09$ (lumi) $] \mathrm{nb}$.

### 5.6 Comparison to theoretical calculations

A comparison of the measured cross-section value to theoretical predictions including next-to-next-to-leading order QCD corrections is shown in Figure 5 (where the electron and muon channels are shown separately) and Figure 6 (where the electron and muon channels are combined). The calculations were performed with the program FEWZ [10] using the MSTW2008 NNLO parton density function parameterisation [11]. The renormalisation scale $\mu_{R}$ and factorisation scale $\mu_{F}$ were chosen to be $\mu_{F}=\mu_{R}=m_{Z}$. Within the experimental uncertainties, the measured cross section agrees well with the calculation $\sigma_{\text {tot }}=(0.964 \pm 0.039) \mathrm{nb}$ within the invariant mass window $66<m_{e e}<116 \mathrm{GeV}$. It should be noted that the theoretical uncertainties resulting from variations of the renormalisation and factorisation scales as well as uncertainties resulting from parton density function parameterisations are not shown in these figures. As discussed in Section 2, these uncertainties are expected to be of the order of $\pm 4 \%$ at 7 TeV . Figures 5 and 6 also display the results of previous measurements of the total $Z$ production

(a)

Figure 5: The measured value of $\sigma_{Z / \gamma^{*}} \times \mathrm{BR}\left(Z / \gamma^{*} \rightarrow \ell \ell\right)$ presented for the electron and muon channels separately, compared to the theoretical predictions based on NNLO QCD calculations. The predictions are shown for both proton-proton and proton-antiproton colliders as a function of $\sqrt{s}$. The calculations are based on the FEWZ program with the MSTW2008 NNLO parton density function parameterisations (see text). In addition, measurements at previous proton-antiproton colliders are shown. The data points at the various energies are staggered to improve readability. The data points are plotted with their total uncertainty.
cross section by the CDF [21] and D0 [22] experiments at $\sqrt{s}=1.96 \mathrm{TeV}$ at the Fermilab Tevatron collider and by the UA1 [23] and UA2 [24] experiments at $\sqrt{s}=0.63 \mathrm{TeV}$ at the CERN Sp $\overline{\mathrm{p} S}$ protonantiproton collider. All measurements are in good agreement with the theoretical prediction. The energy dependence of the total $Z$-production cross section is well described.

## 6 Summary

This note presents a measurement by the ATLAS experiment of the $Z \rightarrow \ell \ell$ production cross section based on 125 candidates produced from $\sqrt{s}=7 \mathrm{TeV}$ proton-proton collisions at the LHC. These results correspond to a total integrated luminosity of approximately $225 \mathrm{nb}^{-1}$. The total inclusive Z-boson production cross section times the charged leptonic branching ratio in proton-proton collisions at $\sqrt{s}=$ 7 TeV was measured to be $[0.72 \pm 0.11$ (stat) $\pm 0.10$ (syst) $\pm 0.08$ (lumi) $] \mathrm{nb}$ for the $Z \rightarrow e e$ channel and $[0.89 \pm 0.10$ (stat) $\pm 0.07$ (syst) $\pm 0.10$ (lumi) $] \mathrm{nb}$ for the $Z \rightarrow \mu \mu$ channel, resulting in a combined result of $[0.83 \pm 0.07$ (stat) $\pm 0.06$ (syst) $\pm 0.09$ (lumi) $] \mathrm{nb}$ all measured within the invariant mass window $66<m_{e e}<116 \mathrm{GeV}$. This constitutes the first $Z$ cross-section measurement by ATLAS in proton-proton collisions and the result obtained is in agreement with theoretical calculations based on NNLO QCD.

(a)

Figure 6: The measured value of $\sigma_{Z / \gamma^{*}} \times \mathrm{BR}\left(Z / \gamma^{*} \rightarrow \ell \ell\right)$ where the electron and muon channels have been combined, compared to the theoretical predictions based on NNLO QCD calculations. The predictions are shown for both proton-proton and proton-antiproton colliders as a function of $\sqrt{s}$. The calculations are based on the FEWZ program with the MSTW2008 NNLO parton density function parameterisations (see text). In addition, measurements at previous proton-antiproton colliders are shown. The data points at the various energies are staggered to improve readability. The data points are plotted with their total uncertainty.

# Evidence for prompt photon production in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

The ATLAS Collaboration

#### Abstract

Photon identification is important for many physics signatures at the LHC. Prompt photon identification in ATLAS relies on the fine granularity of the electromagnetic calorimeter, which provides event-by-event rejection of the dominant background from photons produced by $\pi^{0}$ decays, and on the inner detector, which allows the reconstruction of photon conversions to electron-positron pairs. This note describes the extraction of the isolated prompt photon signal above the background for data from $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$, corresponding to an integrated luminosity of $15.8 \mathrm{nb}^{-1}$, collected with the ATLAS detector at the LHC. Using a two-dimensional sideband background subtraction technique, a statistically significant signal of prompt photons is observed, with a yield $N=(618 \pm 72)$ and a purity $P=(72 \pm 7) \%$ for transverse energies above 20 GeV .

## 1 Introduction

Prompt photon production at hadron colliders provides a handle for testing perturbative QCD predictions [1]. It can also be used to constrain parton structure functions [2]. Furthermore, photon identification is important for many physics signatures, including searches for Higgs boson or graviton decays to photon pairs, decays of excited fermions, and decays of pairs of supersymmetric particles, characterized by the production of two energetic photons and large missing transverse energy. As the Standard Model cross section for inclusive prompt photon production at LHC energies is expected to be rather large, $O(\mu \mathrm{~b})$ for transverse energies above $10 \mathrm{GeV}[3,4]$, a search of this process can already be performed in ATLAS with a modest integrated luminosity. Recent measurements of the inclusive prompt photon production cross section at the Tevatron, in $p \bar{p}$ collision at a centre-of-mass energy $\sqrt{s}=1.96 \mathrm{TeV}$, are reported in Refs. [5, 6].

In the following, all photons produced in proton-proton collisions not coming from hadron decays are considered as "prompt". In Monte-Carlo computation, these include the photons that are either:

- originating from hard-scattering processes,
- emitted from QED radiation off quarks in the initial or final state, or
- produced from non-perturbative fragmentation of quarks and gluons.

Figure 1: Inclusive prompt photon production cross section expected from QCD using the next-to-leading order (NLO) JETPHOX computation, for photons with pseudorapidity $|\eta|<1.37$ or $1.52<|\eta|<2.37$ and transverse energies above 10 GeV .

As an example, Figure 1 shows the expected differential cross section from the NLO QCD computation implemented in the JETPHOX program [3], for prompt photons with transverse energies $\left(E_{\mathrm{T}}\right)$ above 10 GeV and within the pseudorapidity $(\eta)$ acceptance of the ATLAS photon identification. A parton level isolation cut, requiring a total transverse energy below 5 GeV from the partons inside a cone of radius
$\Delta R=\sqrt{\Delta \eta^{2}+\Delta \phi^{2}}=0.4$ in $\eta \times \phi$ around the photon direction, has been used for this computation. This is expected to be close to the experimental isolation cut applied to the data. Varying the parton level isolation cut from 5 to 3 GeV changes the predicted cross section by $3 \%$. Figure 1 also shows the expected factorization and renormalization scale uncertainty (varied between 0.5 and 2.0 times the nominal scale which was set to the transverse energy of the photon) and the expected structure function uncertainty using CTEQ6.1 [7].

In a hadron collider environment, the main background is composed by photons from decays of light neutral mesons like $\pi^{0}$ or $\eta$. They will be called "fake" photons in the following. This note describes how a signal of isolated prompt photons with transverse energies above 10 GeV can be extracted from the background in the early ATLAS data. In Section 2, the note begins by briefly recalling the main characteristics of the ATLAS detector. Section 3 summarizes the data and simulated samples used for this analysis. Section 4 describes the various steps of the photon identification together with a comparison between data and Monte Carlo (MC) simulations. Section 5 illustrates the expected photon identification and trigger efficiencies. Section 6 describes the methods used to derive from the data the background level and to extract the prompt photon signal, together with the associated systematic uncertainties.

## 2 The ATLAS detector

The ATLAS detector is described in detail in Ref. [8]. We summarize here the main features of the subdetectors which are more relevant to this analysis: the calorimeter, in particular its electromagnetic section, and the inner detector.

The electromagnetic calorimeter is a lead-liquid Argon (Pb-LAr) sampling calorimeter with accordion geometry. It is divided in a barrel section covering the pseudorapidity region $|\eta|<1.45$ and two end-cap sections covering the pseudorapidity regions $1.375<|\eta|<3.2$. It consists of three longitudinal layers. The first one, with a thickness between 3 and 5 radiation lengths, has a very high granularity in the $\eta$ direction (between 0.003 and 0.006 depending on $\eta$, with the exception of the regions $1.4<|\eta|<1.5$ and $|\eta|>2.4$ ), sufficient to provide an event-by-event discrimination between single photon showers and double nearby showers coming from a $\pi^{0}$ decay. The second layer of the electromagnetic calorimeter, which collects most of the energy deposited in the calorimeter by the photon shower, has a thickness around 17 radiation lengths and a granularity of $0.025 \times 0.025$ in $\eta \times \phi$, where $\phi$ is the azimuthal coordinate around the beam $z$ axis. A third layer, with thickness varying between 4 and 15 radiation lengths, is used to correct leakage beyond the calorimeter for high energy showers. Before the accordion calorimeter, a thin presampler layer, covering the pseudorapidity interval $|\eta|<1.8$, is used to correct fluctuations of energy loss before the calorimeter. The sampling term $a$ of the energy resolution $(\sigma(E) / E \approx a / \sqrt{E(\mathrm{GeV})})$ varies between $10 \%$ and $17 \%$ as a function of $|\eta|$ [9] and it is the largest contribution to the resolution up to about 200 GeV , where the global constant term $(0.7 \%)$ starts to dominate [10]. During the April and May 2010 data taking, about 20 out of 1524 optical links of the calorimeter readout system were non working, in addition approximately $0.05 \%$ of single channels were affected by readout problem or noise and masked during reconstruction.

A hadronic sampling calorimeter is located beyond the electromagnetic calorimeter. It is made of steel and scintillating tiles in the barrel section, with depth around 7.4 interaction lengths, and of two wheels of copper and liquid argon in each end-cap, with depth around 9 interaction lengths. In this analysis the hadronic calorimeter is used to reduce background due to photons from neutral hadron decays, exploiting the fact that energy leakage in the hadronic calorimeters from isolated prompt photons is much lower than that for fake photons from decays of $\pi^{0}$ or other neutral hadrons in jets, since the latter are accompanied by nearby hadrons produced in the same jet.

The inner detector is comprised of three subsystems: at small radial distance $R$ from the beam axis ( $50.5<R<150 \mathrm{~mm}$ ), pixel silicon detectors are arranged in three cylindrical layers in the barrel and
in three disks in each end-cap; at intermediate radii ( $299<R<560 \mathrm{~mm}$ ), double layers of single-sided silicon microstrip detectors are used, organized in four cylindrical layers in the barrel and nine disks in each end-cap; at larger radii ( $563<R<1066 \mathrm{~mm}$ ), a straw tracker with transition radiation capabilities divided into one barrel section (with 73 layers of straws parallel to the beam line) and two end-caps (with 160 layers each of straws radial to the beam line) is used. These three systems are immersed in a 2 T axial magnetic field provided by a superconducting solenoid. The inner detector has full coverage in $\phi$. The silicon pixel and strip subsystems cover the pseudorapidity range $|\eta|<2.5$, while the transition radiation tracker acceptance is limited to the range $|\eta|<2.0$. The inner detector allows an accurate reconstruction of tracks from the primary proton-proton collision point and also from secondary vertices, permitting an efficient reconstruction of photon conversions in the inner detector material up to a radius of $\approx 80 \mathrm{~cm}$.

The total amount of material before the first active layer of the electromagnetic calorimeter (including the presampler) varies between 2.5 and 6 radiation lengths as a function of pseudorapidity, excluding the transition region $(1.37<|\eta|<1.52)$ between the barrel and the end-caps, where the material thickness increases to 11.5 radiation lengths. A proper description of this material is important for accurate modeling of the calorimeter response including the detailed shape of electromagnetic showers.

## 3 Data sample

This analysis is based on proton-proton collision data collected at a centre-of-mass energy $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector at the LHC in April and May 2010. Events are triggered using the first level (L1) calorimeter trigger, based on the energy deposits in the electromagnetic calorimeter. Using a rougher granularity $(0.1 \times 0.1$ in $\eta \times \phi)$ than that of the electromagnetic calorimeter, electromagnetic clusters with fixed size $0.2 \times 0.2$ are searched for and retained if the total transverse energy in two of their four trigger channels is above a certain programmable threshold. The trigger used in this analysis uses a threshold of 5 GeV , which reaches a plateau of constant efficiency close to $100 \%$ for true photons with $E_{\mathrm{T}}>10$ GeV . Given the moderate peak luminosity $\left(\approx 2 \times 10^{29} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}\right)$, the trigger can be operated at a tolerable rate $(\leq 30 \mathrm{~Hz})$ without prescaling, so that no higher level trigger selection is required. The calorimeter and inner detector are required to be fully operational with good data quality. The collected sample corresponds to an integrated luminosity of $15.8 \pm 1.7 \mathrm{nb}^{-1}$.

For this analysis, events are required to have a reconstructed primary vertex consistent with the average beam spot position and with at least three associated tracks. The efficiency of this requirement is $99.5 \%$ in the data sample and is expected to be around $99.9 \%$ for events containing prompt photons with transverse energies above 10 GeV . The distribution of the time difference between the signals observed in the two endcaps of the detector shows that non-collision background is negligible. The total number of selected events is 2.27 million.

To study the characteristics of signal and background events, Monte Carlo samples are generated using the PYTHIA event generator [11], with parameters set according to the ATLAS MC09 tune [12], and the ATLAS detector response is simulated using the GEANT4 program [13]. These samples are then reconstructed with the same algorithms used for data. More details on the event generation and simulation infrastructure of the ATLAS experiment are provided in Ref. [14]. For the signal, a sample of hard-scattering photons (hard subprocesses $q g \rightarrow q \gamma$ and $q \bar{q} \rightarrow g \gamma$ ) with generated transverse momenta above 7 GeV is used. The equivalent luminosity of this sample, computed assuming a cross section of $1.4 \mu \mathrm{~b}$ as obtained from PYTHIA, is $71 \mathrm{nb}^{-1}$. To study background processes, two samples are simulated. In the first one, generated non-diffractive minimum bias events are filtered requiring at least 6 GeV of transverse energy in a $0.18 \times 0.18$ region in $\eta \times \phi$ at the truth particle level, mimicking a calorimetric L1 trigger requirement. The events passing this filter, whose efficiency is around $5.3 \%$, are then fully simulated. This filter is found to be unbiased for transverse energies above 10 GeV . The equivalent integrated luminosity of this sample, according to the effective production cross section (including the
filter efficiency) $\sigma=2.58 \mathrm{mb}$ returned by PYTHIA, is $11.6 \mathrm{nb}^{-1}$. Since the $E_{\mathrm{T}}$ spectrum of reconstructed fake candidates decreases rapidly above the filter threshold, a second sample, enriched in candidates with higher transverse energies, is used to study fake photon candidates with reconstructed $E_{T}>20 \mathrm{GeV}$. In this sample all relevant $2 \rightarrow 2$ QCD hard subprocesses are switched on, the transverse momentum of the hard-scattering products is required to be greater than 15 GeV and the same filter as for the minimum bias sample, but with a higher threshold at 17 GeV , is used before the full simulation. This sample is found to be unbiased for transverse energies above 20 GeV . Its equivalent integrated luminosity, according to the effective production cross section $\sigma=0.99 \mathrm{mb}$ computed with PYTHIA (taking into account also the filter efficiency, $8.6 \%$ ), is $101 \mathrm{nb}^{-1}$. These QCD background samples contain "fake" photon candidates, as well as prompt photon signals produced by QED radiation emitted from quarks. The higher energy sample contains also the contribution of prompt gamma-jet hard-scattering contribution. Prompt photon contributions are removed when studying background contribution with these samples.

## 4 Photon identification and isolation

Photon reconstruction and identification is seeded by energy clusters in the electromagnetic calorimeter with transverse energies exceeding 2.5 GeV in projective towers of $3 \times 5$ cells in the second layer of the calorimeter. These energy clusters are then matched to tracks that are reconstructed in the inner detector and extrapolated to the calorimeter. Clusters without matching tracks are directly classified as unconverted photon candidates. Clusters with matched tracks are considered as electron candidates. To recover photon conversions, clusters matched to tracks originating from reconstructed conversion vertices in the inner detector or to tracks consistent with coming from a conversion are considered as converted photon candidates. To increase the reconstruction efficiency of converted photons, also converted candidates where one of the two tracks is not reconstructed are retained (see Refs. [10] and [15] for more details on converted photon reconstruction). The final energy measurement is done with only the calorimeter for both converted and unconverted photons, using a cluster size which depends on the photon classification. In the barrel a size corresponding to $3 \times 5$ cells in the second layer is used for unconverted photons and $3 \times 7$ for converted photon candidates (to still collect most of the photon energy despite the opening between the conversion products in the $\phi$ direction in the magnetic field). In the end-cap a size of $5 \times 5$ is used for all candidates. A dedicated energy calibration [9] is then applied to account for upstream energy loss, lateral leakage and longitudinal leakage, separately for converted and unconverted candidates. Photon candidates with calibrated transverse energies above 10 GeV are retained for the successive analysis steps.

To ensure a proper identification, the cluster barycenter in the second layer of the electromagnetic calorimeter is required to lie in the $\eta$ region covered by the very finely segmented first layer, $|\eta|<1.37$ or $1.52 \leq|\eta|<2.37$. In addition, for this analysis, photon candidates are selected to be outside regions of the electromagnetic calorimeter where either the presampler or the first or second layers have non working readout optical links: the full $3 \times 7$ (in the barrel) or $5 \times 5$ (in the end-cap) clusters are required not to overlap with any of these regions. Photon candidates are also rejected if one of the core $3 \times 3$ second layer cells is not working properly or if one of the first layer cells facing the second layer hottest cell is not working. These requirements reject $5.5 \%$ of photon candidates in both data and Monte Carlo samples.

After this preselection, 268992 photon candidates remain in the data sample with transverse energies above 10 GeV . The transverse energy distribution of these candidates is shown in Fig. 2. This distribution is compared to the one predicted from the simulation, where both prompt photons (from the dedicated signal samples for the hard-scattering produced photon and from the QCD samples for the quark QED radiation contribution) and "fake" photons (from the QCD background samples) are included. For $E_{\mathrm{T}}$ above 20 GeV , the higher threshold QCD sample is used. For lower photon candidate energies, the lower
threshold QCD sample is used. It is clear that, at this level, the sample is dominated by "fake" photons. Since the simulation is not expected to accurately predict the fake rate and the background composition, the fake contribution has been normalized such that the sum of fake and prompt photons contributions matches the observed data yield for Figures 2-5. For example in Figure 2 this results in an overall factor of 0.45 applied to the absolute Monte Carlo normalization for the fake component.

Figure 2: Transverse energy distribution of photon candidates after reconstruction and preselection. The data are represented by dots, the histogram represents the expectations from Monte Carlo simulations. The simulated signal distribution (hollow histogram) is normalized to the data luminosity using the leading order PYTHIA cross section. The simulated background distribution is normalized such that the sum of fake and prompt photons (filled blue histogram) matches the observed data yield.

To discriminate signal from background, shape variables computed from the lateral and longitudinal energy profiles of the shower in the calorimeters are used. First, the leakage $\left(E_{\mathrm{T}, \mathrm{had}} / E_{\mathrm{T}}\right)$ in the first layer of the hadronic compartment beyond the electromagnetic cluster is required to be small (below $1-2 \%$ depending on the pseudorapidity of the photon candidate) compared to the cluster energy. Then, the transverse shape in the second layer of the electromagnetic calorimeter is inspected, using ratios of energy deposits in $3 \times 7$ over $7 \times 7$ cells $\left(R_{\eta}\right)$ and $3 \times 3$ over $3 \times 7$ cells $\left(R_{\phi}\right)$ in $\eta \times \phi$, and using the RMS width $\left(w_{\eta 2}\right)^{1}$ of the energy distribution in $\eta$. Examples of these variables are shown in Figure 3 for all the reconstructed photon candidates passing the preselection criteria previously described. The comparison between data and simulation is sensitive to the detailed composition of the background in the simulation, and to the knowledge of the upstream material before the calorimeter, and at smaller level to the modeling of cross-talk between calorimeter cells in the simulation. From these variables, a set of loose photon identification criteria is defined. They rely on simple rectangular cuts on the three variables $E_{\mathrm{T}, \mathrm{had}} / E_{\mathrm{T}}, R_{\eta}$ and $w_{\eta 2}$. The values of the cuts are the same for converted and unconverted candidates. They are independent of the photon candidate transverse energy but depend on its pseudorapidity: they

[^53]have been chosen in order to obtain an efficiency around $99 \%$ with respect to reconstruction for true prompt photons (both converted and unconverted ones) for transverse energies greater than 20 GeV [10].

Figure 3: Examples of discriminating shower shape variables based on the energy deposits in the second longitudinal compartment of the electromagnetic calorimeter for photon candidates with $|\eta|<0.6$. The data are represented by dots, the histograms represent the expectations from Monte Carlo simulations for true prompt photons (hollow white histogram) and all photon candidates from signal and background processes (filled blue histogram). For the normalization of the simulated distributions see caption of Fig. 2. Left: transverse shape variable $R_{\eta}$. Right: transverse shape variable $R_{\phi}$. Top: unconverted photon candidates. Bottom: converted photon candidates.

To reject further the background, the shower shape in the first layer of the calorimeter is examined. Several variables which discriminate single photon showers from overlapping nearby showers originating by photon pairs from neutral meson decays are computed from the energy deposited in the first layer:

- the total RMS width $w_{s, \text { tot }}$ of the energy distribution along $\eta$ over all the cells of the cluster,
- the asymmetry $E_{\text {ratio }}$ between the first and second maxima in the energy profile of the first layer along $\eta$ ( 1 when there is no second maximum),
- the energy difference $\Delta E$ between the second maximum and the minimum between the two maxima ( 0 when there is no second maximum),
- the fraction $F_{\text {side }}$ of the energy in seven cells centered around the first maximum which is not contained in the three core cells centered around the first maximum,
- the RMS width $w_{s 3}$ of the energy distribution computed with the three core cells.

The second and third variables provide rejection against cases where the two showers give separated energy maxima in the first layer. The last two variables provide rejection against cases where the two showers are merged in a wider maximum. Figure 4 illustrates the comparison between data and simulation, after the loose selection, for some of these first layer shower shape variables. After the loose selection, the relative fraction of background candidates originating from a single $\pi^{0}$ is increased, thus this comparison is less sensitive to the uncertainty on the composition of the remaining background. In the central region of the detector, for relatively low values of the pseudorapidity $(|\eta|<0.6)$, the various shower shape variables are rather well described by the simulation. At larger $|\eta|$, shower shapes in the data are systematically broader than in the simulation. The impact of this difference is assessed in the next section. Using the first layer variables, the second layer variable $R_{\phi}$ and tighter selection on the quantities (the second layer variables $R_{\eta}$ and $w_{\eta 2}$ and the leakage in the hadronic calorimeter) exploited in the loose selection, the final tight selection criteria for photon identification are defined. Similarly to the loose photon identification criteria, in the early stage of the ATLAS data taking it has been chosen to base the tight photon identification criteria on simple cuts on each of the discriminating variables, instead of using more refined but - at the present level of understanding of the detector performance - less robust multivariate techniques. The values of the cuts are independent of the photon candidate transverse energy but depend on its pseudorapidity. They have been optimized using samples of simulated signal and background events prior to data taking. Different criteria are applied to converted and unconverted photon candidates: they have been chosen in order to obtain an efficiency around $85 \%$ with respect to reconstruction for true prompt photons in both categories for transverse energies greater than 20 GeV [10]. 11890 photon candidates are selected in the data sample after the tight selection.

Isolation is also an important variable for prompt photon studies: the prompt photon signal is expected to be more isolated from hadronic activity than the fake background from $\pi^{0}$ (or other neutral hadrons), which comes from jet production where the $\pi^{0}$ is very unlikely to carry the full original jet energy. Also, because of the mixture of hard-scattering and bremsstrahlung contributions in the prompt photon signal, it is important to have a well modeled isolation variable that can be linked to the parton level isolation cut used in next to leading order QCD computations. For the study discussed here, the isolation variable is computed using calorimeter cells from both the electromagnetic and hadronic calorimeters, in a cone of radius 0.4 in the $\eta-\phi$ space around the photon candidate. The contributions from $5 \times 7$ electromagnetic calorimeter cells in the $\eta-\phi$ space around the photon barycenter are not included in the calculation. The small leakage from the photon outside this region, evaluated as a function of photon transverse energy on simulated samples of single photons (thus avoiding additional contributions from the underlying event), is then subtracted from the isolation variable. After this correction the isolation energy becomes independent of the photon transverse energy. To reduce uncertainties from underlying event modeling, the isolation is then further corrected using a method suggested in Ref. [16]. For each of two different pseudorapidity regions ( $|\eta|<1.5$ and $1.5<|\eta|<3.0$ ), low energy jets are used to compute an ambient energy density, which is then multiplied by the area of the isolation cone and subtracted from the isolation energy. After this correction, whose average size is around 0.5 GeV , the distribution of the isolation variable is centered at zero for photons from the hard-scattering, with fluctuations that are dominated by electronic noise from the calorimeter measurement. The different isolation distributions for signal and background candidates from the simulation, as well as the distribution of selected candidates in data, are shown in Figure 5 for reconstructed photon candidates passing the preselection and the loose identification criteria. In the following, photon candidates having isolation energies lower than 3 GeV are considered as "isolated". This criterion is expected to be $96 \%$ efficient for photons from the hard-scattering and slightly less efficient for photons from parton bremsstrahlung and fragmentation, which have more hadronic activity nearby that gives rise to the asymmetric positive tail of the prompt photon signal distribution in Figure 5. The same criterion is expected to reject $44 \%$ of

Figure 4: Examples of discriminating shower shape variables based on the energy deposit in the first longitudinal compartment of the electromagnetic calorimeter, for all photon candidates (converted and unconverted) passing the preselection and the loose identification criteria. The data are represented by dots, the histograms represent the expectations from Monte Carlo simulations for true prompt photons (hollow white histogram) and all photon candidates from signal and background processes (filled blue histogram). For the normalization of the simulated distributions see caption of Fig. 2. Left: $E_{\text {ratio }}$. Right: $F_{\text {side }}$. Top: photon candidates with pseudorapidity $|\eta|<0.6$. Bottom: photon candidates with pseudorapidity $1.8 \leq|\eta|<2.37$.
background candidates with transverse energy above 10 GeV . Photon candidates with isolation energies higher than 5 GeV are considered as "non-isolated".

## 5 Efficiency of the photon identification and trigger criteria

### 5.1 Photon identification efficiency

The efficiency of the photon reconstruction and identification criteria (excluding the trigger efficiency, which is determined directly on data), is determined from the hard-scattering photon PYTHIA Monte Carlo sample. The reconstruction and identification efficiency as a function of the true photon transverse energy, after the preselection criteria described in the previous section have been applied is shown in Figure 6 . The efficiency is slightly lower for photons from QED radiation which are less isolated.

To estimate the systematic uncertainties from the description of material before the calorimeter, dedicated single photon samples with different geometry layouts have been simulated. In these samples, additional dead material has been placed in the inner detector volumes, in the electromagnetic calorime-

Figure 5: Distribution of the isolation energy of reconstructed photon candidates passing the preselection and the loose identification criteria. The data are represented by dots, the histograms represent the expectations from Monte Carlo simulations for true prompt photons (hollow white histogram) and all photon candidates from signal and background processes (filled blue histogram). For the normalization of the simulated distributions see caption of Fig. 2.
ter cryostat and between the presampler and the first layer of the calorimeter. In the first case, inactive material has been added to the pixel system (from 1 to $4 \%$ of a radiation length at $\eta=0$ ), to the silicon microstrip detector (from 1 to $10 \%$ of a radiation length at $\eta=0$ ), and in the transition radiation detector (from 0 to $15 \%$ of a radiation length depending on $\eta$ ). The material in the cryostat and between the presampler and the first calorimeter layer have been increased by $10 \%$ and $5 \%$ of a radiation length, respectively. From these simulations, a $0.3 \%$ efficiency decrease per $1 \%$ radiation length material increase before the calorimeter is expected. From the a priori knowledge of the material before the calorimeter, uncertainties of a few $\%$ are then expected. The amount of cross-talk between calorimeter cells has also been varied in the simulation to estimate its impact on the photon efficiency which is found to be at the $2 \%$ level at $E_{\mathrm{T}}$ close to 10 GeV when the cross-talk is increased by $50 \%$.

Another approach consists in starting from the shower shape comparisons shown in the previous section for the background dominated candidates and to derive scale factors between data and simulation for each variable that can then be applied to the signal Monte Carlo samples. This approach is sensitive in addition to uncertainties in the background composition modeling, as well as to statistical uncertainties in the data. Typical effects of $5-10 \%$ on the efficiency are obtained this way. In the future, samples of clean electrons should provide a better check of the shower shape simulation and of the photon efficiency uncertainty.

The impact of the classification between converted and unconverted photon candidates is also studied varying the efficiency of correctly classifying converted photon candidates in the simulation and is found to be $1 \%$ on the overall efficiency for a $10 \%$ change in the efficiency to classify correctly converted photons.

Figure 6: Expected photon reconstruction and identification efficiency as a function of the true photon transverse energy, as obtained from a simulated sample of prompt photons produced in hard-scattering $\gamma$-jet events, for the loose (triangles) and tight (dots) selections.

### 5.2 Efficiency of the trigger selection

The efficiency of the L1 calorimeter trigger, relative to the photon reconstruction and offline selection, is estimated in two steps. First, using a prescaled sample of minimum bias triggers, the efficiency of a lower ( 2 GeV ) threshold L1 calorimeter trigger is determined. The measured efficiency, $\varepsilon=(99.88 \pm$ $0.11) \%$, is very close to $100 \%$ for reconstructed photon candidates with $E_{\mathrm{T}}$ above 10 GeV passing tight identification criteria. Then, using the sample of events passing the L 1 calorimeter trigger with a 2 GeV threshold, the efficiency of the higher ( 5 GeV ) threshold L1 calorimeter trigger, used for this analysis, is measured. The efficiencies with respect to the offline selection are computed for tight photon candidates as a function of the transverse energy. The results are shown in Figure 7.

The trigger efficiencies for transverse energies above 10 GeV are summarized also in Table 1, for loose and tight photon candidates. Monte Carlo samples are used to check the possible bias introduced by using photon candidates from data, which are a mixture of prompt and fake photons instead of only prompt photons. This bias, obtained from the absolute difference of the trigger efficiency for a pure signal simulated sample and a pure background simulated sample, is found to be smaller than $0.3 \%$ for tight photon candidates.

## 6 Background estimation and signal extraction

As the simulation cannot be trusted to predict accurately the fake rate, a data driven method is used to estimate the background and extract the prompt photon signal. This method relies on the use of the isolation variable and of the shower shape variables based on the energy measurement in the first layer of the electromagnetic calorimeter to define a two dimensional plane as illustrated in Fig. 8. We define the signal region as the region with isolated candidates (isolation energy lower than 3 GeV ) passing

Figure 7: Photon trigger efficiency with respect to the offline photon selection, as measured in data (circles) and simulated background events (triangles) on photon candidates passing the tight identification criteria.

Table 1: Trigger efficiency with respect to the offline photon selection for photons with transverse energies greater than 10 GeV . Only the statistical uncertainty is quoted. The systematic uncertainty is estimated to be smaller than $0.3 \%$ for tight photon candidates.

| $\|\eta\|$ interval | $\|\eta\|<0.6$ | $0.6 \leq\|\eta\|<1.37$ | $1.52 \leq\|\eta\|<1.8$ | $1.8 \leq\|\eta\|<2.37$ | All |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Efficiency (loose photons) [\%] | $99.71 \pm 0.03$ | $99.47 \pm 0.05$ | $98.33 \pm 0.12$ | $99.20 \pm 0.08$ | $99.32 \pm 0.03$ |
| Efficiency (tight photons) [\%] | $99.91 \pm 0.05$ | $99.87 \pm 0.05$ | $99.45 \pm 0.15$ | $99.70 \pm 0.13$ | $99.77 \pm 0.04$ |

the tight identification criteria, and three background enriched regions, two with non-isolated candidates (isolation energy greater than 5 GeV ) either passing or failing some of the first layer shower shape criteria of the tight selection, and one with isolated candidates not passing some of the first layer shower shape criteria. We define the number of candidates observed in data in the four regions as $N^{A}$ (signal region), $N^{B}$ (non-isolated candidates passing the shower shape requirements), $M^{A}$ and $M^{B}$ (candidates failing the shower shape criteria and which are respectively isolated or non-isolated). Assuming that the signal contribution in the three control regions is negligible, the observed numbers of candidates in these three regions ( $N^{B}, M^{A}$ and $M^{B}$ ) are due only to the background contribution. Assuming also that for the background the isolation (measured outside the cluster) is independent of the shape of the energy deposit in the cells of the first layer, the background rejection of the isolation requirement can be measured in the background control sample of candidates failing the first layer shower shape selection criteria from the ratio $M^{A} / M^{B}$, and then applied to the background yield in the non-isolated region passing the first layer shower shape cuts $\left(N^{B}\right)$ to obtain a data-driven estimate for the background yield in the signal region,

Figure 8: Illustration of the two-dimensional plane, defined by means of the isolation and a subset of the photon identification (ID) variables, used for estimating, from the observed yields $N^{B}, M^{A}$ and $M^{B}$ in the three control regions, the background yield in the signal region where the observed total yield is $N^{A}$.
$N_{\mathrm{bkg}}^{A}=N^{B} \times M^{A} / M^{B}$. The estimated signal yield $\left(N_{\text {sig }}^{A}\right)$ and purity $(P)$ in the signal region are therefore:

$$
\begin{align*}
N_{\mathrm{sig}}^{A} & =N^{A}-N^{B} \frac{M^{A}}{M^{B}}  \tag{1}\\
P & =1-\frac{N^{B}}{N^{A}} \frac{M^{A}}{M^{B}} \tag{2}
\end{align*}
$$

Provided the two assumptions above are satisfied, this method does not rely on any other inputs.
The choice of the shower shape variables to be used for the definition of the background control regions is driven by two main criteria. To minimize correlations between the isolation variable and the first layer variables, one would prefer to revert only the cuts on a small subset of shower shape variables that are less correlated with isolation in the background enriched samples. The natural choice would therefore be to revert the selection criteria on the two variables, $F_{\text {side }}$ and $w_{s 3}$, that use fewer cells from the first electromagnetic calorimeter layer, i.e. only the ones in the core of the cluster, thus expected to be the less correlated with the energy deposit outside the cluster. On the other hand, since the measurement presented here is significantly limited by the available statistics, and in particular the Poisson fluctuations of the data in the background control region, the more shower shape criteria are reverted the larger is the background in the control regions, which allows us to obtain a more precise extrapolation of the background in the signal region. A reasonable tradeoff has been found by reverting the requirements on four of the five shower shape variables (all but $w_{s, \text { tot }}$ ) for defining the background control regions. With this configuration, the correlation is computed in the background Monte Carlo sample and found to be typically lower than $15 \%$ in each of the twelve $\left(|\eta|, E_{\mathrm{T}}\right)$ bins under study. The values of the ratio $R=\frac{N_{\mathrm{bkg}}^{A} M_{\mathrm{bkg}}^{B}}{N_{\mathrm{bkg}}^{B} M_{\mathrm{bkg}}^{A}}$ integrated over the full pseudorapidity range are summarized in the first row of Table 2. The results of the measurement are then corrected in order to take into account residual non-zero correlations between the isolation and the shower shape variables as explained below. Moreover, the finite precision of this check will be taken into account as a systematic error on the background estimate.

The assumption that the signal contamination in the background control regions is small is checked using the prompt photon Monte Carlo sample. The control region most affected by signal is the one with isolated candidates failing the first layer shower shape cuts. The fraction of signal events which fall in this control region is found to be decreasing as a function of the photon transverse energy, from about $18 \%$ between 10 and 15 GeV to below $6 \%$ above 20 GeV (see Table 2). The three quantities $c_{i}$ represent the fractions of signal candidates in the three control regions relative to the signal yield in the signal region, and are obtained from simulated signal events. The fraction of signal events with respect to the total number of events in this control region is therefore expected to be around $5 \%$. This is then a small correction to the background extraction, which can anyway be taken into account explicitly in the formula for the estimated signal yield and purity as described in the following.

Table 2: Background pseudo-correlation factor $R=\frac{N_{\mathrm{bkg}}^{A} M_{\mathrm{bkg}}^{B}}{N_{\mathrm{bkg}}^{B} N_{\mathrm{bkg}}^{A}}$ and ratios $c_{1}=\frac{N_{\text {sig }}^{B}}{N_{\text {sig }}^{A}}, c_{2}=\frac{M_{\text {sig }}^{A}}{N_{\text {sig }}^{A}}$ and $c_{3}=\frac{M_{\text {sig }}^{B}}{N_{\text {sig }}^{A}}$ between the expected signal photons in the three control regions and the expected signal photons in the signal region, in different intervals of the reconstructed photon transverse energy.

| $E_{\mathrm{T}}$ interval $[\mathrm{GeV}]$ | $10 \leq E_{\mathrm{T}}<15$ | $15 \leq E_{\mathrm{T}}<20$ | $E_{\mathrm{T}} \geq 20$ |
| :--- | :---: | :---: | :---: |
| $R$ | $1.10 \pm 0.03$ | $0.91 \pm 0.05$ | $1.02 \pm 0.02$ |
| $c_{1}$ | $(1.8 \pm 0.2) \times 10^{-2}$ | $(3.1 \pm 0.5) \times 10^{-2}$ | $(5.3 \pm 0.3) \times 10^{-2}$ |
| $c_{2}$ | $(18.0 \pm 0.6) \times 10^{-2}$ | $(11.3 \pm 0.7) \times 10^{-2}$ | $(6.6 \pm 0.2) \times 10^{-2}$ |
| $c_{3}$ | $(5.3 \pm 1.1) \times 10^{-3}$ | $(2.5 \pm 1.3) \times 10^{-3}$ | $(6.9 \pm 1.0) \times 10^{-3}$ |

Since both the background correlation from the simulation and the signal leakage in the background control regions are found to be small but not negligible, they are accounted for in the background determination. The signal leakage in the three control regions is included by replacing, in Equation 1, the observed data yields with the yields corrected for the expected signal contribution, $N^{B} \rightarrow N^{B}-c_{1} N_{\text {sig }}^{A}$, $M^{A} \rightarrow M^{A}-c_{2} N_{\text {sig }}^{A}, M^{B} \rightarrow M^{B}-c_{3} N_{\text {sig }}^{A}$, and solving the resulting second order polynomial equation for $N_{\text {sig }}^{A}$. The correlations between the isolation and the shower shape variables are taken into account by correcting the estimated background yield in the signal region by the ratio between the true $\left(N_{\text {bkg }}^{A}\right)$ and the estimated $\left(N_{\mathrm{bkg}}^{B} \frac{M_{\mathrm{bkg}}^{A}}{M_{\mathrm{bkg}}^{B}}\right)$ background yield, obtained from simulated background events. The two corrections can be applied simultaneously in order to obtain the final measurement of the signal yield and purity in the signal region:

$$
\begin{align*}
N_{\mathrm{sig}}^{A} & =N^{A}-\left[\left(N^{B}-c_{1} N_{\mathrm{sig}}^{A}\right) \frac{M^{A}-c_{2} N_{\mathrm{sig}}^{A}}{M^{B}-c_{3} N_{\mathrm{sig}}^{A}}\right]\left(\frac{N_{\mathrm{bkg}}^{A}}{N_{\mathrm{bkg}}^{B}} \frac{M_{\mathrm{bkg}}^{B}}{M_{\mathrm{bkg}}^{A}}\right)  \tag{3}\\
P & =\frac{N_{\mathrm{sig}}^{A}}{N^{A}} \tag{4}
\end{align*}
$$

Figure 9(a) shows the distribution of the $F_{\text {side }}$ variable for the two regions "A", i.e. the isolated background control region and the signal region (full circles). Taking the shape of the background from the non-isolated background control regions (regions "B") and normalizing it to the number of events failing first layer shower cuts in the isolated sample (i.e. scaling it by $M^{A} / M^{B}$ ), the background in the isolated regions "A" is computed (open triangles). A clear excess at small $F_{\text {side }}$ can be observed which is consistent with the expected shape for the prompt photon signal (dashed histogram). Using the same technique, Figure 9(b) shows the total isolation energy distribution (full circles) and the background isolation distribution (open triangles), using the first layer variables to define the background enriched
control region and the signal region. Again a clear excess of isolated candidates in the sample fulfilling the first layer shower shape cuts can be seen.

Figure 9: (a) $F_{\text {side }}$ distribution for photon candidates with $E_{\mathrm{T}}>20 \mathrm{GeV}$ passing tight identification criteria (after releasing the criteria on $F_{\text {side }}, w_{s 3}, \Delta E$ and $E_{\text {ratio }}$ ), respectively belonging to the isolated (full circles) or non-isolated (open triangles) region. The latter have been scaled by the ratio $M^{A} / M^{B}$ defined in the text. (b) Isolation distribution for photon candidates with $E_{\mathrm{T}}>20 \mathrm{GeV}$ either passing the tight identification criteria (full circles), or passing the tight identification criteria after relaxing the requirements on four layer one shower shape variables (open triangles). The latter have been scaled by the ratio $N^{B} / M^{B}$ defined in the text. In both figures, the dashed line represent the prompt photon signal distribution, for candidates either passing the isolation (left) or identification (right) criteria. The signal has been normalized to the signal yield estimated in data in the signal region, divided by the expected efficiency of the identification or the isolation criteria, respectively.

The purity estimated with this method is shown in Fig. 10 in three different transverse energy bins, for four different pseudo-rapidity bins and averaged over the whole $|\eta|$ range. In this figure, only statistical uncertainties from the data and simulated samples are shown. The purity is clearly increasing with transverse energy, as expected from earlier simulation studies. The number of photon candidates in each $E_{\mathrm{T}}$ bin in the signal region in data, together with the estimated purity, are summarized in Table 3.

Table 3: Number of candidates in data, estimated signal purity and signal yield in the signal region (photon with isolation energy below 3 GeV and passing tight identification criteria), and corresponding systematic uncertainties, in three intervals of the photon transverse energy.

| $E_{\mathrm{T}}$ interval [GeV] | $10 \leq E_{\mathrm{T}}<15$ | $15 \leq E_{\mathrm{T}}<20$ | $E_{\mathrm{T}} \geq 20$ |
| :--- | :---: | :---: | :---: |
| Number of candidates | 5271 | 1213 | 864 |
| Estimated purity $P[\%]$ | $24 \pm 5$ | $58 \pm 5$ | $72 \pm 3$ |
| Systematic uncertainty on $P[\%]$ | 24 | 8 | 6 |
| Estimated signal yield $N_{\text {sig }}^{A}$ | $1289 \pm 297$ | $706 \pm 69$ | $618 \pm 42$ |
| Systematic uncertainty on $N_{\text {sig }}^{A}$ | 1362 | 86 | 59 |

In addition to the statistical uncertainty on the correction factors in Eq. 3 (the signal leakage fractions $c_{i}$ and the background pseudo-correlation factor $\frac{N_{\mathrm{bkg}}^{A}}{N_{\mathrm{bkg}}^{B}} \frac{M_{\mathrm{bkg}}^{B}}{M_{\mathrm{bkg}}^{A}}$, originating from the limited size of the simulated samples and included in the statistical uncertainty on the measured purity, the following effects are

Figure 10: Estimated prompt photon purity in data, as a function of photon transverse energy, for four different pseudo-rapidity bins and in the whole $|\eta|$ range. The points corresponding to the measurements in the full $|\eta|$ range (full circles) have been positioned, along the horizontal axis, at the average transverse energy of all selected photon candidates in the signal region in data, in the three intervals $10 \leq E_{\mathrm{T}}<15$ $\mathrm{GeV}, 15 \leq E_{\mathrm{T}}<20 \mathrm{GeV}$ and $E_{\mathrm{T}}>20 \mathrm{GeV}$ (identified by the dotted vertical lines). The points corresponding to the measurements in sub-intervals of the full $|\eta|$ range have been displaced arbitrarily along the horizontal axis for displaying purposes.
studied to investigate systematic uncertainties on the purity:

- The purity is evaluated after changing the isolation control region definition. The minimum isolation energy required for candidates in the non-isolated control regions, which is set to 5 GeV in the nominal measurement, is changed to 4 and 6 GeV . This would be sensitive to uncertainties in the contribution of prompt photons from QED quark radiation, which are less isolated than photons originating from the hard process. Alternative measurements are also performed where a maximum value of the isolation energy is set to 10 or 15 GeV for candidates in the non-isolated control regions, in order to reduce the correlation between the isolation variable and the shower shape distributions that is seen in simulated events in candidates belonging to the upper tail of the isolation distribution. The purity changes by at most $3.2 \%, 1.6 \%$ and $1.2 \%$ respectively for photons with transverse energies between 10 and 15 GeV , between 15 and 20 GeV and above 20 GeV .
- The number of shower shape variables that is used to define the background control region is reduced. This decreases the statistics of the background control sample but on the other hand should also reduce the correlation with the isolation variable. When using a subset formed by only the two variables ( $F_{\text {side }}$ and $w_{s 3}$ ) that are expected to be less correlated with the isolation variable, since they are computed with only the cells that are in the narrow core of the energy distribution
in the first layer of the calorimeter, the purity decreases by $21 \%$ in the low $E_{\mathrm{T}}$ bin and by less than $3 \%$ in the two $E_{\mathrm{T}}$ bins above 15 GeV .
- The systematics of the photon signal subtraction in the background control region is estimated using Monte Carlo samples with additional material before the electromagnetic calorimeter and additional cross-talk within the calorimeter cells. An upper limit of $5 \%$ on the fraction of signal photons being misidentified and therefore contributing the yields $M^{A}$ and $M^{B}$ observed in the two background control regions is derived. The purity, measured after varying the leakage coefficients $c_{2}$ and $c_{3}$ accordingly, changes by about $3.5 \%$ in all the $E_{\mathrm{T}}$ range. An additional source of uncertainty related to the signal subtraction originates from the different isolation distributions for the hard-scattering and bremsstrahlung signal photons, the latter being characterized by larger activity nearby and therefore by usually (slightly) larger values of the isolation energy. As a consequence, the fractions $c_{1}$ and $c_{3}$ of signal photons belonging to the non-isolated control regions and contributing to the observed yields $N^{B}$ and $M^{B}$ depend on the relative amount of prompt and bremsstrahlung photons in the selected sample. In the nominal measurement, we assume the fraction of hard-scattering photons in the signal region to be $60 \%$ of the total prompt photon signal as determined from simulation. We assign a systematic uncertainty on the purity due to this assumption by redoing the measurement after changing this fraction to $20 \%$ or $100 \%$. The measured value of the purity changes by $0.6,1.5$ and $2.4 \%$ respectively for photon with transverse energies between 10 and 15 GeV , between 15 and 20 GeV and above 20 GeV .
- The systematics from the uncertainty on the correlation in background events between the isolation energy and the shower shape variables used to define the four signal and background control regions is estimated by comparing the nominal purity measurement with the result obtained when neglecting completely this correlation (i.e. assuming $\frac{N_{\mathrm{bkg}}^{A}}{N_{\mathrm{bkg}}^{B}} \frac{M_{\mathrm{bkg}}^{B}}{M_{\mathrm{bkg}}^{A}}=1$ ). In addition, we perform again the purity measurement after varying the background pseudo-correlation factor by the difference (0.06) observed between our nominal simulated background sample and an alternative sample of $2 \rightarrow 2$ QCD hard-scattering events (excluding prompt photon production) generated with Herwig[17]. The purity result changes by at most $9.5 \%, 4.7 \%$ and $1.9 \%$ for photons with transverse energies between 10 and 15 GeV , between 15 and 20 GeV and above 20 GeV , respectively.
- The uncertainty on the electromagnetic energy scale, transported from test-beam measurements before in-situ determination, is $3 \% .^{2}$ We repeat the measurement after changing by $3 \%$, for each photon candidate, the cluster energy, the isolation and the cell energies used in the photon identification variables. The purity changes by at most $5 \%$, while the impact on the signal yield is higher (up to $25 \%$ between 10 and 15 GeV ).

The various systematic uncertainty sources and the corresponding uncertainties on the signal yield and purity in the three transverse energy intervals are summarized in Tables 4 and 5 . Combining the different effects above, we estimate the total systematic uncertainty on the purity to be between $24 \%$ and $6 \%$ as a function of transverse energy. The total systematic uncertainties for the purity measurements in each $E_{\mathrm{T}}$ bin are summarized in the last row of Table 3.

Some additional cross-checks have been performed to confirm the robustness of the method, but they have not been included in the systematic uncertainties:

[^54]Table 4: Systematic uncertainties on the estimated signal yield in three intervals of the photon transverse energy.

| $E_{\mathrm{T}}$ interval [GeV] | $10 \leq E_{\mathrm{T}}<15$ | $15 \leq E_{\mathrm{T}}<20$ | $E_{\mathrm{T}} \geq 20$ |
| :--- | :---: | :---: | :---: |
| Alternative non-isolated control region | 496 | 19 | 11 |

| Total | 1362 | 86 | 59 |

Table 5: Systematic uncertainties on the signal purity in three intervals of the photon transverse energy.

| $E_{\mathrm{T}}$ interval [GeV] | $10 \leq E_{\mathrm{T}}<15$ | $15 \leq E_{\mathrm{T}}<20$ | $E_{\mathrm{T}} \geq 20$ |
| :--- | :---: | :---: | :---: |
| Alternative non-isolated control region | 0.03 | 0.02 | 0.01 |
| Alternative non-identified control region | 0.21 | 0.02 | 0.03 |
| Signal inefficiency of the identification criteria | 0.03 | 0.03 | 0.04 |
| Signal composition | 0.01 | 0.02 | 0.02 |
| Correlation between isolation and identification | 0.10 | 0.05 | 0.02 |
| Energy scale | 0.05 | 0.05 | 0.01 |
| Total | 0.24 | 0.08 | 0.06 |

- The purity is measured separately for converted and unconverted samples. The total signal yield when summing both samples is consistent with the yield estimated from the combined sample within less than 0.4 times the statistical error on the signal yield (the total yield changes by $9 \%$ for transverse energies between 10 and 15 GeV , by $3.5 \%$ between 15 and 20 GeV , and by $1 \%$ above 20 GeV ). Above 15 GeV we have a clear evidence of both unconverted and converted photons: their yields are respectively $868 \pm 72$ and $425 \pm 49$ (including statistical error only, from data and from the limited size of the simulated samples). The purity for unconverted photons is about $10 \%$ higher than for converted ones. We note that the ratio between the converted and the unconverted signal yields for transverse energies above $15 \mathrm{GeV},(0.49 \pm 0.07)$, is in good agreement with Monte Carlo expectations $(0.45 \pm 0.01)$.
- The purity is measured separately in four pseudorapidity intervals, where the background level and the correlations between the isolation and the shower shape variables are expected to be different. The total signal yield when summing the yields in the four pseudorapidity ranges is consistent with that estimated from the combined sample within $10 \%$ or less of the statistical uncertainty on the signal yield (the total yield changes by $2.2 \%$ for transverse energies between 10 and 15 GeV , by $1.0 \%$ between 15 and 20 GeV , and by $0.2 \%$ above 20 GeV ).
- an alternative method which relies more finely on the shape of the isolation variable is used to estimate the purity. The isolation energy background distribution is subtracted from the observed distribution in data for photon candidates passing the tight identification criteria. The background template is obtained by scaling by the ratio $N^{B} / M^{B}$ the isolation energy distribution in a background enriched control data sample, formed by the photon candidates failing the tight criteria on the shower shape variables used to define the background control sample in the nominal measure-
ment. This method gives consistent results (always within at most $2 \%$, but typically within less than $1 \%$ in most of the $|\eta|$ and $E_{\mathrm{T}}$ bins) with those obtained from the simpler counting method used in this analysis when neglecting the signal in the background regions and neglecting correlations between the isolation and the identification variables in background.

## 7 Conclusion

A signal of prompt photon production has been extracted from a small set of $7 \mathrm{TeV} p p$ collision data collected at the LHC with the ATLAS detector. After tight identification cuts, a statistically significant prompt photon yield above 15 GeV is found, as well as a prompt photon purity which increases as a function of the photon transverse energy. For transverse energies above 20 GeV a signal yield of ( $618 \pm 72$ ) prompt photons with a purity of $(72 \pm 7) \%$ is measured, including statistical and systematic uncertainties. Together with the first estimates of the photon efficiency measurement, this gives confidence that a measurement of the prompt photon production cross section will soon be possible and that physics studies with photons in the final state are promising.

# Search for the Higgs boson in the diphoton final state with $38 \mathbf{~ p b}^{-1}$ of data recorded by the ATLAS detector in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ 

The ATLAS collaboration

#### Abstract

This note reports on a search for the Standard Model Higgs boson in the diphoton decay channel with the ATLAS detector at a proton-proton center-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$, with an integrated luminosity of $38 \mathrm{pb}^{-1}$. In the Higgs mass range $110<m_{H}<140 \mathrm{GeV}$, the expected upper limit on the cross-section for this search is about 20 times larger than the Standard Model prediction. The observed exclusions range from 8 times the Standard Model prediction at 127 GeV , to 38 times at 116 GeV . A simulation-based study of signal, incorporating the best current knowledge of the detector performance, is presented and used in the limit setting.

## 1 Introduction

This note presents the first result of the ATLAS search for the Standard Model (SM) Higgs boson in the diphoton decay channel with the $38 \mathrm{pb}^{-1}$ of data collected in 2010 at a center-of-mass energy of 7 TeV . The general analysis strategy, the expected background estimation and the details of the data-driven background measurements follow closely the analysis described in [1]. The main goal of the previous work was to assess the background to this search with the first data taken in 2010. Despite the limited statistics, this measurement of the overall background is significantly more precise than all previous predictions based on simulation. Estimating the background directly in the data also allowed a consistent use of next-to-next-to-leading order (NNLO) cross sections for the signal compared to the background, since the simulation of backgrounds never reached this order in perturbative QCD . Based on the profile likelihood method introduced in [2,3] and used in [4], the exclusion limit on $H \rightarrow \gamma \gamma$ channel is set with current data. The impact of systematic uncertainties on the sensitivity is discussed.

## 2 Data sample

In comparison to the previous work [1], this analysis benefits from an improved estimation of the integrated luminosity [5], an additional $2 \mathrm{pb}^{-1}$ of recovered data, an improved photon identification which yields reduced systematic uncertainties, and finer-grained offline energy calibrations, evaluated with a sample of $Z \rightarrow e^{+} e^{-}$events, that improve the photon energy resolution and the corresponding uncertainties on the diphoton invariant mass resolution. The events are selected by a trigger which requires two photon candidates each with a transverse energy exceeding 15 GeV . In addition the events have to fulfill the criteria that the detector was fully operational. For the surviving events, at least two photon candidates in the central detector region with $p_{T}>25 \mathrm{GeV}$, and passing a loose photon identification criterion are required. Then kinematic cuts demanding transverse energy larger than 40 GeV and 25 GeV are applied on the leading and subleading photon candidates respectively. In addition tight photon identification and isolation criteria are applied [6]. The direction of the photon candidates is measured using the information from the first sampling of the electromagnetic calorimeter and on the measured position of the primary vertex. For events with more than one vertex reconstructed, the vertex associated with tracks having the highest sum of $p_{T}$ is used. The invariant mass is then deduced from the two photons with respect to this primary vertex. The final 2010 data sample has 99 events with a diphoton invariant mass between 100 and 150 GeV .

The number of diphoton, photon-jet and dijet events ( $N_{\gamma \gamma}, N_{\gamma j}+N_{j \gamma}$ and $N_{j j}$, where the first and second indices refer to the leading and subleading photon candidates, respectively) in the data sample are estimated by means of a double-sideband method, where the photon purity is evaluated by extrapolating to the signal region the background estimated from control regions located in the sideband plane of identification and isolation variables. The estimates of the sample composition are reported in Table 1, together with the predictions for the background components made in [7], corrected to take into account the effects of data quality, pile-up and the changes in the selection criteria. The contribution arising from Drell-Yan events is evaluated with a data-driven technique [1], and is not counted in the diphoton component. Figure 1 shows the diphoton invariant mass distribution, together with the predictions for the irreducible (diphoton) and reducible (photon-jet plus dijet) components of the backgrounds, and the composition estimated with the double-sideband method.

## 3 Signal modeling

At the LHC, there are several possible Higgs boson production processes, with cross sections calculated at different levels of precision. Monte Carlo (MC) samples for each subprocess, produced by the ATLAS

Table 1: The number of irreducible $\left(N_{\gamma \gamma}\right)$, reducible $\left(N_{\gamma j}+N_{j \gamma}, N_{j j}\right)$ and Drell-Yan $\left(N_{\mathrm{DY}}\right)$ background events to the $H \rightarrow \gamma \gamma$ search in the $100-150 \mathrm{GeV}$ mass range. For the measured number of events, the errors are statistical and systematic, respectively. For the expected number of events, the errors on the irreducible and reducible components arise from the theoretical uncertainty on the prediction; for the Drell-Yan component, the corresponding uncertainty arises from the MC statistics.

|  | $N_{\gamma \gamma}$ | $N_{\gamma j}+N_{j \gamma}$ | $N_{j j}$ | $N_{\mathrm{DY}}$ |
| :---: | :---: | :---: | :---: | :---: |
| Data | $75.0 \pm 13.3_{-3.6}^{+2.7}$ | $19.6 \pm 7.5 \pm 3.9$ | $1.5 \pm 0.7_{-0.5}^{+1.8}$ | $2.9 \pm 0.1 \pm 0.6$ |
| Expected | $86 \pm 23$ | $31 \pm 15$ | $1 \pm 1$ | $2.7 \pm 0.2$ |

Figure 1: Left: the diphoton invariant mass for the 99 events composing the data sample. The overlaid histograms represent the cumulative Drell-Yan (red solid), dijet (blue dotted), photon-jet (blue dashed) and diphoton (blue solid) components of the background, according to the predictions from theoretical models and simulation obtained in [7] and summarized in Table 1. The dark yellow band is the uncertainty for the reducible background components, and the yellow band is the total uncertainty on the reducible plus irreducible backgrounds. Right: the results of the double-sideband method for the 99 events composing the data sample. For the diphoton, photon-jet and dijet components, the extracted number of events on data (black dots) are compared with the corresponding predictions (yellow, mediumdark yellow and dark yellow bands, respectively). For the Drell-Yan component, the number of events is compared with the expected number of events predicted from simulation.
detector simulation package, and for values of the Higgs boson mass ranging from 110 to 140 GeV , are used to extract the efficiency of the signal reconstruction and the invariant mass resolution. Given the bunch structure and the instantaneous luminosities reached in 2010, the average number of proton-proton collisions per bunch-crossing was about 2.3. In order to mimic this effect, the MC event samples were produced with a configuration where the average number of interactions per bunch-crossing is equal to 2.2.

Table 2 summarizes the expected number of events from Higgs signals, as calculated from the Monte Carlo samples. The dominant uncertainties on the expected number of events, discussed in detail in Section 4 and summarized in Table 3, arise from the photon identification and isolation efficiencies and the theoretical uncertainties on the Higgs boson production cross-section [8].

The probability-density function (PDF) for the signal invariant mass is modeled by a Crystal Ball function (CB) (which takes into account the core resolution and a non-Gaussian tail extending towards
lower mass values) added to a small, wider Gaussian component (which takes into account outliers in the distribution). Figure 2 shows the invariant diphoton mass distribution for a sample of simulated events with a 120 GeV Higgs decaying into two photons and the PDF used to describe it. The resolution functions for Higgs at masses other than the simulated values are obtained through a linear interpolation of the PDF parameters.

Table 2: The expected Higgs signal yields for various mass points, for an integrated luminosity of 38 $\mathrm{pb}^{-1}$. The error combines the experimental systematic uncertainties and the theoretical uncertainty on the SM Higgs boson production cross-section [8].

| Higgs boson mass [GeV] | 110 | 115 | 120 | 130 | 140 |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Number of signal events | $0.43_{-0.09}^{+0.11}$ | $0.45_{-0.10}^{+0.11}$ | $0.45_{-0.10}^{+0.11}$ | $0.41_{-0.08}^{+0.10}$ | $0.31 \pm 0.08$ |

Figure 2: The distribution of the diphoton invariant mass for simulated events with a 120 GeV Higgs boson decaying into two photons. The data points are the output of the MC simulations. To reproduce the behaviour in data, the photon energy and resolution corrections described in Section 2 are applied on the invariant mass distribution. Furthermore, the fitted curve shows the PDF describing the invariant mass distribution; this represents also the resolution function used in the statistical analaysis described in Section 5. The FWHM of the distribution is 4.4 GeV .

The data points are the output of the MC simulations. To reproduce the behaviour in data the photon energy and resolution corrections described in Section 2 are applied on the invariant mass distribution. In addition, the fitted curve is shown.

## 4 Systematics

The background in the signal region is described with an exponential functional form using two nuisance parameters (a negative exponential coefficient and the overall normalization) which are fitted to the data.

The systematic uncertainties related to the signal can be divided into four main categories, and are summarized in Table 3. The first is the uncertainty on the luminosity which is common and correlated
among all Higgs decay channels. The second is the theoretical uncertainty on the overall normalization of the signal, dominated by the uncertainty on the computation of the production cross section as estimated in [8] (mostly due to scale dependence and uncertainties on the parton density functions). The third category corresponds to uncertainties on the efficiency, whose two main components are the uncertainty on the photon identification and on the isolation; these uncertainties are estimated from comparisons of data and fully simulated MC samples of photons and electrons. The fourth category of systematic uncertainties is on the invariant mass resolution. The contributions arising from uncertainties on the photon energy resolution are estimated using a fine-grained energy recalibration extracted from Z decays to electrons taking into account possible biases from the electron-to-photon extrapolation. An additional contribution arises from the impact of pile-up on the invariant mass resolution.

|  | Source | Uncertainty |
| :---: | :--- | :---: |
|  | Luminosity | $\pm 3.4 \%$ |
| Theory | Cross-section (scales) | ${ }_{-15}^{+20} \%$ |
| Efficiency | Photon identification | $\pm 11 \%$ |
|  | Photon isolation | $\pm 10 \%$ |
|  | Trigger | ${ }_{-3.7}^{+1.1} \%$ |
| Resolution | Calibration |  |
|  | $e \rightarrow \gamma$ extrapolation | $\pm 13 \%$ |
|  | Pile-up |  |

Table 3: Relative systematic uncertainties associated to the signal normalization and invariant mass resolution. For the resolution, the quoted uncertainty is relative to the width of the invariant mass.

Systematic uncertainties are treated by adding nuisance parameters and penalty PDFs that reflect the impact of these uncertainties in the likelihood function that is used in the definition of the test statistic. These penalty PDFs are in general simple Gaussian functions, with the exception of the trigger efficiency and theoretical cross-section, for which a double-sided Gaussian function is used.

## 5 Observed Sensitivity

The limits are set using a Power Constrained Limit (PCL) method. The procedure uses the profile likelihood ratio described in [2,3], with the p-value or $\mathrm{CL}_{s+b}$ extracted from the distribution of the profile likelihood ratio by toy MC. To protect against excluding the (signal) null hypothesis in cases of downward fluctuations of the background, the observed limit is not allowed to fluctuate below the $-1 \sigma$ expected limit. This is equivalent to restricting the statistical power of the analysis not to go below $16 \%$. This method is therefore referred to as the Power Constrained Limit $\mathrm{PCL}_{s+b}$. We therefore avoid showing the $-2 \sigma$ band in the resulting limit plot. Results using the $\mathrm{CL}_{s}$ (confidence level of excluding the signal hypothesis) method [9] are also provided as a reference.

Table 4 shows the upper bound on the exclusion at the $95 \%$ CL, in units of the SM Higgs boson cross-section, as a function of the Higgs boson mass for different methods. The systematic uncertainties introduced in Section 4 are taken into account in the limit setting by incorporating the corresponding penalty PDFs in the likelihood function used to model the data sample. On average, the incorporation of systematics degrades the exclusion limit by up to $10 \%$. With $38 \mathrm{pb}^{-1}$ of data, the obtained limits are mostly driven by statistical uncertainty, which explains the limited impact of systematic uncertainties. As expected, results from the $\mathrm{CL}_{s}$ methods are more conservative than those from the $\mathrm{CL}_{s+b}$ method.

Figure 3 shows the distribution of upper limits expected in the absence of any signal, indicated
by the median expected limit and $\pm 1 \sigma$ and $+2 \sigma$ contours, in addition to the observed limit. As the observed limit is constrained not to lie below the $-1 \sigma$ band for the expected limit, the $-2 \sigma$ band is not displayed in the plot. For Higgs masses around 127,132 and 140 GeV , the PCL constraint prevents a false exclusion due to a downwards background fluctuation. With an integrated luminosity of $38 \mathrm{pb}^{-1}$, this analysis shows that, in the median, cross-sections larger than about 20 times the prediction for the SM Higgs boson may be excluded. This limit is already comparable with recent results from Tevatron in the $H \rightarrow \gamma \gamma$ channel [10, 11, 12]. As a comparison, Figure 4 in Appendix A shows the observed exclusion computed with the $\mathrm{CL}_{s}$ method, for which the limits are around 5 units larger than the corresponding results using the $\mathrm{CL}_{s+b}$ method.

Table 4: Upper limits on the cross-section as a function of mass, in units of the SM prediction for the Higgs boson, at the $95 \% \mathrm{CL}$ for the $38 \mathrm{pb}^{-1}$ of data taken in 2010. $\mathrm{PCL}_{s+b}$ means the $\mathrm{CL}_{s+b}$ method with Power Constrained Limit technique for the computation of the observed limit. Results using $\mathrm{CL}_{s}$ are also provided as a reference.

| $\mathrm{m}_{H}[\mathrm{GeV}]$ | Expected limit |  | Observed limit |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{CL}_{s+b}$ | $\mathrm{CL}_{s}$ | $\mathrm{PCL}_{s+b}$ | $\mathrm{CL}_{s}$ |
| 110 | 22.1 | 27.9 | 16.1 | 24.0 |
| 115 | 20.1 | 25.5 | 37.9 | 39.7 |
| 120 | 19.9 | 24.4 | 23.6 | 27.2 |
| 130 | 19.1 | 24.0 | 9.3 | 18.3 |
| 140 | 23.0 | 29.9 | 8.0 | 20.7 |

Figure 3: The excluded Higgs production cross-section at the $95 \%$ CL, normalized by the SM prediction, as a function of the Higgs boson mass with $38 \mathrm{pb}^{-1}$ of data. The black solid line and the red dotted line correspond to the observed limit and expected limit, respectively. The green (yellow) band corresponds to the expected exclusion in the case of a $1 \sigma(2 \sigma)$ fluctuation of the background. The exclusion results are computed using $\mathrm{CL}_{s+b}$ with PCL.

## 6 Conclusion

In this note, the search for the $H \rightarrow \gamma \gamma$ search is reported with $38 \mathrm{pb}^{-1}$ data of proton-proton collisions at 7 TeV center-of-mass energy collected by the ATLAS experiment in 2010. Compared to [1], a modified photon identification and a set of finer-grained photon energy corrections are used in this analysis. The background to the $H \rightarrow \gamma \gamma$ signal is shown to be dominated by diphoton events. The study of the signal and systematics with current data are described. With the baseline $\mathrm{CL}_{s+b}$ method using the Power Constrained Limit technique for the observed exclusion, upper limits at the $95 \%$ Confidence Level are set on the cross-section for the $H \rightarrow \gamma \gamma$ process, in units of the expectation for the SM , as a function of the Higgs boson mass in the range $110-140 \mathrm{GeV}$. The exclusion limit ranges from 8 times the SM cross-section at $m_{H}=127 \mathrm{GeV}$ to 38 times the SM cross-section at $m_{H}=116 \mathrm{GeV}$. The expected limit based on CLs is comparable with recent results from the Tevatron in this channel [10, 11, 12].

## Appendix A Results of exclusion with the $\mathbf{C L}_{s}$ method

Figure 4 shows the expected $1 \sigma$ and $2 \sigma$ exclusion intervals for the background-only test statistic in addition to the expected and observed exclusion limits. This method gives more conservative results than PCL in the region where the sensitivity to the signal is weak.

Figure 4: The excluded Higgs production cross-section at the $95 \%$ CL, normalized by the SM prediction, as a function of the Higgs boson mass with $38 \mathrm{pb}^{-1}$ of data. The black solid line and the red dotted line correspond to the observed limit and expected limit respectively. The green (yellow) band correspond to the expected exclusion in the case of $\mathrm{a} \pm 1 \sigma( \pm 2 \sigma)$ fluctuation of the background. The results are computed using the $\mathrm{CL}_{s}$ method.

## ATLAS NOTE

ATLAS-CONF-2011-032
March 22, 2011

# Jet energy scale and its systematic uncertainty in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ with ATLAS 2010 data 

The ATLAS collaboration

#### Abstract

The jet energy scale (JES) and its systematic uncertainty are determined for jets measured with the ATLAS detector using $35 \mathrm{pb}^{-1}$ proton-proton collision data at $\sqrt{s}=7 \mathrm{TeV}$. Jets are reconstructed with the anti- $k_{t}$ algorithm with distance parameters $R=0.4$ and $R=0.6$, and are calibrated to the hadronic energy scale using Monte Carlo. The JES systematic uncertainty is evaluated for calorimeter jets with calibrated transverse momenta $p_{\mathrm{T}}^{\text {iet }}>20 \mathrm{GeV}$ and pseudorapidities $|\eta|<4.5$. It is estimated using a combination of insitu techniques and an analysis of systematic variations in Monte Carlo simulations, and it is found to be of similar size for both jet distance parameters studied. The smallest JES uncertainty of less than $2.5 \%$ is found in the central calorimeter region $(|\eta|<0.8)$ for jets with $60 \mathrm{GeV} \leq p_{\mathrm{T}}^{\text {jet }}<800 \mathrm{GeV}$. The JES uncertainty is the largest for low- $p_{\mathrm{T}}$ ( $20 \mathrm{GeV} \leq p_{\mathrm{T}}^{\text {jet }}<30 \mathrm{GeV}$ ) jets in the most forward region $3.2 \leq|\eta|<4.5$ where it amounts to $14 \%$. The additional energy due to multiple proton-proton interactions is corrected for and the remaining uncertainty is less than $1.5 \%$ per additional interaction for jets with $p_{\mathrm{T}}^{\text {jet }}>50 \mathrm{GeV}$ and decreases with $p_{\mathrm{T}}$. The JES is validated up to $p_{\mathrm{T}}^{\text {jet }}=1 \mathrm{TeV}$ using several in-situ methods.

## 1 Introduction

Over the course of the year 2010, the ATLAS detector [1] has been collecting data from proton-proton collisions at a center-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ delivered by the Large Hadron Collider (LHC). Understanding and measuring the performance of jets is crucial for many physics analyses at the LHC. The uncertainty of the jet energy calibration (jet energy scale, or JES) is the dominant experimental uncertainty for numerous physics results, for example the cross-section measurement of the inclusive jets, dijets and multijets [2-5], as well as vector boson accompanied by jets [6], and new physics searches with jets in the final state [7-10].

A first estimate of the JES uncertainty in the ATLAS detector was based on information available before the first LHC collisions and exploiting transverse momentum balance in di-jet events, and is described in Ref. [11]. An updated estimate of the JES uncertainty has been derived in Ref. [12] using in-situ measurements of the single hadron response [13,14]. These measurements allowed a significant reduction of the JES uncertainty in the central detector region. This note presents a further reduction of the JES systematic uncertainty in light of the increased knowledge of the detector performance gained during the analysis of the first year of ATLAS data [2,13-19] and results from the JES validation using in-situ techniques [20-22].

The estimate of the JES uncertainty described in this note follows closely the procedure described in Refs. [11, 12]. A reduction in the overall JES uncertainty is achieved thanks to more precise in-situ measurement of the calorimeter response to isolated hadrons and of the absolute electromagnetic energy scale of the calorimeters from the analysis of $Z$-boson decays in the electron channel $(Z \rightarrow e e)$.

The outline of the note is as follows: Sections 2-4 describe the ATLAS calorimeters, the Monte Carlo (MC) simulation framework, the event samples used for the estimate of the JES and the jet reconstruction procedure. Section 5 describes the jet calibration. It also details the jet selections applied to the Monte Carlo simulation samples used for the estimate of the jet energy scale and its uncertainty. Section 6 describes the sources of systematic uncertainties for the jet energy scale and their derivation using simulated and collision data. The effect of multiple proton-proton interactions (pile-up) that occur in addition to the event of interest on the jet energy measurement is discussed in Section 7. The combination of the individual uncertainty contributions is described in Section 8. A summary of the validation of the JES uncertainty using in-situ techniques is described in Section 9.

## 2 The ATLAS detector

The ATLAS detector consists of a tracking system (inner detector, or ID in the following) in a 2 T solenoidal magnetic field up to a pseudorapidity ${ }^{1}|\eta|<2.5$, sampling electromagnetic and hadronic calorimeters up to $|\eta|<4.9$, and muon chambers in a toroidal magnetic field. A detailed description of the ATLAS experiment can be found elsewhere [1].

Jets are reconstructed using the ATLAS calorimeter detectors, whose granularity and material varies as a function of $\eta$. The electromagnetic calorimeters employ liquid argon as the active material and lead for the accordion-shaped absorbers, and they cover up to $|\eta|<3.2$ (the barrel-endcap transition is at $1.37<|\eta|<1.52$ ). Liquid argon presamplers upstream of the electromagnetic calorimeter allow for corrections of the energy loss in front of the calorimeter due to the presence of the barrel solenoid and inner detector cryostat. The hadronic calorimeters make use of plastic scintillator and steel for the barrel and extended barrels (covering $0<|\eta|<0.8$ and $0.8<|\eta|<1.7$, respectively), and liquid argon and

[^55]copper for the endcaps $(1.5<|\eta|<3.2)$. The forward calorimeter is a liquid argon and tungsten/copper detector, and extends the calorimetry up to $|\eta|<4.9$.

## 3 Monte Carlo simulation of jets in the ATLAS detector

### 3.1 Event generators

Inclusive QCD jet events from proton-proton collisions at a center-of-mass of $\sqrt{s}=7 \mathrm{TeV}$ are generated using Pythia [23] 6.4.24 and Alpgen [24].

Pythia simulates non-diffractive proton-proton collisions using a $2 \rightarrow 2$ matrix element in leadingorder of the strong coupling to model the hard subprocess, and use parton showers to model additional radiation in the leading-logarithmic approximation. Mutliple parton interactions, as well as fragmentation and hadronisation are also simulated within PYthia. The parton distribution function (PDF) used for the Pythia samples is the modified leading order set MRST LO* [25].

ALPGEN is a leading order matrix-element generator for hard multi-parton processes in hadronic collisions. It is interfaced to the HERWIG generator [26] to produce parton showers in leading-logarithmic approximation. Parton showers are matched to the matrix element with the MLM matching scheme [27]. The hadronization is described by the cluster model also simulated within HERWIG. For the hadronization HERWIG is used and soft multiple parton interaction are modelled using Jimmy [28]. The PDF used for the Alpgen samples is CTEQ6L1 [29].

The parameters used for tuning the underlying event models in the Pythia and Alpgen event generators have been derived from minimum bias measurement in ATLAS data [30,31], and are denoted as ATLAS MC10 tune. No additional interactions within the same bunch crossing are simulated in any of the Monte Carlo samples used for the JES calibration and the determination of its uncertainty.

### 3.2 Simulation of the ATLAS detector

The Geant4 software toolkit [32] within the ATLAS simulation framework [33] propagates the generated particles through the ATLAS detector and simulates their interactions with the detector material. The energy deposited by particles in the active detector material is converted into detector signals with the same format as the ATLAS detector read-out. The detector signals are in turn reconstructed with the same reconstruction software as used for the data [33].

For the simulation of hadronic interactions in the detector, the GEANT4 set of processes called QGSP_BERT is chosen [34]. In this set of processes, the Quark Gluon String model [35] is used for the fragmentation of the nucleus, and the Bertini cascade model [36] for the description of the interactions of hadrons in the medium of the nucleus. The GEANT4 simulation and in particular the hadronic interaction model have been validated with test-beam measurements for the barrel [37-41] and the endcap [42-44] calorimeters. Further tests have been carried out in-situ using identified single particles from kaon and lambda decays produced in proton-proton collisions [45]. Excellent agreement between simulation and data has been found for pions and protons in the range of a few hundred MeV to 6 GeV , while the response of anti-protons is underestimated by about $10 \%$.

### 3.3 Nominal Monte Carlo simulation sample

The baseline (nominal) Monte Carlo sample used to derive the jet energy scale and to estimate the sources of its systematic uncertainty is composed by inclusive QCD jet events generated with the PYTHIA event generator and passed through the full ATLAS detector simulation. ATLAS jet data have been shown to be reasonably well described by PYthia MC simulations before and after jet calibration is applied [2, 13-19].

Studies of the material of the inner detector upstream the calorimeters have been performed using secondary hadronic interactions $[46,47]$. The ATLAS detector geometry used in the simulation of the nominal sample reflect the geometry of the detector as best known at the time of this study.

## 4 Jet reconstruction in the ATLAS detector

Jets are reconstructed using the anti- $k_{t}$ algorithm [48] with distance parameters $R=0.6$ and $R=0.4$ using the FastJet software [49, 50]. In the following, only anti- $k_{t}$ jets with distance parameter $R=0.6$ are discussed in detail. The results for jets with $R=0.4$ are similar unless stated otherwise. The fourmomentum recombination scheme is used.

The constituents of calorimeter jets are topological clusters (topoclusters) [51] that group together calorimeter cells. They are designed to follow the shower development taking advantage of the fine segmentation of the ATLAS calorimeters. The topocluster formation algorithm starts from a seed cell, whose signal-to-noise ratio (estimated as the energy deposited in the calorimeter cell over the RMS of the energy distribution measured in random events) is above a threshold of 4 . Cells neighboring the seed that have a signal-to-noise ratio of at least 2 are included iteratively, and finally all neighboring cells are added to the topocluster. The topoclustering algorithm also includes a splitting step: All cells in a cluster are searched for local maxima in terms of energy content, and the local maxima are then used as seeds for a new iteration of topological clustering, which will split the original cluster in more topoclusters. A topocluster is defined to have an energy equal to the energy sum of all the included cells, zero mass and a reconstructed direction as that of a unit vector originating from the center of the ATLAS coordinate system pointing to the energy-weighted topocluster barycenter.

Monte Carlo truth jets are reconstructed from the stable particles with a lifetime longer than 10 ps in the MC event record (excluding muons and neutrinos) using the same jet algorithm as for calorimeter jets. The four-momentum of a jet (before further calibration) is equal to the vectorial sum of the fourmomenta of its constituents.

## 5 Jet energy scale calibration

Jets are reconstructed at the electromagnetic scale, which is the basic signal scale for the ATLAS calorimeters. It accounts correctly for the energy deposited in the calorimeter by electromagnetic showers. This energy scale is established using test-beam measurements for electrons in the barrel [37,52-55] and endcap calorimeters [42,43]. The absolute calorimeter response to energy deposited via electromagnetic processes has also been validated in the hadronic calorimeters using muons, both from testbeams [37,56] and produced by cosmic-rays in-situ [57]. The energy scale of the electromagnetic calorimeters has been corrected using the invariant mass of $Z \rightarrow e e$ events from collision events ${ }^{2}$.

The goal of the jet energy scale calibration is to correct the energy and momentum of the jets measured in the calorimeter to those of the jet at the hadronic scale. The hadronic jet energy scale is on average restored using data-derived corrections and calibration constants derived from the comparison of the reconstructed jet kinematics to the one of the corresponding truth level jet in Monte Carlo studies. The jet energy scale calibration is then validated with in-situ techniques.

The jet calibration corrects for detector effects that affect the jet energy measurement:

1. partial measurement of the energy deposited by hadrons (calorimeter non-compensation),
2. energy losses in inactive regions of the detector (dead material),

[^56]3. energy deposits from particles not contained in the calorimeter (leakage),
4. energy deposits of particles inside the truth jet that are not included in the reconstructed jet,
5. signal losses in calorimeter clustering and jet reconstruction.

Presently, ATLAS uses a simple calibration scheme that applies jet-by-jet corrections as a function of the jet energy and pseudorapidity to jets reconstructed at the electromagnetic scale. This calibration scheme (called EM+JES) allows a direct evaluation of the systematic uncertainty and is therefore suitable for first physics analyses. The additional energy due to multiple proton-proton interactions within the same bunch crossings (pile-up) is corrected for before the hadronic energy scale is restored, so that the derivation of the jet energy scale calibration constants is factorised and does not depend on the number of additional interactions measured.

Other calibration schemes, described in Refs. [18,58], use additional cluster-by-cluster and/or jet-byjet information to reduce some of the sources of fluctuations in the jet energy response, thereby improving the jet resolution. These calibration techniques are presently undergoing commissioning in ATLAS.

The EM + JES calibration scheme consists of three subsequent steps as outlined below and detailed in the following sub-sections:

1. the average additional energy due to pile-up is subtracted from the energy measured in the calorimeters using correction constants extracted from an in-situ measurement,
2. the position of the jet is corrected such that the jet direction points to the primary vertex of the interaction instead of the geometrical centre of ATLAS detector,
3. the jet energy and position as reconstructed in the calorimeters are corrected using constants derived from the comparison of the kinematics of reconstructed jets and corresponding truth jets in Monte Carlo.

The calibration restores the jet energy scale within $2 \%$ for the full kinematic range, and a systematic uncertainty is assigned for the remaining non-closure as discussed in Section 6.2.

### 5.1 Pile-up correction

The energy of jets can include energy that does not come from the event of interest, but is instead produced by multiple proton-proton interactions within the same bunch crossing. A correction is derived from minimum bias data as a function of number of reconstructed primary vertices $N_{\mathrm{PV}}$ and jet pseudorapidity $\eta$, and takes into account the average additional energy deposited in a fixed grid of $0.1 \times 0.1$ in the $(\eta, \phi)$-plane (calorimeter towers) and the average number of such towers in a jet. This correction is applied at the electromagnetic scale as the first step of the calibration scheme. Further details on the pileup offset correction can be found in in Ref. [59]. The sensitivity of the jet energy resolution to pile-up has been studied and it has been found to be smaller than $1 \%$.

### 5.2 Jet origin correction

Calorimeter jets are reconstructed using the geometrical center of the ATLAS detector as reference to calculate the direction of jets and their constituents (see Section 4). The direction of each topocluster is corrected to point back to the primary vertex with the highest associated sum of track transverse momenta squared ( $\sum p_{T, \text { track }}^{2}$ ) in the event. The kinematics of each topocluster is recalculated using the vector from the primary vertex to the topocluster centroid as its direction. The raw jet four-momentum is thereafter redefined as the vector sum of the topoclusters four-momenta. This correction improves the angular resolution, resulting in a small improvement $(<1 \%)$ in the jet $p_{T}$ response. The jet energy is unaffected.

### 5.3 Final jet energy correction

The final step of the EM+JES jet calibration restores the reconstructed jet energy to the energy of the Monte Carlo truth jet. Since pile-up effects have already been corrected for, the Monte Carlo samples used to derive the calibration do not include multiple proton-proton interactions within the same bunch crossing.

The calibration is derived using all isolated calorimeter jets that have a matching isolated truth jet within $\Delta R=0.3\left(\Delta R=\sqrt{\Delta \eta^{2}+\Delta \phi^{2}}\right)$. Here, an isolated calorimeter (truth) jet is defined as a jet that has no other calorimeter (truth) jet with EM-scale (truth) $p_{T}>7 \mathrm{GeV}$ within $\Delta R=2.5 R$, where $R$ is the distance parameter of the jet algorithm. The EM-scale energy response $\mathcal{R}=E_{\text {calo }}^{\mathrm{EM}} / E_{\text {truth }}$ for each calorimeter-truth jet pair is measured in bins of the truth jet energy $E_{\text {truth }}$ and calorimeter jet detector pseudorapidity $\eta_{\text {det }}$, referring to the pseudorapidity of the original reconstructed jet before the origin correction. For each $\left(E_{\text {truth }}, \eta_{\text {det }}\right)$-bin, the measured EM-scale energy response $\langle\mathcal{R}\rangle$ is defined as the peak position of a Gaussian fit to the $E_{\text {calo }}^{\mathrm{EM}} / E_{\text {truth }}$ distribution, and the average calorimeter jet energy $\left\langle E_{\text {calo }}^{\mathrm{EM}}\right\rangle$ is determined. For a given $\eta_{\text {det }}$-bin $k$, a function $\mathcal{F}_{\text {calib, } k}\left(E_{\text {calo }}^{\mathrm{EM}}\right)$ of the jet response is obtained using a fit of the $\left(\left\langle E_{\text {calo }}^{\mathrm{EM}}\right\rangle_{j},\langle\mathcal{R}\rangle_{j}\right)$ points for each $E_{\text {truth }}$-bin $j$, where the fitting function is parameterised as:

$$
\begin{equation*}
\mathcal{F}_{\text {calib }, k}\left(E_{\text {calo }}^{\mathrm{EM}}\right)=\sum_{i=0}^{N_{\max }} a_{i}\left(\ln E_{\text {calo }}^{\mathrm{EM}}\right)^{i}, \tag{1}
\end{equation*}
$$

where $a_{i}$ are free parameters, and $N_{\max }$ is chosen between 1 and 6 depending on the goodness of the fit. The final jet energy scale correction that relates the measured calorimeter jet energy scale to the hadronic scale is then defined as $1 / \mathcal{F}_{\text {calib }, k}\left(E_{\text {calo }}^{\mathrm{EM}}\right)$ in the following:

$$
\begin{equation*}
E_{\text {calo }}^{\mathrm{EM}+\mathrm{JES}}=\frac{E_{\text {calo }}^{\mathrm{EM}}}{\mathcal{F}_{\text {calib }}\left(E_{\text {calo }}^{\mathrm{EM}}\right) \mid \eta_{\text {det }}}, \tag{2}
\end{equation*}
$$

where $\left.\mathcal{F}_{\text {calib }}\left(E_{\text {calo }}^{\mathrm{EM}}\right)\right|_{\eta_{\text {det }}}$ is $\mathcal{F}_{\text {calib,k}}\left(E_{\text {calo }}^{\mathrm{EM}}\right)$ for the relevant $\eta_{\text {det }}-$ bin $k$. The average jet energy scale correction $\left\langle 1 / \mathcal{F}_{\text {calib }, k}\left(E_{\text {calo }}^{\mathrm{EM}}\right)\right\rangle$ is shown as a function of calibrated jet transverse momentum $p_{\mathrm{T}}^{\text {jet }}$ for three jet $\eta$ intervals in Figure 1. The correction is only shown over the accessible kinematic range, i.e. values for jets above the kinematic limit are not shown. This is also the case for the following figures in this note. The calorimeter jet response $\mathcal{R}$ is shown for various energy- and $\eta_{\text {det }}$-bins in Figure 2. The value of the correction factor ranges from about 2.1 at low jet transverse momentum to less than 1.2 for high energy jets in the most forward region.

After the jet origin and energy corrections, the origin corrected jet $\eta$ is further corrected for a bias due to poorly instrumented regions of the calorimeter. In these regions topoclusters are reconstructed with a lower energy with respect to better instrumented regions (see Figure 2). This will cause the jet direction to be biased towards the better instrumented calorimeter regions.

The $\eta$-correction is derived as the average $\Delta \eta=\eta_{\text {truth }}-\eta_{\text {origin }}$ in $\left(E_{\text {truth }}, \eta_{\text {det }}\right)$-bins, and is parameterised as a function of the jet $E_{\text {calo }}^{\mathrm{EM}+\mathrm{JES}}$ and $\eta_{\text {det }}$. It is very small $(\Delta \eta<0.01)$ for most regions of the calorimeter but larger in the transition regions. The size of the bias is illustrated as a function of uncorrected detector pseudorapidity $\left|\eta_{\text {det }}\right|$ and EM + JES calibrated jet energy in Figure 3.

In the following, the EM+JES calibrated calorimeter jet transverse momentum will be denoted as $p_{\mathrm{T}}^{\text {jet }}$, and the corrected pseudorapidity simply as $\eta$.

## 6 Jet energy scale uncertainties

The JES systematic uncertainty is derived combining information from in-situ and single pion test-beam measurements, uncertainties on the material budget of the ATLAS detector, the description of the electronic noise, and the Monte Carlo modelling used in the event generation.

Figure 1: Average jet energy scale correction as a function of calibrated jet transverse momentum for three representative $\eta$-intervals. The correction is only shown over the accessible kinematic range, i.e. values for jets above the kinematic limit are not shown.

Dedicated Monte Carlo simulation test samples are generated with different conditions with respect to the nominal Monte Carlo sample described in Section 3.3. These variations are expected to provide an estimate of the systematic effects contributing to the JES uncertainty. The energy scale of jets for all the samples is calibrated using the calibration constants derived from the nominal Monte Carlo sample with the procedure described in Section 5.

The pseudorapidity bins used for the estimate of the JES uncertainty divide the ATLAS detector in the seven $\eta$ regions specified in Table 1.

Table 1: Detector regions and corrected pseudorapidity bins used for the estimate of the JES uncertainty.

| $\eta$ region | ATLAS detector regions |
| :---: | :---: |
| $0<\|\eta\| \leq 0.3$ | Central (Barrel) |
| $0.3<\|\eta\| \leq 0.8$ |  |
| $0.8<\|\eta\| \leq 1.2$ | Endcap |
| $1.2<\|\eta\| \leq 2.1$ | (Barrel-Endcap Transition and HEC) |
| $2.1<\|\eta\| \leq 2.8$ |  |
| $2.8<\|\eta\| \leq 3.2$ | Transition (HEC-FCal Transition) |
| $3.2<\|\eta\| \leq 3.6$ |  |
| $3.6<\|\eta\| \leq 4.5$ | Forward (FCal) |

The JES systematic uncertainty for all jets with pseudorapidity beyond $\eta=0.8$ is determined using the JES uncertainty for the central barrel region $(0.3<|\eta|<0.8)$ as a baseline, and adding a contribution from the relative calibration of the jets with respect to the central barrel region. This choice is motivated by the better knowledge of the detector geometry in the central region, and by the use of test-beam measurements only extending to the Tile calorimeter barrel for the estimate of the calorimeter response uncertainties.

This section focuses on the description of the sources of systematic uncertainties and their effect on

Figure 2: Simulated jet energy response at the electromagnetic scale as a function of EM +JES calibrated jet energy $E_{\text {calo }}^{\mathrm{EM}+\mathrm{JES}}$ and detector pseudorapidity $\eta_{\text {det }}$. Also shown are the $\eta$-intervals used to evaluate the JES uncertainty (see Table 1). The inverse of the response shown in each bin is equal to the average jet energy scale correction (and therefore equal to $\mathcal{F}_{\text {calib }}$ ).
the response of EM+JES calibrated jets. In Section 6.1, the selection of jets used to derive Monte-Carlo based components of the JES systematic uncertainty is outlined. The contributions to the JES systematics belonging to the categories below are then described:

1. the uncertainty due to the JES calibration method (Section 6.2);
2. the uncertainty due to the calorimeter response (Section 6.3);
3. the uncertainty due to the detector simulation (Section 6.4);
4. the uncertainty due to the physics model and parameters employed in the Monte Carlo event generator (Section 6.5);
5. the uncertainty due to the relative calibration for jets with $\eta>0.8$ (Section 6.6).

The JES systematic uncertainty is derived for isolated jets, while inclusive jets were considered in the previous uncertainty estimates $[11,12]$. This choice is motivated by the minor differences observed in the average kinematic jet response of the baseline QCD Monte Carlo samples and by the need to factorize the topology dependence of the close-by jet energy scale uncertainty for final states other than the QCD jets considered. The response of jets as a function of the distance to the closest reconstructed jet needs to be studied and corrected for separately if the measurement relies on the absolute jet energy scale. The additional uncertainty associated to close-by jets is discussed in Section 8.1.

### 6.1 Jet selection for the Monte Carlo based contributions to the JES uncertainty

The JES uncertainty components derived from Monte Carlo samples are obtained by studying the average calorimeter energy response of calibrated jets. This average response, defined as $\langle\mathcal{R}\rangle=\left\langle E_{\text {calo }}^{\mathrm{EM}+\mathrm{JES}} / E_{\text {truth }}\right\rangle$ or $\langle\mathcal{R}\rangle=\left\langle p_{\mathrm{T}}^{\text {jet }} / p_{\mathrm{T}}^{\text {truth }}\right\rangle$, is obtained by matching isolated calorimeter jets to MC truth jets as described in Section 5.3, but excluding the isolation cut for truth jets ${ }^{3}$. This is done separately for the nominal and

[^57]

Figure 3: Jet pseudorapidity bias as a function of the jet EM + JES calibrated calorimeter jet energy $E$ and uncorrected detector pseudorapidity $\left|\eta_{\text {det }}\right|$.
each of the alternative Monte Carlo samples. Only MC truth jets with $p_{\mathrm{T}}^{\text {truth }}>15 \mathrm{GeV}$, and calorimeter jets with a $p_{\mathrm{T}}^{\text {jet }}>7 \mathrm{GeV}$ after calibration, are considered. The calibrated response $\langle\mathcal{R}\rangle$ is studied in bins of truth jet transverse momentum $p_{\mathrm{T}}^{\text {truth }}$. The $p_{\mathrm{T}}^{\text {truth }}$ corresponding to the bin center is transformed on average to the calibrated $p_{\mathrm{T}}^{\text {jet }}$ value using a simple inversion procedure as described in Section 5.1 of Ref. [11]. The shifts between the Monte Carlo truth level $p_{\mathrm{T}}^{\text {truth }}$ bin centers and the reconstructed $p_{\mathrm{T}}^{\text {jet }}$ bin centers are negligible with respect to the chosen $p_{T}$ bin widths. Hence the average jet response can be obtained to good approximation as a function of $p_{\mathrm{T}}^{\mathrm{jet}}$.

### 6.2 Uncertainty due to the JES calibration

After the nominal inclusive jet Monte Carlo simulation sample is calibrated, the jet energy and $p_{T}$ response still shows slight deviations from unity at low $p_{T}$ (non-closure). This can be seen in Figure 4, showing the jet response for $p_{T}$ and energy as a function of $p_{\mathrm{T}}^{\text {jet }}$ for the nominal Monte Carlo sample in the barrel and endcap regions for anti- $k_{t}$ jets with $R=0.6$.

Any deviation from unity (non-closure) in $p_{\mathrm{T}}^{\mathrm{jet}}$ and energy response after the application of the JES to the nominal Monte Carlo sample implies that the kinematics of the calibrated calorimeter jet are not restored to that of the corresponding particle jets. This is mostly due to the following:

1. There is an underlying assumption that every constituent needs the same average compensation when deriving the calibration constants;
2. The same correction factor for energy and transverse momentum are used. In the case of a non-zero jet mass that does not reflect the truth jet mass, restoring only the jet energy and pseudorapidity will lead to a bias in the $p_{T}$ calibration.

The systematic uncertainty due to the non-closure of the nominal JES calibration is taken as the largest deviation of the response from unity between energy and $p_{\mathrm{T}}$. In the barrel region $0.3<|\eta|<0.8$ this contribution amounts to about $2 \%$ at low $p_{\mathrm{T}}^{\text {jet }}$ and smaller than $1 \%$ for $p_{\mathrm{T}}^{\text {jet }}>30 \mathrm{GeV}$. In the endcap and forward region, the closure is better than $1 \%$ for $p_{\mathrm{T}}^{\text {jet }}>20 \mathrm{GeV}$, while the energy response is within

Figure 4: Simulated jet $p_{T}$ response (full circles) after the EM + JES calibration and jet energy response (open squares) as a function of $p_{\mathrm{T}}^{\text {jet }}$ for the nominal sample for jets in the central (a), endcap (b) and forward (c) calorimeter regions.
$1 \%$ for jets with transverse momentum above 30 GeV . The deviation of the jet response from unity after calibration is taken as an additional source of systematic uncertainty.

### 6.3 Uncertainty on the calorimeter response

The response and corresponding uncertainties of single particles interacting in the ATLAS calorimeters can be used to derive the jet energy scale uncertainty in the central calorimeter region as detailed in Ref. [60]. The ATLAS simulation infrastructure allows for linking the true calorimeter energy deposits in each calorimeter cell to the particles generated in the collision. The uncertainty of the calorimeter response to jets can then be obtained from the response uncertainty of the individual particles constituting the jet. The in-situ measurement of the single particle response detailed in Ref. [60] significantly reduces the uncertainty due to the limited knowledge of the exact detector geometry, in particular those due to the presence of additional dead material, and the modelling of the interactions of particles in the detector.

The following single particle response measurements are used:

- the single hadron energy measured in a cone around an isolated track with respect to the track momentum $(E / p)$ in the momentum range from $0.5<p<20 \mathrm{GeV}$,
- the pion response measurements performed in the 2004 combined ATLAS test-beam, where a full slice of the ATLAS detector has been exposed to pion beams with momenta between 20 and 350 GeV [61].

Uncertainties for charged hadrons are estimated from these measurements as detailed in Ref. [60]. Additional uncertainties accounted for (see Sections 4.2 and 4.3 of Ref. [60]) include:

- effects related to the calorimeter acceptance,
- uncertainties related to particles with $p>400 \mathrm{GeV}$,
- baseline absolute electromagnetic scale for the hadronic and electromagnetic calorimeters for particles not measured in-situ,
- uncertainties connected to neutral hadrons.

At high transverse momentum, the dominating contribution to the calorimeter response uncertainties is due to particles with $p>400 \mathrm{GeV}$. The uncertainty for these particles has been conservatively estimated as $10 \%$ to take into account calorimeter non linearities and longitudinal leakage.

In the pseudorapidity range $0 \leq|\eta|<0.8$ the shift of the relative jet energy scale is up to $\approx 1 \%$, and the uncertainty on the shift is from 1 to $3 \%$. The total envelope (the shift added linearly to the uncertainty) of about $1.5-4 \%$ depending on the jet transverse momentum is taken as the relative JES calorimeter uncertainty.

### 6.4 Uncertainties due to the detector simulation

### 6.4.1 Calorimeter cell noise thresholds

As described in Section 4, topoclusters are constructed based on the signal-to-noise ratio of calorimeter cells, where the noise refers to (the RMS of) the measured cell energy distribution in events with no energy depositions from collision events. Discrepancies between the simulated noise and the real noise in data can lead to differences in the cluster shapes and to the presence of fake clusters, which affect the jet reconstruction. For data, the noise can change over time ${ }^{4}$, while the noise RMS used in the

[^58]simulation are fixed at the time of the production of the simulated data. This can lead to biases in the jet reconstruction and calibration if the simulated electronic noise injected in the Monte Carlo simulation does not reflect the noise in data.

The effect of the calorimeter cell noise (mis-)modelling on the jet response is estimated by reconstructing topoclusters, and thereafter jets, in Monte Carlo using the noise RMS measured in data. The actual energy and noise simulated in the MC are left unchanged, but the values of the thresholds used to include a given calorimeter cell in a topocluster are based on the cell noise RMS measured in data. The response of jets reconstructed with the modified noise thresholds are compared with the response of the jets reconstructed in exactly the same sample using the default MC noise thresholds. A series of cell noise thresholds values $(10 \%, 7 \%, 5 \%)$ were used to shift the noise thresholds for all cells (see Section 6.2 of Ref. [11] for details on this technique) to further study the effect on the jet response: increasing the cell thresholds in MC by $7 \%$ for each cell was found to give a similar shift in the jet response to using the noise RMS from data. Raising and lowering the cell thresholds by $7 \%$ shows that that the effect on the jet response from varying the cell noise thresholds is symmetric. This allows to use the calorimeter cell noise thresholds derived from data as a representative sample of the uncertainty on the jet energy scale. This covers both the case when more and less noise is present in data with respect to the simulation.

The maximal observed change in jet response is used to estimate the uncertainty on the jet energy measurement due to the calorimeter cell noise modelling. It is found to be below $3 \%$ for the whole pseudorapidity range, and negligible for jets with transverse momenta above 45 GeV . The uncertainties assigned to jets with transverse momenta below 45 GeV are:

- $1 \%$ and $2 \%$ for $20 \mathrm{GeV} \leq p_{\mathrm{T}}^{\mathrm{jet}}<30 \mathrm{GeV}$ for anti- $k_{t}$ with distance parameters $R=0.4$ and $R=0.6$ jets respectively,
- $1 \%$ for $30 \mathrm{GeV} \leq p_{\mathrm{T}}^{\text {jet }}<45 \mathrm{GeV}$.

### 6.4.2 Additional detector material

The jet energy scale is affected by possible deviations in the material description: the jet energy scale calibration has been derived to restore the energy lost under the assumption of the geometry simulated in the nominal Monte Carlo sample. Simulated detector geometries that include systematic variations to the material budget have been designed using test-beam measurements [53], in addition to 900 GeV and 7 TeV data $[46,47,62,63]$. Specific Monte Carlo samples have been produced using these distorted geometries.

In the case of uncertainties derived with in-situ techniques, such as those coming from the $E / p$ measurements detailed in Section 6.3, most of the effects on the jet response due to additional dead material are already taken into account because the measurement is performed directly on the ATLAS detector. However, The quality criteria on the track selection for the $E / p$ measurement effectively only allow particles that have not interacted in the inner detector to be included in the measurement. Therefore the effect of dead material in the inner detector needs to be taken into account for particles in the momentum range of the $E / p$ measurement. This is achieved using a specific Monte Carlo sample where the material budget is systematically varied adding $5 \%$ of material to the existing inner detector services. The uncertainty derived from the comparison of the distorted material response to the nominal response is then scaled by the fraction of particles within the $E / p$ momentum range. This uncertainty is shown in Figure 5.

Electrons, photons and hadrons with momenta $p>20 \mathrm{GeV}$ are not included in the $E / p$ measurements and therefore there is no in-situ estimate on the effect of any additional material in front of the calorimeters. This uncertainty is estimated using a dedicated Monte Carlo simulation sample where the overall detector material is systematically varied within the current uncertainties on the detector geometry knowledge. The overall changes in the detector geometry include:

- the increase in the inner detector material mentioned above;
- an extra 0.1 radiation length $\left(X_{0}\right)$ has been placed in the cryostat in front of the barrel of the electromagnetic calorimeter $(|\eta|<1.5)$;
- an extra $0.05 X_{0}$ has been placed between the presampler and the first layer of the electromagnetic calorimeter;
- an extra $0.1 X_{0}$ has been placed in the cryostat after the barrel of the electromagnetic calorimeter;
- extra material has also been placed in the in barrel-endcap transition region in the electromagnetic calorimeter ( $1.37<|\eta|<1.52$ ).

The uncertainty contribution due to the overall additional detector material is estimated by comparing the calibrated EM + JES jet response in the Monte Carlo sample with the distorted geometry with the nominal jet response (see Figure 5), and scaled by the average fraction of electrons, photons and high transverse momentum hadrons within a jet as a function of $p_{T}$.

### 6.5 Uncertainties due to the event modelling in the Monte Carlo generators

The contributions to the JES uncertainty from the modelling of the fragmentation and underlying event and other parameters of the Monte Carlo event generator are obtained using the following Monte Carlo samples:

- Alpgen + Herwig + Jimmy: the combination of the Alpgen generator interfaced to HERWIG and JIMMY is used to test the effects of a different modelling of the hard subprocess and soft processes. This configuration is tuned to ATLAS minimum bias data in a manner similar to the Pythia MC10 tune, and it has been described in Section 3.1. This model is different to the nominal Pythia sample in many respects, namely:
- the leading order matrix element calculation of multiple partons (legs) in the final state ( $2 \rightarrow 2$ to $2 \rightarrow 5$ for ALPGEN compared to $2 \rightarrow 2$ only for PYTHIA), and the matrix element matching to the parton shower with the MLM algorithm,
- the CTEQ6L1 parton distribution function used for Alpgen, compared to the MRST LO* set used for Pythia,
- the angular-ordered parton shower in HERWIG, compared with the $p_{T}$ ordered shower in Pythia,
- the cluster model for fragmentation implemented in HERWIG, compared to the PYTHIA string model,
- the underlying event implemented in JIMmy, compared to the PYthia model.
- Perugia2010 Pythia tune: this is an independent tune to the main hadron collider data with an increased final state radiation to better reproduce the jet shapes and hadronic event shapes using LEP and Tevatron data [64]. Also parameters sensitive to the production of particles with strangeness and related to jet fragmentation have been adjusted.

By comparing the baseline Pythia Monte Carlo sample to the Pythia Perugia2010 tune, the effects of soft physics modelling (e.g. underlying event) are tested. The Perugia2010 tune provides in particular a better description of the internal jet structure recently measured in ATLAS [4]. The Alpgen Monte Carlo uses different models for all phases of the event generation and therefore gives a reasonable estimate of

Figure 5: Simulated jet energy response (a) and $p_{\mathrm{T}}^{\mathrm{jet}}(\mathrm{b})$ response as a function of $p_{\mathrm{T}}^{\text {jet }}$ in the central region $(0.3<|\eta| \leq 0.8)$ in the case of additional dead material in the inner detector (full triangles) and in both the inner detector and the calorimeters (open squares). The response within the nominal Monte Carlo sample is shown for comparison (full circles).
the systematic variations. However, the possible compensation of effects that shift the jet response in opposite directions cannot be excluded.

Figure 6 shows the calibrated jet kinematic response for the two Monte Carlo generators and tunes used to estimate the effect of Monte Carlo theoretical model on the jet energy scale uncertainty, together with the kinematic response for the nominal sample shown for comparison. The ratio of the nominal response to the response for each of the two samples described is used to estimate a systematic uncertainty to the jet energy scale, and the procedure is detailed in Section 8.1.

### 6.6 Uncertainties due to the relative calibration in the endcap and forward regions

The JES uncertainty, determined in the central detector region using the single particle response and systematic variations of the Monte Carlo simulations, is transferred to the forward regions by exploiting the transverse momentum balance of a central and a forward jet in events with dijet topologies (where additional jets are vetoed as detailed in [65]). In such events, the responses of the forward jets are

Figure 6: Simulated energy response (a) and $p_{\mathrm{T}}^{\text {jet }}$ response (b) and as a function of $p_{\mathrm{T}}^{\text {jet }}$ in the central region $(0.3<|\eta| \leq 0.8)$ for Alpgen+Herwig+Jimmy (open squares) and Pythia with the Perugia2010 tune (full triangles). The response of the nominal Monte Carlo sample is shown for comparison (full circles).
measured relative to those of the central jets following a technique called "the matrix method" detailed in $[19,65]$. Measurements of this relative jet response are performed using the ATLAS 2010 data-set corresponding to an intergrated luminosity of $\approx 35 \mathrm{pb}^{-1}$, as well as using several MC generator event samples detailed in [65]. It is found that the MC predictions for the relative jet response diverge for low- $p_{\mathrm{T}}$ forward jets, while the data lie between the predictions.

These effects are accounted for in the uncertainty by including the intercalibration results for jets with $|\eta|>0.8$ in the total JES uncertainty as in the following:

- the total JES uncertainty in the central region $0.3<|\eta|<0.8$ is kept as a baseline,
- the uncertainty from the relative intercalibration is taken as the RMS deviation of the MC predictions from the data and is added in quadrature to the baseline uncertainty.

The intercalibration uncertainty is measured in bins of the average $p_{\mathrm{T}}$ of the two leading jets, labelled $p_{\mathrm{T}}^{\text {avg }}$. Due to momentum balance, this quantity is on average very similar to the average transverse
momenta of any of the two jets. The measurements are performed for transverse momenta in the range $20 \leq p_{\mathrm{T}}^{\text {avg }}<110 \mathrm{GeV}$. The uncertainty for jets with $p_{\mathrm{T}}>100 \mathrm{GeV}$ is taken as the uncertainty of the last available $p_{\mathrm{T}}$-bin. This is justified by the decrease of the intercalibration uncertainty with $p_{\mathrm{T}}$, but cannot completely exclude the presence of calorimeter non linearities for jet energies above those used for the intercalibration.

The uncertainties are evaluated separately for jets reconstructed with distance parameters $R=0.4$ and $R=0.6$, and are in general found to be slightly larger for $R=0.4$.

Figure 7 shows the relative jet response, and the associated intercalibration uncertainty calculated as detailed above, as a function of jet $|\eta|$ for two representative $p_{\mathrm{T}}^{\text {avg }}$-bins.

Figure 7: Jet $p_{\mathrm{T}}$ response measured relative to a central reference jet in data and various MC generator samples for jet $p_{\mathrm{T}}$ in the ranges $30-45 \mathrm{GeV}$ (left) and $80-110 \mathrm{GeV}$ (right). The resulting uncertainty component is shown as a shaded band around the data points.

## 7 Uncertainty due to multiple interactions

Particles produced by multiple soft proton-proton interactions in the same bunch crossing additional to the event of interest (in-time pile-up) can produce additional energy deposits that are reconstructed within the jet. As briefly described in Section 5, and fully detailed in Ref. [59], an average offset correction is applied to account for the average increase of the jet energy due to pile-up. This correction is parameterised as a function of the measured primary vertices $N_{\text {PV }}$.

The estimate of the remaining uncertainty on the jet energy scale after applying the pile-up correction is based on the studies described in Section 5 of Ref. [59]. The contributions to the uncertainty are estimated from studies that account for:

- the variation of the average offset-corrected calorimeter jet energy for calorimeter jets matched to track-jets as a function of the number of primary vertices,
- the effect of variations of the trigger selection on the measured tower energy distribution that is input to the offset correction,
- the mapping of the tower-based offset correction to a per-jet offset correction,
- the non-closure of the tower-based offset correction as evaluated by the dependence of the corrected calorimeter jet energy for calorimeter jets matched to track-jets as a function of the number of primary vertices.

The uncertainty on the jet energy scale is conservatively estimated by adding all uncertainties in quadrature, including the one from the non-closure of the correction. Since the track-jet method can be used only up to $|\eta|<1.9$ due to the limited coverage of the tracking detector, the di-jet balance method that is used for the $\eta$ intercalibration uncertainty and detailed in Section 6.6 have been used to estimate the uncertainty for $|\eta|>1.9$ by comparing the relative jet response in events with only one reconstructed vertex with the response measured in events with several reconstructed vertices. The dijet balance method yields uncertainties similar to those intrinsic to the method also in the case of $|\eta|<1.9$.

The offset correction and its uncertainty are derived as a function of the number of reconstructed vertices. This allows the correction and its uncertainty to be valid also for data periods where the number of reconstructed primary vertices is higher than the period where the correction is derived.

Figure 8: Relative pile-up uncertainty for anti- $k_{t}$ jets with $\mathrm{R}=0.6$ in the case of two measured primary vertices, $N_{\mathrm{PV}}=2$, for central $(0.3<|\eta| \leq 0.8$, full circles), endcap $(2.1<|\eta| \leq 2.8$, open squares) and forward ( $3.6<|\eta| \leq 4.5$, full triangles) jets as a function of jet $p_{\mathrm{T}}$.

Figure 8 shows the relative uncertainty due to pile-up in the case of two measured primary vertices. In this case, the uncertainty due to pile-up for central jets with $p_{T}=20 \mathrm{GeV}$ and pseudorapidity $|\eta| \leq 0.8$ is about $1 \%$, while it amounts to about $2 \%$ for jets with pseudorapidity $2.1<|\eta|<2.8$ and to less than $2.5 \%$ for all jets with $|\eta| \leq 4.5$. In the case of three primary vertices, the pile-up uncertainty is approximately twice that of $N_{\mathrm{PV}}=2$, and with four primary vertices the uncertainty for central, endcap and forward jets is less than $3 \%, 6 \%$ and $8 \%$, respectively. The relative uncertainty due to pile-up for events with up to 5 additional interactions becomes less than $1 \%$ for all jets with $p_{T}>200 \mathrm{GeV}$. The pile-up uncertainty needs to be added separately to the estimate of the total jet energy scale uncertainty detailed in Section 8.

The effect of additional proton-proton interactions from different bunch crossings that can be caused by trains of consecutive bunches (out-of-time pile-up) has been studied separately. The effect of out-oftime pile-up on jet reconstruction has been found to be negligible in the 2010 data-set.

## 8 Summary of the jet energy scale systematic uncertainty

### 8.1 Method to estimate the jet energy scale systematic uncertainty

The total jet energy scale uncertainty has been derived by considering all the individual contributions described in Section 6. In the central region $(|\eta|<0.8)$, the estimate proceeds as follows:

1. For each $p_{\mathrm{T}}^{\text {jet }}$ and $\eta$ bin, the uncertainty due to the calibration procedure is calculated as described in Section 6.2 for both jet energy and $p_{\mathrm{T}}$ response. For each bin, the maximum deviation from unity between the energy and $p_{\mathrm{T}}$ response is taken as the final non-closure uncertainty.
2. The calorimeter response uncertainty is estimated as a function of jet $\eta$ and $p_{T}$ from the propagation of single particle uncertainties to the jets, as detailed in Section 6.3.
3. Sources of uncertainties estimated using Monte Carlo samples with a systematic variation are accounted as follows:
(a) the response in the test sample $\mathcal{R}_{\text {var }}$ and the response in the nominal sample $\mathcal{R}_{\text {nom }}$ is considered as a starting point for the estimate of the JES uncertainty. The deviation of this ratio from unity is defined as:

$$
\begin{equation*}
\Delta_{\mathrm{JES}}\left(p_{T}^{\text {jet }}, \eta\right)=\left|1-\frac{\mathcal{R}_{\mathrm{var}}\left(p_{T}^{\text {jet }}, \eta\right)}{\mathcal{R}_{\mathrm{nom}}^{\text {jot }}\left(p_{T}^{\text {et }}, \eta\right)}\right| . \tag{3}
\end{equation*}
$$

This deviation is calculated from both the energy and $p_{T}$ response, leading to $\Delta_{\mathrm{JES}}^{\mathrm{E}}\left(p_{T}^{\text {jet }}, \eta\right)$ for the deviation in the energy response, and to $\Delta_{\mathrm{JTS}}^{\mathrm{pT}}\left(p_{T}^{\text {jet }}, \eta\right)$ for the deviation in the transverse momentum response.
(b) The largest $\Delta_{\mathrm{JES}}$ in each bin derived from the jet energy $(E)$ or transverse momentum ( $p_{T}$ ) response is considered as the contribution to the final JES systematic uncertainty due to the specific systematic effect:

$$
\begin{equation*}
\Delta_{\mathrm{JES}}\left(p_{T}^{\text {jet }},|\eta|\right)=\max \left(\Delta_{\mathrm{JES}}^{\mathrm{E}}\left(p_{T}^{\text {jet }}, \eta\right), \Delta_{\mathrm{JES}}^{\mathrm{pT}}\left(p_{T}^{\text {jet }}, \eta\right)\right) . \tag{4}
\end{equation*}
$$

4. The estimate of the uncertainty contributions due to additional material in the inner detector and overall additional dead material is estimated as described in point 3. above. These uncertainties are then scaled by the average fraction of particles forming the jet that are within $p<20 \mathrm{GeV}$ (for the inner detector distorted geometry) and by the average fraction of particles outside the $E / p$ in-situ measurements (for the overall distorted geometry).

For each $p_{\mathrm{T}}^{\text {jet }}, \eta$ bin, the contributions from the calorimeter, non-closure, Monte Carlo variations and dead material listed above are added in quadrature.

For pseudorapidities beyond $|\eta|>0.8$, the $\eta$ intercalibration contribution is estimated for each pseudorapidity bin in the endcap region as detailed in Section 6.6. The intercalibration contribution is added in quadrature to the total JES uncertainty determined in the $0.3 \leq|\eta|<0.8$ region to estimate the JES uncertainty for jets with $|\eta|>0.8$, with the exception of the non-closure term that is retained for the specific $\eta$ region. For low jet $p_{T}$, this choice leads to partially double count the contribution from the dead material uncertainty, but it is considered as a conservative estimate in a region where it is difficult to estimate the accuracy of the material description.

The contribution to the uncertainty due to additional proton-proton interactions described in Section 7 needs to be added separately, depending on the number of primary vertices in the event. In the following, only the uncertainty in the case of a single proton-proton interaction is shown in detail.

The jet energy scale has been derived using the simulated sample of QCD jets described in section 3.3, with a particular mixture of quark and gluon initiated jets and with a particular selection of isolated jets. The differences in fragmentation between quark and gluon initiated jets and the effect of close-by jets give rise to a particular topology and flavor dependence of the energy scale. Since the event topology and flavor composition (quark and gluon fractions) may be different in final states other than the QCD
jets considered, the dependence of the jet energy response on jet flavor and topology has to be accounted for in physics analyses.

The effect on the jet energy scale uncertainty due to close-by jets needs to be estimated separately, since the jet response depends on the angular distance to the closest jet. An additional analysis-dependent correction needs to be applied to jets with another jet close-by, and the additional uncertainty can be estimated from the Monte Carlo to data comparison of the $p_{T}$ ratio between calorimeter jets and matched track jets in inclusive dijet events as a function of the isolation radius. The analysis where this uncertainty is derived is described in Section 7 of Ref. [3]: it is found that simulated events reproduce the response of close-by-jets to within $1-3 \%$ as a function of the distance to the nearest jet, and an additional uncertainty is assigned.

As in the case of the topology dependence of the jet energy scale, specific flavor dependent corrections should be derived separately by different physics analysis. The systematic uncertainty will depend on the difference in the fraction of quark and gluon jets and on the flavor dependence of the jet energy response between data and simulation. This uncertainty has to be evaluated for each individual physics analysis.

### 8.2 Total jet energy scale systematic uncertainty

Figures 9,10 and 11 show the final fractional jet energy scale systematic uncertainty and its individual contributions as a function of jet $p_{\mathrm{T}}^{\mathrm{jet}}$ for three selected $\eta$ regions.

The fractional JES uncertainty in the central region amounts to 2 to $4 \%$ for $p_{\mathrm{T}}^{\mathrm{jet}}<60 \mathrm{GeV}$, and it is between 2 and $2.5 \%$ for $60 \mathrm{GeV} \leq p_{\mathrm{T}}^{\text {jet }}<800 \mathrm{GeV}$. For jets with $p_{\mathrm{T}}^{\text {jet }}>800 \mathrm{GeV}$, the uncertainty goes from 2.5 to $4 \%$, due to the larger uncertainties for particles with momentum beyond 400 GeV comprised in these jets. The uncertainty amounts to up to $7 \%$ and $3 \%$, respectively, for $p_{\mathrm{T}}^{\text {jet }}<60 \mathrm{GeV}$ and $p_{\mathrm{T}}^{\mathrm{jet}}>60 \mathrm{GeV}$ in the endcap region, where the central uncertainty is taken as a baseline and the uncertainty due to the relative calibration is added. In the forward region, a $13 \%$ uncertainty is present for $p_{\mathrm{T}}^{\text {jet }}<60 \mathrm{GeV}$ : the increase in the uncertainty is dominated by the modelling of the soft physics in the forward region that is accounted for in the intercalibration contribution.

The dominant contribution to the uncertainty for jets with the highest transverse momenta measurable in ATLAS is the calorimeter uncertainty, and more specifically the uncertainty due to particles in jets with $p>400 \mathrm{GeV}$. As stated in Section 6.3 and in [60], this uncertainty contribution is estimated conservatively.

Table 2 presents a summary of the maximum uncertainties in the different $\eta$ regions for anti- $k_{t}$ jets with distance parameter of $R=0.6$ and with $p_{\mathrm{T}}^{\text {jet }}$ of $20 \mathrm{GeV}, 200 \mathrm{GeV}$ and 1.5 TeV as an example.

The same study has been repeated for anti- $k_{t}$ jets with distance parameter $R=0.4$, and the estimate of the JES uncertainty is comparable to anti- $k_{t}$ jets with $R=0.6$. The JES uncertainty for anti- $k_{t}$ jets with $R=0.4$ is between $\approx 4 \%(8 \%, 14 \%)$ at low jet $p_{\mathrm{T}}^{\text {jet }}$ and $\approx 2.5-3 \%(2.5-3.5 \%, 5 \%)$ for jets with $p_{\mathrm{T}}>60 \mathrm{GeV}$ in the central (endcap, forward) region, and it is summarised in Table 3.

## 9 Validation using in-situ techniques

The jet energy calibration can be tested in-situ using a well calibrated object as reference and comparing data to the Pythia Monte Carlo simulation tuned to ATLAS data [30]. The following in-situ techniques have been used by ATLAS:

Direct transverse momentum balance between a jet and a photon [20]
Events with a photon and one jet at high transverse momentum are used to compare the jet transverse momentum to the one of the photon. To account for effects like soft radiation and energy

Figure 9: Fractional jet energy scale systematic uncertainty as a function of $p_{\mathrm{T}}^{\text {jet }}$ for jets in the pseudorapidity region $0.3 \leq|\eta|<0.8$ in the calorimeter barrel. The total uncertainty is shown as the solid light blue area. The individual sources are also shown, with uncertainties from the fitting procedure if applicable.

Figure 10: Fractional jet energy scale systematic uncertainty as a function of $p_{\mathrm{T}}^{\text {jet }}$ for jets in the pseudorapidity region $2.1 \leq|\eta|<2.8$. The JES uncertainty in the endcap region is extrapolated from the barrel uncertainty, with the uncertainty contribution from the $\eta$ intercalibration between central and endcap jets in data and Monte Carlo added in quadrature. The total uncertainty is shown as the solid light blue area. The individual sources are also shown, with uncertainties from the fitting procedure if applicable.

Figure 11: Fractional jet energy scale systematic uncertainty as a function of $p_{\mathrm{T}}^{\text {jet }}$ for jets in the pseudorapidity region $3.6<|\eta|<4.5$. The JES uncertainty for the forward region is extrapolated from the barrel uncertainty, with the uncertainty contribution from the $\eta$ intercalibration between central and forward jets in data and Monte Carlo added in quadrature. The total uncertainty is shown as the solid light blue area. The individual sources are also shown, with uncertainties from the fitting procedure if applicable.
migrating out of the jet area the data are compared to the Monte Carlo simulation. The comparison is done in the jet $\eta$ range $0 \leq|\eta|<1.2$ and for photon transverse momenta $25 \mathrm{GeV} \leq p_{\mathrm{T}}^{\text {jet }}<$ 250 GeV . The systematic uncertainties associated to the method itself are estimated to be about $1.5 \%$.

Photon balance using the missing transverse momentum projection [20]
The photon transverse momentum is balanced against the full hadronic calorimeter response using the projection of the missing transverse energy on the photon direction. This method does not involve explicitly a jet algorithm. The comparison is done in the same kinematic region as the direct photon balance method. The systematic uncertainty of the method is about $1 \%$.

Balance between a high- $p_{\mathrm{T}}$ jet recoiling against one or more lower- $p_{\mathrm{T}}$ jets [3]
If jets at low transverse momentum are well calibrated one can assess the calibration of jets at high transverse momentum by balancing against a recoil system of low transverse momentum jets. This method allows to probe the jet energy scale up to the TeV-regime. The $\eta$ range used for the comparison is $0 \leq|\eta|<2.8$. The systematic effects are evaluated to be about $4 \%$.

Comparison of jet calorimeter energy to the momentum carried by tracks associated to a jet [21] The mean transverse momentum sum of tracks that are within a cone with size R provide an independent test of the calorimeter energy scale over the total measured $p_{\mathrm{T}}^{\text {jet }}$ range within the tracking acceptance. The comparison is done in the jet $\eta$ range $0 \leq|\eta|<1.2$ and the systematic effects associated to the method are evaluated to be about $3 \%$.

The comparison of data to Monte Carlo simulation for all in-situ techniques are shown in Figure 12 together with the JES uncertainty for the $0 \leq|\eta|<1.2$ region as estimated from the single hadrons

Table 2: Summary of the maximum EM+JES jet energy scale systematic uncertainties for different $p_{\mathrm{T}}^{\mathrm{jet}}$ and $\eta$ regions from Monte Carlo-based study for anti- $k_{t}$ jets with $R=0.6$.

| $\eta$ region | Maximum fractional JES Uncertainty |  |  |
| :---: | :---: | :---: | :---: |
|  | $p_{T}^{\text {jet }}=\mathbf{2 0} \mathbf{~ G e V}$ | $p_{T}^{\text {jet }}=\mathbf{2 0 0} \mathbf{G e V}$ | $p_{T}^{\text {jet }}=\mathbf{1 . 5} \mathbf{~ T e V}$ |
| $0<\|\eta\|<0.3$ | $4.6 \%$ | $2.3 \%$ | $3.1 \%$ |
| $0.3<\|\eta\|<0.8$ | $4.5 \%$ | $2.2 \%$ | $3.3 \%$ |
| $0.8<\|\eta\|<1.2$ | $4.5 \%$ | $2.4 \%$ | $3.4 \%$ |
| $1.2<\|\eta\|<2.1$ | $5.5 \%$ | $2.5 \%$ | $3.5 \%$ |
| $2.1<\|\eta\|<2.8$ | $7.1 \%$ | $2.5 \%$ |  |

| $3.2<\|\eta\|<3.6$ | $8.7 \%$ | $3.0 \%$ |  |
| $3.6<\|\eta\|<4.5$ | $12.6 \%$ | $2.9 \%$ |  |

Table 3: Summary of the maximum EM+JES jet energy scale systematic uncertainties for different $p_{\mathrm{T}}^{\mathrm{jet}}$ and $\eta$ regions from Monte Carlo based study for anti- $k_{t}$ jets with $R=0.4$.

| $\eta$ region | Maximum fractional JES Uncertainty |  |  |
| :---: | :---: | :---: | :---: |
|  | $p_{T}^{\text {jet }}=\mathbf{2 0} \mathbf{~ G e V}$ | $p_{T}^{\text {jet }}=\mathbf{2 0 0} \mathbf{G e V}$ | $p_{T}^{\text {jet }}=\mathbf{1 . 5} \mathbf{~ T e V}$ |
| $0<\|\eta\|<0.3$ | $4.1 \%$ | $2.3 \%$ | $3.1 \%$ |
| $0.3<\|\eta\|<0.8$ | $4.3 \%$ | $2.4 \%$ | $3.3 \%$ |
| $0.8<\|\eta\|<1.2$ | $4.3 \%$ | $2.5 \%$ | $3.5 \%$ |
| $1.2<\|\eta\|<2.1$ | $5.2 \%$ | $2.6 \%$ | $3.6 \%$ |
| $2.1<\|\eta\|<2.8$ | $8.2 \%$ | $2.9 \%$ |  |
| $2.8<\|\eta\|<3.2$ | $10.1 \%$ | $3.5 \%$ |  |
| $3.2<\|\eta\|<3.6$ | $10.3 \%$ | $3.7 \%$ |  |
| $3.6<\|\eta\|<4.5$ | $13.8 \%$ | $5.3 \%$ |  |

response and systematic variations of the Monte Carlo simulations. For the track-jet results the $\eta$ range used for the comparison in the figure is $0 \leq|\eta|<0.3$. The results of the in-situ techniques support the estimate of the JES uncertainty obtained using an independent method.

## 10 Conclusions

The jet energy scale uncertainty for jets produced in $p p$ collisions at a centre-of-mass energy of $\sqrt{s}=$ 7 TeV , and reconstructed with the anti- $k_{t}$ algorithm with distance parameters $R=0.4$ and $R=0.6$, has been estimated. The JES and its uncertainty are evaluated up to the kinematic limit (jet energies up to 3500 GeV ) and for calibrated jet pseudorapidities $|\eta|<4.5$.

Jets are calibrated in three subsequent steps starting from the electromagnetic scale measured in the calorimeter. First, additional energy due to multiple proton-proton interactions within the same bunch crossing is removed via an offset correction, then the jet origin is set to the primary collision vertex, and finally the jet energy scale and pseudorapidity are restored with calibration constants based on the true jet kinematics derived from the Monte Carlo simulation.

Compared to the previous jet energy scale uncertainty determination [11, 12], the uncertainty presented herein is significantly improved thanks to the reduced calorimeter response uncertainties. These

Figure 12: Jet energy scale uncertainty as a function of $p_{\mathrm{T}}^{\mathrm{jet}}$ in $0 \leq|\eta|<1.2$. This plot shows the data to Monte Carlo simulation ratios for several in-situ techniques that test the jet energy scale exploiting photon jet balance (direct balance or using the missing transverse momentum projection technique), the balance of a leading jet with a recoil system of two or more jets at lower transverse momentum (multijets) or using the momentum measurement of tracks in jets.
improvements are due to new measurements of the single hadron response, to a more detailed analysis of the uncertainties associated to neutral hadrons and to the recalibration of the electromagnetic scale of calorimeter with $Z \rightarrow e e$ events measured in-situ.

The total jet energy scale uncertainty decreases by up to a factor of two with respect to the update of the estimate in Ref. [12]. The jet energy scale calibration and the reduction in its uncertainty are validated by the comparison of calibrated jets in data and Monte Carlo simulation using in-situ techniques (tracks in jets, multi-jet balance, direct photon-jet balance, missing transverse energy projection fraction technique) up to jet transverse momenta of 1 TeV .

The jet energy scale uncertainty is found to be similar for jets reconstructed with both the jet distance parameters studied: $R=0.4$ and $R=0.6$. In the central region $(|\eta|<0.8)$ the uncertainty is lower than $4.6 \%$ for all jets with $p_{\mathrm{T}}>20 \mathrm{GeV}$, while for jet transverse momenta between 60 and 800 GeV the uncertainty is below $2.5 \%$.

In the endcap and forward region the relative intercalibration uncertainty dominates. The JES uncertainty amounts to a total of about $14 \%$ for the most forward pseudorapidities up to $\eta=4.5$.

The jet energy scale uncertainty is estimated for isolated jets, and similar results have been obtained using inclusive QCD jets. An additional correction due to the presence of close-by jets needs to be applied and an uncertainty of $1-3 \%$ added to the current estimate as a function of the distance to the nearest reconstructed jet. An additional flavour-dependent systematic uncertainty has to be evaluated for individual physics analyses.

The JES uncertainty due to proton-proton collisions occurring in addition to the event of interest (pile-up) after a dedicated correction is applied is estimated separately as a function of the number of primary vertices. In the case of two primary vertices per event, the uncertainty due to pile-up for jets with $p_{T}=20 \mathrm{GeV}$ and pseudorapidity $0.3 \leq|\eta|<0.8$ is about $1 \%$ while it amounts to about $2 \%$ for jets with pseudorapidity $2.1 \leq|\eta|<2.8$. For jets with transverse momentum above 200 GeV , the uncertainty due to pile-up is negligible $(<1 \%)$ for jets in the full pseudorapidity range $(|\eta|<4.5)$.

## Appendix A: additional jet energy scale uncertainty plots for comparison with ICHEP JES uncertainty

This section contains the JES uncertainty summary plots of section 8 for the central and endcap $\eta$ regions with the same axis range as Ref. [11] and Ref. [12].

Figure 13: Fractional jet energy scale systematic uncertainty as a function of $p_{\mathrm{T}}^{\mathrm{jet}}$ for jets in the pseudorapidity region $0.3 \leq|\eta|<0.8$ in the calorimeter barrel. The total uncertainty is shown as the solid light blue area. The individual sources are also shown, with statistical uncertainties if applicable.

Figure 14: Fractional jet energy scale systematic uncertainty as a function of $p_{\mathrm{T}}^{\text {jet }}$ for jets in the pseudorapidity region $2.1 \leq|\eta|<2.8$. The JES uncertainty in the endcap region is extrapolated from the barrel uncertainty, with the uncertainty contribution from the $\eta$ intercalibration between central and endcap jets in data and Monte Carlo added in quadrature. The total uncertainty is shown as the solid light blue area. The individual sources are also shown, with statistical uncertainties if applicable.

# A Search for Randall-Sundrum Gravitons Decaying to Photon Pairs in $\sqrt{s}=7$ TeV pp Collisions 

The ATLAS Collaboration

#### Abstract

A search has been performed for evidence of a narrow resonance in the diphoton invariant mass spectrum. The analysis uses the ATLAS 2010 data set of proton-proton collisions at a center-of-mass energy of 7 TeV , produced by the CERN Large Hadron Collider, corresponding to an integrated luminosity of $36 \mathrm{pb}^{-1}$. No evidence of a narrow resonance above the Standard Model background is observed. The results exclude at $95 \%$ confidence level Randall-Sundrum graviton masses below $545 \mathrm{GeV}(920 \mathrm{GeV})$, for values of the dimensionless coupling $k / \bar{M}_{\mathrm{Pl}}$ of $0.02(0.1)$.

## 1 Introduction

The difference in the Standard Model (SM) between the Planck scale and the electroweak scale is known as the hierarchy problem. Recently, there has been great interest in models which resolve the hierarchy problem through the existence of extra spatial dimensions. One popular example is the Randall-Sundrum (RS) model [1], which postulates the existence of a fifth spatial dimension that has a "warped" geometry.

In the RS model, the 5 -dimensional spacetime is bounded by two ( $3+1$ )-dimensional branes. The particles of the SM are localized on one brane, while gravity is localized on the other. Given this spacetime configuration, TeV scales are naturally generated from the Planck scale due to a geometric "warp" factor:

$$
\begin{equation*}
\Lambda_{\pi}=\bar{M}_{\mathrm{Pl}} \exp \left(-k \pi r_{c}\right) \tag{1}
\end{equation*}
$$

where $\bar{M}_{\mathrm{Pl}}=M_{\mathrm{Pl}} / \sqrt{8 \pi}$ is the reduced Planck scale, and $k$ and $r_{c}$ are the curvature and compactification radius of the extra dimension, respectively. Given the exponential form of Eq. 1, the observed large hierarchy of scales is reproduced if $k r_{c} \approx 12$.

In the minimal RS model, gravitons are the only particles that can propagate in the bulk. As a result, a series of massive graviton excitations, known as a Kaluza-Klein (KK) tower, is predicted. These KK gravitons should have spin 2 , a mass splitting between successive KK levels on the TeV scale, and a universal dimensionless coupling $k / \bar{M}_{\mathrm{PI}}$ to the SM fields. The degrees of freedom of the RS model can be expressed in terms of $k / \bar{M}_{\mathrm{PI}}$ and the mass $M_{G}$ of the lightest KK graviton excitation. To address the hierarchy problem without the need for fine-tuning, $M_{G}$ should be in the TeV range. Coupling values in the range $0.01<k / \bar{M}_{\mathrm{Pl}}<0.1$ are favored, though values in the range $0.01<k / \bar{M}_{\mathrm{Pl}}<1.0$ have been considered in theoretical calculations [2].

A striking signature of the RS model at hadron colliders would be graviton production [2], followed by their decay to pairs of SM fermions or bosons. The graviton decay $G \rightarrow \gamma \gamma$ is a particularly interesting example, since observation of a resonance in the diphoton final state would rule out some possible alternative interpretations, such as a $Z^{\prime}$ boson. The production cross section of the diphoton final state is expected to be twice that of charged leptons, making this channel more sensitive to a potential graviton decay. For the ranges of graviton masses and couplings considered, the graviton would appear experimentally as a rather narrow resonance. The experimental backgrounds in the diphoton final state are relatively low, and the excellent energy resolution of the electromagnetic (EM) calorimeter would provide a good mass resolution. At a hadron collider, the leading production processes arise from $q \bar{q}$ annihilation and from gluon-gluon fusion, as depicted in Fig. 1, which shows leading order (LO) Feynman diagrams for graviton production and decay to the diphoton final state.

Figure 1: Leading order Feynman diagrams depicting RS graviton production at a hadron collider, followed by the decay $G \rightarrow \gamma \gamma$.

The most stringent existing limits on RS graviton production come from the D 0 experiment [3] at the Tevatron, which presented limits using $5.4 \mathrm{fb}^{-1}$ that combines results of the $G \rightarrow \gamma \gamma$ and $G \rightarrow e^{+} e^{-}$ channels. CDF has recently submitted to PRL the results [4] which they obtained from an analysis of the
$G \rightarrow \gamma \gamma$ final state using $5.4 \mathrm{fb}^{-1}$. The corresponding graviton mass limits from the Tevatron for values of $k / \bar{M}_{\mathrm{Pl}}=0.01$ and 0.1 are summarized in Table 1 .

| Value of <br> $k / \bar{M}_{\mathrm{Pl}}$ |  | 95\% CL Mass Limit (GeV) |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | D0 Expt | CDF Expt |  |  |
| 0.01 | 560 | 472 |  |  |
| 0.10 | 1050 | 976 |  |  |

Table 1: $95 \%$ CL lower limits on the RS graviton mass obtained by D0 [3] and CDF [4] for the values $k / \bar{M}_{\mathrm{Pl}}=0.01$ and 0.10 .

Given the larger center-of-mass-energy of the LHC, ATLAS should be able, even with relatively little integrated luminosity, to probe higher graviton masses than possible at the Tevatron. This note describes the analysis of the $G \rightarrow \gamma \gamma$ final state using $36 \mathrm{pb}^{-1}$ of data recorded by ATLAS in 2010.

## 2 Experimental Setup

The ATLAS detector [5] is a multipurpose particle physics apparatus with a forward-backward symmetric cylindrical geometry and nearly $4 \pi$ solid angle coverage ${ }^{1}$.

Closest to the beamline are tracking detectors which use layers of silicon-based and straw-tube detectors, located inside a thin superconducting solenoid that provides a 2 T magnetic field, to measure the trajectories of charged particles. The solenoid is surrounded by a hermetic calorimeter system. The liquid-argon (LAr) sampling calorimeter is divided into a central barrel calorimeter and two end-cap calorimeters, each housed in a separate cryostat. Fine-grained LAr EM calorimeters, with excellent energy resolution, provide coverage for $|\eta|<3.2$. In the region $|\eta|<2.5$, the EM calorimeters are segmented into three longitudinal layers and the second layer, in which most of the EM shower energy is deposited, is divided into cells of granularity of $\Delta \eta \times \Delta \phi=0.025 \times 0.025$. A presampler, covering $|\eta|<1.8$, is used to correct for energy lost upstream of the calorimeter.

An iron-scintillator tile calorimeter provides hadronic coverage in the range $|\eta|<1.7$. In the end-caps ( $|\eta|>1.5$ ), LAr hadronic calorimeters match the outer $|\eta|$ limits of the end-cap EM calorimeters. LAr forward calorimeters provide both EM and hadronic energy measurements, and extend the coverage to $|\eta|<4.9$. Outside the calorimeters is an extensive muon system including large air-core superconducting toroidal magnets.

## 3 Data and Monte Carlo Samples

The analysis uses the dataset collected in 2010 with the ATLAS detector at the LHC during stable beam periods of $p p$ collisions at a center-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$. The data were collected during the period from June through October 2010, and correspond to an integrated luminosity of $36 \mathrm{pb}^{-1}$.

Monte Carlo (MC) signal samples were produced using the implementation of the RS model in PYTHIA [6] version 6.424, which is fully specified by providing the values of $M_{G}$ and $k / \bar{M}_{\mathrm{Pl}}$. MC signal samples were produced for a range of $M_{G}$ and $k / \bar{M}_{\mathrm{Pl}}$ values. No background MC samples were used since we determine the expected number of background events from a data-driven method. The

[^59]MC samples used the MC09 parameter tune [7], and were processed through the ATLAS detector simulation [8] based on GEANT4 [9]. Some MC samples have been produced with a modified description of the detector material to study systematic effects. MC samples including multiple proton-proton collisions were produced, approximately reproducing the pile-up in data. Differences between data and MC are accounted for by re-weighting the simulated vertex multiplicity so that it matches the data.

## 4 Event Selection

Events selected for this analysis had to satisfy triggers that required the presence of photon candidates in the event. In the early running period, the only trigger requirement was that the first level ("Level-1") calorimeter trigger system identify at least one deposit of transverse energy above 14 GeV in the EM calorimeter with a shape consistent with an EM shower. Due to the moderate LHC collision rate in the first periods of data taking, the output rate for this trigger was low enough that no further trigger selection was needed. In later running, a diphoton trigger was used to cope with the increasing instantaneous luminosity delivered by the LHC. The diphoton trigger used a three level trigger which, at Level 1 , required at least two pairs of adjacent trigger towers with $E_{T}>10 \mathrm{GeV}$. The higher level trigger selection used a refined cluster reconstruction algorithm, in which the cluster is required to pass shower shape selections and to have $E_{T}>15 \mathrm{GeV}$. These trigger conditions were fully efficient for MC signal events which pass the offline reconstruction.

The data selection required at least one primary vertex candidate in the event, with at least three tracks associated to it. Events were required to also pass the ATLAS data quality requirements indicating that the relevant detectors were in working order during the given data taking period.

The reconstruction of photons is described in detail in Ref. [10]. To select photon candidates, EM calorimeter clusters were required to pass several quality criteria and to lie outside problematic calorimeter regions. Photon candidates were required to have $E_{\mathrm{T}}>25 \mathrm{GeV}$, to satisfy $|\eta|<2.37$ and to be outside the transition region $1.37<|\eta|<1.52$ between the barrel and end-cap calorimeters. The analysis uses a "loose" photon identification which includes cuts on the energy in the hadronic calorimeter as well as on variables that require the transverse width of the shower, measured in the second EM calorimeter layer, be consistent with the narrow width expected for an EM shower. The loose selection provides a high photon efficiency ( $\approx 94 \%$ ) with modest rejection against the background from jets. Finally photons were required to pass some quality selections to remove fakes initiated by noisy cells in the calorimeter and to avoid photons reconstructed close to regions of dead modules.

A total of 8090 events were selected with at least two photons that survived all analysis cuts. Of these, 1650 events have diphoton mass values above 120 GeV .

## 5 Background Description and Analysis Method

The main backgrounds for this analysis include the irreducible background from SM diphoton production, and reducible backgrounds from QCD $\gamma+$ jet and multijet events with at least one fake photon. The inclusive shape of the diphoton invariant mass distribution of the background is determined from a fit to a control region of masses between 120 and 500 GeV , which is a region in which the Tevatron results already exclude an RS graviton within the preferred range of values of $k / \bar{M}_{\mathrm{Pl}}(<0.1)$. When setting a limit for a 500 GeV graviton the background fit is restricted to the range between 120 and 430 GeV .

Figure 2 shows the diphoton candidate invariant mass spectrum in the control region. As expected, the background follows a smooth distribution. Superimposed on the figure is the result of a fit to the data of a sum of two exponential functions with freely varying parameters and relative strength. As seen from the figure, the background is described well by this parametrization; the p-value of the fit using a $\chi^{2}$ test is $94 \%$.

Figure 2: Diphoton candidate invariant mass distribution measured in the control region of 120 500 GeV . Superimposed is the result of a fit to the data of the background parametrization of the sum of two exponential functions.

To search for evidence of a resonance signal for a given graviton mass and coupling $k / \bar{M}_{\mathrm{P}}$, the observed invariant mass distribution within a window around the test mass was compared with histograms of the expected signal and background templates. The background prediction was determined by extrapolating the background fit function, with the parameters fixed to the values determined in the fit to the control region, into the search region of higher diphoton masses. The signal templates were determined from the signal MC samples, and include effects of both the natural graviton width and the experimental mass resolution.

One example of such templates for a 700 GeV graviton with $k / \bar{M}_{\mathrm{Pl}}=0.035$ is shown in Fig. 3. Each bin of the histograms is treated as a separate counting channel. Systematic uncertainties are included as nuisance parameters on the expected number of events with Gaussian distributions [11]. A given systematic uncertainty is taken as fully correlated across all bins of a histogram. The various systematic uncertainties are assumed to be uncorrelated with each other.

For each graviton mass, a different mass window was chosen for the search, in order to contain at least $90 \%$ of the signal in the window, including both the dependence of the resonance natural width on the value of $k / \bar{M}_{\mathrm{Pl}}$ and the $E_{T}$ dependence of the detector resolution. The chosen mass windows are given in Table 2, together with the expected number of signal and background events and the observed number of candidates.

## 6 Systematic Uncertainties

The various relative systematic uncertainties on the predicted RS graviton signal yield are summarized in Table 3. There is a $3.4 \%$ uncertainty on the integrated luminosity [12]. An uncertainty of $1 \%$ is attributed to the limited MC statistics and another $1 \%$ to the photon trigger efficiency. Uncertainties on the efficiency for reconstructing and identifying the $\gamma \gamma$ pair arise due to differences between MC and data in the distributions of the photon identification variables, the need to extrapolate these studies to the higher $E_{\mathrm{T}}$ values typical of the RS graviton signal photons, the impact of the photon quality

| G Mass [GeV] | $k / \bar{M}_{\mathrm{Pl}}$ | Mass Window [GeV] | $N_{\text {Exp }}^{S}$ | $N_{\text {Exp }}^{B}$ | $N_{\text {Obs }}$ |

Table 2: Mass windows chosen to compute the $\mathrm{CL}_{\mathrm{s}}$ for each predicted graviton signal of a given mass and $k / \bar{M}_{\mathrm{Pl}}$ value. The expected number of signal $\left(N_{\text {Exp }}^{S}\right)$ and background ( $N_{\text {Exp }}^{B}$ ) events within the mass window are also shown, together with the number of observed data events ( $N_{\mathrm{Obs}}$ ). The errors shown are quadrature sums of the statistical and systematic uncertainties.

Figure 3: Expected signal (dashed) and background (solid), and observed (points) distributions in a mass window $\pm 30 \mathrm{GeV}$ around the resonance mass. The uncertainty on the signal and background is not shown in this illustration. The MC signal represents a 700 GeV graviton with $k / \bar{M}_{\mathrm{Pl}}=0.035$ and is normalized to the number of expected signal events for these parameter values.
selections, and uncertainties in the detailed material composition of the detector. Together these result in a systematic uncertainty of $3.8 \%$ on the efficiency for selecting diphoton events. The bunch-crossing uncertainty arises from the ability to determine the correct bunch crossing when pulse saturation occurs in the trigger digitization. This gives a systematic uncertainty of $2.0 \%$. The influence of pile-up gives a systematic uncertainty of $3.6 \%$.

While the previous uncertainties contribute to an uncertainty on the graviton signal yield, there are other sources of uncertainties that affect the shape of the diphoton candidate invariant mass distribution. The uncertainty on the photon energy resolution and energy scale impact the expected signal shape. Similarly, uncertainties in the determination of the background shape in the control region, and the extrapolation into the signal region, affect the background shape.

The photon energy scale and resolution systematics were determined by changing the signal MC templates. For the photon energy scale, shifts of $\pm 3 \%$ were applied to the photon $E_{\mathrm{T}}$ scale in signal MC events. The resolution was smeared by modifying the constant term in the resolution by $100 \%$ ( $400 \%$ ) for photons in the barrel (end-cap) calorimeter. In addition, a $20 \%$ smearing of the sampling term was applied. These uncertainties reflect the current understanding of the EM calorimeter calibration and reconstruction.

In order to study the systematic uncertainty attributed to the background tails which might not be correctly described by the extrapolation function, the background parametrization was fit to data in different ranges of the diphoton invariant mass. For a given test mass the fit was performed up to 100 GeV away from the test mass in steps of 100 GeV . The largest difference in the expected number of events from these various fits and the nominal fit up to 500 GeV was taken as the systematic uncertainty of the fit extrapolation and added in quadrature to the statistical uncertainty. The result of the background extrapolation uncertainty as a function of diphoton candidate invariant mass is shown as the brown band on Fig. 4.

The statistical uncertainty on the background shape extrapolation was determined by considering the statistical uncertainty on the background fit parametrization. To determine this effect, pseudoexperiments were performed by varying each bin in the control region according to a Poisson distribution around the measured value, refitting the so-obtained pseudo-data sample, and determining the fluctuation of the expected number of background events within the fit window. The $\pm 1(2)$ standard deviation bands were then determined by taking the integral of the spread of background around the nominal value such that $68 \%$ ( $95 \%$ ) of events were contained within the range. The statistical and systematic uncertainties determined are represented by green and yellow bands on Fig. 4.

The MRST2007lomod parton distribution function (PDF) set [13] has been used to determine the cross section of the graviton signals with PYTHIA. In order to estimate the systematic uncertainties due to the choice of PDF, the MSTW2008lo90cl PDF [14] set was used to change the value of the 20 eigenvalues by $\pm 1 \sigma$. The uncertainty coming from the PDF was estimated using the difference given by the modified PDF sets and the central value. The systematic uncertainty increases with the mass of the graviton. The uncertainty varies from $5.2-9.2 \%$ for masses between $500-1250 \mathrm{GeV}$. The systematic uncertainty due to the factorization and renormalization scales was estimated by changing the scale from the nominal value of 1 to 0.5 and 2 . This modification has at most a $6 \%$ effect on the graviton signal cross section.

| Source | Uncertainty (\%) |
| :--- | :---: |
| Luminosity | 3.4 |
| MC statistics | 1.0 |
| Photon trigger | 1.0 |
| Photon efficiency and ID | 3.8 |
| Photon quality | 0.5 |
| Bunch crossing ID | 2.0 |
| Pile-up | 3.6 |
| Photon energy resolution | Shape |
| Photon energy scale | Shape |
| PDF | $5.2-9.2$ |
| Fact. and renorm. scales | 6.0 |

Table 3: Summary of systematic uncertainties attributed to signal. The ones labeled 'Shape' involve modification of the signal templates.

## 7 Results

The invariant mass spectrum for diphoton candidates passing the selection cuts including loose photon identification is shown in Fig. 4 for the full mass range above 120 GeV . Superimposed is the result of the fit to the background in the control region below 500 GeV , which has been extrapolated to higher masses using the result of the fit. Also shown are graviton signals of masses 550, 700 and 1000 GeV and couplings $k / \bar{M}_{\mathrm{Pl}}=0.03,0.05$ and 0.11 , respectively. The three highest mass objects around 1000 GeV do not pass a more stringent photon selection that is designed to reduce the background due to jets, and are likely to be fake photon candidates. In fact, the highest mass diphoton candidate that passes the more stringent selection has a diphoton invariant mass of 679 GeV . An event display of this candidate is shown in Fig. 5.

The data are found to be well described by the smooth background parametrization over the entire

Figure 4: Reconstructed $m_{\gamma \gamma}$ distribution for data (points) and expected background (red line). Also shown are graviton signals of masses 550,700 and 1000 GeV and couplings $k / \bar{M}_{\mathrm{Pl}}=0.03,0.05$ and 0.11 , respectively. The signal is normalized to the number of expected events in an integrated luminosity of $36 \mathrm{pb}^{-1}$.

Figure 5: An event display of the highest invariant mass diphoton event in which both candidate photons satisfy the more stringent photon identification cuts. The highest transverse momentum photon has $\mathrm{p}_{\mathrm{T}}=194 \mathrm{GeV}$ and $(\eta, \phi)=(-1.32,-0.44)$. The trailing photon has $\mathrm{p}_{\mathrm{T}}=173 \mathrm{GeV}$ and $(\eta, \phi)=(1.10,2.82)$. The diphoton invariant mass is equal to 679 GeV .
mass range, and there is no evidence of a narrow resonance. For example, the p -value returned from evaluation of the spectrum using the BumpHunter tool [15] is $9 \%$, indicating agreement between the data and the background-only hypothesis.

Therefore, limits on graviton production were set using a log-likelihood ratio (LLR) defined as LLR $=-2 \ln (L($ data| $\mathrm{s}+\mathrm{b}) / L($ data $\mid \mathrm{b}))$ as the test statistic, where $L($ data| $\mathrm{s}+\mathrm{b})$ is the likelihood of the data using the signal plus background hypothesis and $L$ (data|b) is the likelihood of the data using the background only hypothesis.

The modified frequentist method [16] is used to determine the limit by performing pseudo-experiments to calculate $\mathrm{CL}_{\mathrm{s}+\mathrm{b}}=P\left(\mathrm{LLR} \geq \mathrm{LLR}_{\mathrm{obs}} \mid \mathrm{s}+\mathrm{b}\right)$ and $\mathrm{CL}_{\mathrm{b}}=P\left(\mathrm{LLR} \geq \mathrm{LLR}_{\mathrm{obs}} \mid \mathrm{b}\right)$, with $P$ representing the conditional probabilities. $\mathrm{CL}_{\mathrm{s}}$ is then defined as $\mathrm{CL}_{\mathrm{s}}=\mathrm{CL}_{\mathrm{s}+\mathrm{b}} / \mathrm{CL}_{\mathrm{b}}$. By repeating implementations of the procedure described in Section 5, for each mass point, the CL in the signal $\left(\mathrm{CL}_{\mathrm{s}}\right)$ as a function of a cross-section scaling factor $\mu$ was obtained keeping the mass window fixed. A scan is performed over a range of $\mu$ until one crosses the $\mathrm{CL}_{\mathrm{s}}=0.05$ value.

The scaling factor $\mu$ for a $95 \%$ CL exclusion was calculated by a linear interpolation between these points and then converted into an upper limit. For a given mass, a re-scaling of the cross-section would imply a change in the width of the resonance. Thus, for each mass point, the available signal template with the $k / \bar{M}_{\mathrm{Pl}}$ value closest to the expected $95 \%$ limit was chosen. This way, the change in the shape was minimized.

Figure 6 shows the $95 \%$ CL limits on the production cross section times branching ratio of an RS model graviton decaying into two photons as a function of the lightest graviton mass. Superimposed are the theoretical cross section predictions for a variety of $k / \bar{M}_{\mathrm{Pl}}$ values with the bands representing the uncertainty on the cross sections as described in section 6 . The results are interpreted in the $k / \bar{M}_{\mathrm{Pl}}$ versus graviton mass plane in Fig. 7 and compared to the Tevatron results.

Figure 6: The $95 \% \mathrm{CL}$ on the production cross section times branching ratio of an RS model graviton decaying into two photons $(\sigma \times \operatorname{Br}(G \rightarrow \gamma \gamma))$ as a function of the graviton mass. Superimposed are the theoretical cross section prediction bands for a variety of $k / \bar{M}_{\mathrm{Pl}}$ values.

Figure 7: $95 \%$ CL excluded region in the plane of $k / \bar{M}_{\mathrm{Pl}}$ versus graviton mass. Also shown are the expected limit and published limits from the Tevatron experiments [3] [4].

## 8 Summary

No evidence of a narrow resonance decaying into a pair of photons above the continuum background is observed. The results are used to set limits on the production of Randall-Sundrum gravitons decaying into diphoton final states. The results exclude at 95\% CL RS graviton masses below 545 (920) GeV for the dimensionless RS coupling $k / \bar{M}_{\mathrm{Pl}}=0.02(0.1)$.

## Data-driven estimation of the background to charged Higgs boson searches using hadronically-decaying $\tau$ final states in ATLAS

The ATLAS Collaboration

#### Abstract

The experimental observation of charged Higgs bosons, $H^{ \pm}$, which are theoretically predicted by many non-minimal Higgs scenarios, would indicate new physics beyond the Standard Model. In the Minimal Supersymmetric Standard Model, for example, the dominant production mode at the LHC for these Higgs bosons, when $m_{H^{+}}<m_{t}$, takes place in $t \bar{t}$ events via the top-quark decay $t \rightarrow H^{+} b$ with $H^{+} \rightarrow \tau v$ dominating for most values of $\tan \beta$. Two channels with a hadronically decaying $\tau$ coming from the charged Higgs boson are studied. The delivery of the first $37 \mathrm{pb}^{-1}$ of $\sqrt{s}=7 \mathrm{TeV}$ collision data allows many significant backgrounds to be estimated with data-driven methods, which represent the primary focus of this note and a crucial step towards ATLAS searches for the charged Higgs boson.

## 1 Introduction

The charged Higgs boson is predicted by many non-minimal Higgs scenarios such as models containing Higgs triplets and 2-Higgs-Doublet Models (2HDM) [1, 2, 3]. The experimental observation of charged Higgs bosons ${ }^{1}, H^{ \pm}$, would indicate new physics beyond the Standard Model. The first experimental evidence for the Minimal Supersymmetric Standard Model (MSSM) might very well come from their discovery at the Large Hadron Collider (LHC), if the model is realized in nature, and supersymmetric particles are heavy enough to evade detection [4]. The analyses in this note only consider the 2HDM, more specifically the Type II-2HDM, which describes the Higgs sector of the MSSM.

The dominant production mode at the LHC for these Higgs bosons for the case that the charged Higgs boson mass ( $m_{H^{+}}$) is smaller than the top-quark mass $\left(m_{t}\right)$ are $t \bar{t}$ events via the top-quark decay $t \rightarrow H^{+} b$ with $H^{+} \rightarrow \tau v$ (see Figure 1). The $H^{+} \rightarrow \tau v$ decay mode dominates if the ratio of the vacuum expectation values of the two Higgs doublets $(\tan \beta)$ is larger than 3. Production in the $\tau+\mathrm{jets}$ channel occurs when one of the two top quarks decays to $W b \rightarrow j j b$. Similarly, signal events considered by the $\tau+$ lepton channel come about when one of the top quarks decays to $W b \rightarrow l v b$ ( $l=e, \mu$ or leptonically decaying $\tau$ ). Both channels are studied here, but this note only considers a hadronically-decaying $\tau$ coming from the charged Higgs boson.

The background processes that enter these searches include the production of $t \bar{t}$, single top-quark, $W+$ jets, $Z+$ jets, and QCD multi-jet events. The delivery of the first collision data with a centre-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ allows many significant backgrounds to be estimated in a data-driven way, a crucial step toward searches for these bosons in the near future using ATLAS datasets with larger integrated luminosity. The methods used for background estimation are based on embedding $\tau$ jets in events with muons, and on the measured probabilities for jets, electrons, and muons to be misidentified as $\tau$ jets. Finally, the QCD multi-jet background is estimated in the $\tau+$ jets analysis using a data-driven control sample. The studies are based on proton-proton collision data collected at the LHC at a centre-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ in 2010. Only data-taking runs where all detector systems were fully operational and stable beam conditions were fulfilled are used. The total investigated luminosity corresponds to up to $37 \mathrm{pb}^{-1}$ and depends slightly on the trigger streams used.

Figure 1: Leading-order Feynman diagram for the production of a charged Higgs boson through gluongluon fusion in $t \bar{t}$ decays.

## 2 Physics processes and cross sections

The Monte Carlo (MC) simulation of $t \bar{t}$ and single top-quark events from proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ is done with MC@NLO [5] using HERWIG [6] for hadronization and JIMMY [7] for the

[^60]underlying event. Overlap between $t \bar{t}$ and single top-quark final states is removed in these MC@NLO samples [8]. A $t \bar{t}$ production cross section of 164.6 pb [9] obtained from NLO+NNLL calculations [10] is used (both for Standard-Model-like $t \bar{t}$ and decays via $H^{+}$); the MC@NLO values are used for single top-quark production.

ALPGEN [11] is used for the generation of $W$ and $Z$ events with up to five additional partons, again together with HERWIG/JIMMY. The MLM matching scheme [12] is employed, with the jet $p_{T}$ and $\Delta R$ cuts set to 20 GeV and 0.7 , respectively. The ALPGEN cross sections are rescaled by a factor $1.20(W)$ and $1.25(Z)$ to match NNLO calculations [4]. The $b \bar{b}$ and $H^{+}$events are generated with PYTHIA [13], using TAUOLA [14] for $\tau$ lepton decays and PHOTOS [15] for photon radiation off charged leptons. Events hadronized by PYTHIA use the ATLAS MinBias Tune 1 [16], while HERWIG/JIMMY samples use the ATLAS Underlying Event Tune 1 [17]. The simulated events and cross sections used are summarized in Table 1. The expected number of events is given by the production cross section times the integrated luminosity, which is $37 \mathrm{pb}^{-1}$ for the lepton triggers, and $36 \mathrm{pb}^{-1}$ for the hadronically-decaying- $\tau$ plus $E_{\mathrm{T}}^{\text {miss }}$ trigger. All events are passed through a detailed ATLAS detector simulation [18] using GEANT4 [19] and reconstructed by the same algorithms as the data.

Table 1: Simulated events used in this study. The $W / Z+j e t s, t \bar{t}$, as well as the $s$ - and $t$-channel single top-quark events are only simulated for decays involving leptons ( $e, \mu$, or $\tau$ ), and the cross section given includes this branching ratio. NLO+NNLL calculations are used for $t \bar{t}$, NLO for single top-quark, NNLO for $W / Z+$ jets, and LO for $b \bar{b}$. The $b \bar{b}$ cross section is given for the phase space with at least one muon in the decay chain with $p_{T}>15 \mathrm{GeV}$. The $H^{+}$sample uses $m_{H^{+}}=130 \mathrm{GeV}$ and $\tan \beta=35$ as input.

| Process | Generator | Cross section [pb] |
| :--- | :--- | ---: |
| $t \bar{t}$ with $\geq 1 \ell$ | MC@NLO | 89.7 |
| single top-quark $(s, t, W t$ channel $)$ | MC@NLO | $21.4,1.41,14.6$ |
| $W \rightarrow \ell v+$ jets | ALPGEN | $3.1 \cdot 10^{4}$ |
| $Z \rightarrow \ell \ell+$ jets | ALPGEN | $3.2 \cdot 10^{3}$ |
| $b \bar{b}$ with $\mu$ filter | PYTHIAB | $7.4 \cdot 10^{4}$ |
| $t \bar{t} \rightarrow b H^{ \pm} b W$ with $H^{ \pm} \rightarrow \tau v$ | PYTHIA | 18.5 |

## 3 Object reconstruction

In this section, the common object reconstruction for the $\tau+$ jets and $\tau+$ lepton event selections are detailed. For data-driven background estimation methods based on fake rates, requirements on the tag objects are explained in the respective sections should they differ.

Event-level cleaning cuts For both the $H^{+}$event selection and the data-driven background estimates several general-purpose event quality requirements [20] are always applied. To further reject noncollision backgrounds, only events with a reconstructed primary vertex with at least five associated tracks are considered.

Jets Jets are reconstructed with the anti- $k_{T}$ algorithm [21, 22] with a size parameter value of 0.4 , using three-dimensional topological clusters as input [23, 24]. The electromagnetic calibration of the ATLAS calorimeters is converted to the hadronic scale by a calibration scheme depending on $p_{T}, \eta$ and the number of primary vertices in the event [25]. Jets are required to have $p_{T}>20 \mathrm{GeV}$ and $|\eta|<4.9$. While the standard ATLAS definition is $|\eta|<4.5$, a looser pseudorapidity cut is used in this work.
$\tau$ jets For the reconstruction of hadronically-decaying $\tau \mathrm{s}$, anti- $k_{T}$ jets in the calorimeter with $E_{T}>10$ GeV are used as seeds. Electron and muon vetoes are applied at this stage, and $p_{T}>20 \mathrm{GeV},|\eta|<$ 2.5 , and 1 or 3 associated tracks are required. Objects passing this selection are referred to as " $\tau$ jet candidates". Additionally, medium (tight) quality cuts on the $\tau$ log-likelihood identification are applied for 1 -track (multi-track) $\tau$ jet candidates [26], to discriminate $\tau$ jets from jets not initiated by $\tau$ leptons.
$b$ jets A secondary-vertex tagger with a nominal efficiency of about $50 \%$ is used to identify those jets containing $b$ quarks among all jets passing the reconstruction discussed above [27].

Electrons Electrons are reconstructed by matching energy depositions in clusters of electromagnetic calorimeter cells to a track in the inner tracking detector [28]. The shower-shape information is used to increase the quality of the electron identification. Candidates are required to have $p_{T}>20 \mathrm{GeV}$ (for lepton vetoes, this value is lowered to 10 GeV ), and to be in the pseudorapidity ranges $0<|\eta|<1.37$ or $1.52<|\eta|<2.47$. Only isolated electrons are considered by requiring that the deposited energy in a calorimeter cone of $\Delta R<0.2$ around the electron ${ }^{2}$ is less than 4 GeV plus $2.3 \%$ of the electron $E_{T}$.

Muons Objects are considered as muon candidates if an inner detector track matches a track reconstructed in the muon spectrometer [29]. Candidates are required to have $p_{T}>20 \mathrm{GeV}$ (for lepton vetoes, this value is lowered to 10 GeV ) and $|\eta|<2.5$. Only isolated muons are considered by requiring that in a cone of $\Delta R<0.3$ around the muon, both the energy deposited in the calorimeters and the momentum of all inner detector tracks total less than 4 GeV . Additionally, an angular distance to any jet with $E_{T}>20$ GeV of $\Delta R>0.4$ is required.

Missing transverse energy, transverse energy sum The missing transverse energy, $E_{\mathrm{T}}^{\mathrm{miss}}$, is based on the energy deposited in the calorimeter and the momentum of tracks identified as associated to muons. The contribution of the calorimeter cells is calibrated differently depending on the object to which they are associated. For all jets, the same hadronic calibration scheme as for jet reconstruction is used while electrons are calibrated at the electromagnetic scale [30].

The transverse energy sum, $\Sigma E_{\mathrm{T}}$, is defined as the sum of the transverse energy of all objects which have been reconstructed as detailed in this section, i.e., electrons, muons, $\tau$ jets, $b$-tagged jets, light jets, and $E_{\mathrm{T}}^{\mathrm{miss}}$.

The missing transverse energy significance, $E_{\mathrm{T}}^{\text {miss }} / \sqrt{\Sigma E_{T}}$, is a complex quantity used to suppress QCD multi-jet events without losing a large number of signal events (simply increasing the $E_{\mathrm{T}}^{\text {miss }}$ requirement would be detrimental to the $\tau+$ jets analysis). As discussed in Reference [31], investigations have shown that this quantity is well-modeled for events with a large amount of true $E_{\mathrm{T}}^{\mathrm{miss}}$.

Overlap removal When candidates selected using the above criteria overlap within $\Delta R<0.2$, this is resolved by calling the object a muon, electron, $\tau$ jet, or jet, in this order of priority.

### 3.1 Object-related systematic uncertainties

Uncertainties on the reconstruction and identification of leptons, $\tau$ jets and other jets, as well as the momentum or energy resolution/scale of these objects, comprise the dominant detector-related contributions to the systematic uncertainties. Additionally, uncertainties due to missing transverse energy reconstruction, the trigger, and measured luminosity are considered.

[^61]In lieu of a sizeable sample of true $\tau$ jets collected from collision data, the systematic uncertainty for the $\tau+E_{\mathrm{T}}^{\mathrm{miss}}$ trigger is estimated from the differences between simulation and data observed for this trigger in QCD multi-jet events. This results in a conservative estimate as the comparison is done on QCD multi-jet events rather than true $\tau$ jets-where the systematic effect is expected to be smaller. The statistical uncertainty on the ratio of the simulation-to-data trigger efficiencies (which is compatible with 1), in a region of transverse energy that benefits from large statistics, is taken as the systematic uncertainty on the $\tau$ trigger efficiency ( $11 \%$ ). For the $E_{\mathrm{T}}^{\text {miss }}$ trigger efficiency, the systematic uncertainty is taken as the largest simulation-to-data discrepancy observed for events with $E_{\mathrm{T}}^{\text {miss }}>50 \mathrm{GeV}$ (where the bulk of selected data lies) and is $5 \%$. The $\tau$ and $E_{\mathrm{T}}^{\text {miss }}$ trigger uncertainties are combined under the assumption that they are uncorrelated.

The dominating experimental systematic uncertainties for the $H^{+}$studies are summarized in Table 2. To assess the impact of most systematic sources on either the $\tau+$ jets or the $\tau+$ lepton channel, the selection cuts for each analysis are applied after shifting a particular parameter to its upper and lower extrema. The luminosity and the trigger uncertainty with respect to the offline efficiency both serve directly as scale factors on the event yield.

The effect of various systematic uncertainties on data-driven background estimates based on either $\tau$ jet fake rates, embedding, or the inversion of event selection criteria, some of which are unique to the methods themselves, is explored in Section 5.

Table 2: Object-related systematic uncertainties.

| Source of uncertainty | Uncertainty used in this analysis |
| :--- | :--- |
| Luminosity | $\pm 11 \%$ |
| $E_{\mathrm{T}}^{\text {miss }}$ resolution | Add or subtract object uncertainties into the $E_{\mathrm{T}}^{\text {miss }}$, up to $\pm 20 \%$ |
| Jet energy resolution (JER) | $\approx \pm 14 \%$, depending on $\eta$, see Reference [32] |
| Jet energy scale (JES) | $< \pm 10 \%$ for $p_{\mathrm{T}}>15 \mathrm{GeV}$ and $\|\eta\|<4.5$, see Reference [33] |
| b-tagging efficiency | $p_{\mathrm{T}}$ dependent scale factor uncertainties, $\pm 10-12 \%$, see Reference [27] |
| b-tagging mistag rate | Up to $\pm 26 \%$, Reference [27] with further refinements |
| Tau identification efficiency | $\pm 6-12 \%$, depending on $p_{\mathrm{T}}$ and number of associated tracks |
| Tau energy scale | $\pm 5 \%$ |
| Electron selection efficiency | $\pm 6-16 \%$ as a function of $p_{\mathrm{T}}$ |
| Electron energy scale | $\pm 1 \%$ for $\eta \mid<1.4, \pm 3 \%$ for $1.4<\|\eta\|<2.5$ |
| Electron energy resolution | Sampling term $\pm 20 \%$, a small constant term has a large variation with $\eta$ |
| Muon selection efficiency | $\pm 1.2 \%$ for $p_{\mathrm{T}}<20 \mathrm{GeV}$ and $\pm 0.4 \%$ for $p_{\mathrm{T}}>20 \mathrm{GeV}$ |
| Muon momentum scale | $\eta$ dependent scale offset in $p_{\mathrm{T}}$, up to $\pm 3.5 \%$ |
| Muon momentum resolution | $p_{\mathrm{T}}$ and $\eta$ dependent resolution smearing functions, $\leq \pm 10 \%$ |
| $\tau+E_{\mathrm{T}}^{\text {miss }}$ trigger | $\pm 12 \%$ with respect to offline, References [34,35] with further refinements |

## 4 Event selection

### 4.1 Event selection in the $\tau+$ jets final state

A topology of interest in the search for a charged Higgs boson decaying to $\tau v$ is

$$
\begin{equation*}
t \bar{t} \rightarrow\left[H^{+} b\right]\left[W^{-} \bar{b}\right] \rightarrow\left[\left(\tau^{+} v\right) b\right][(j j) \bar{b}] \tag{1}
\end{equation*}
$$

where both the $W$ boson and the $\tau$ lepton decay hadronically; the neutrinos result in a large amount of $E_{\mathrm{T}}^{\mathrm{miss}}$. This topology has several advantages: the fact that the $W$ boson can be reconstructed fully; the $H^{+}$candidate mass can be reconstructed in the transverse plane (analogous to the transverse mass in
a $W$ decay); and the larger branching fraction for $W$ decaying into hadrons. However, there are also potentially serious challenges, such as the inherent presence of multi-jet final states which may make it difficult to distinguish this topology from the QCD multi-jet background.

The event selection is based on $E_{\mathrm{T}}^{\text {miss }}$ and $\tau$-trigger selection, followed by the offline selection involving jets, $b$ jet tagging, $\tau$ identification, and the selection of the highest- $p_{T} j j b$ candidate (i.e., the reconstructed top-quark candidate from the decay $t \rightarrow W b \rightarrow$ jet-jet-b). The baseline selection is based on the objects and definitions in Section 3 and consists of the following requirements:

1. Event preselection:
(a) event-level cleaning cuts as described in Reference [20], with further refinements;
(b) $E_{\mathrm{T}}^{\text {miss }}$ plus $\tau$-trigger;
(c) at least 4 jets with $p_{T}>20 \mathrm{GeV}$ and $|\eta|<4.9$.
2. Exactly one $\tau$ jet candidate with $p_{T}>20 \mathrm{GeV}$.
3. Events with any identified electrons or muons with $p_{T}>10 \mathrm{GeV}$ are vetoed.
4. $E_{\mathrm{T}}^{\mathrm{miss}}>20 \mathrm{GeV}$.
5. $E_{\mathrm{T}}^{\mathrm{miss}} / \sqrt{\Sigma E_{\mathrm{T}}}>3 \mathrm{GeV}^{1 / 2}$.
6. At least one $b$-tagged jet.
7. The $j j b$ system candidate with the highest $p_{T}^{j j b}$ value must satisfy $m(j j b) \in[120,240] \mathrm{GeV}$.

The final discriminating variable is the $\tau+E_{\mathrm{T}}^{\text {miss }}$ transverse mass, $m_{T}$, which in the case of most backgrounds corresponds to the transverse $W$ mass and in the case of the signal hypothesis corresponds to the transverse $H^{+}$mass. Explicitly, $m_{T}$ is defined as

$$
\begin{equation*}
m_{T}=\sqrt{2 p_{T}^{\tau} E_{\mathrm{T}}^{\mathrm{miss}}(1-\cos \Delta \phi)} \tag{2}
\end{equation*}
$$

where $\Delta \phi$ is the angle between the $\tau$ jet and the missing momentum in the transverse plane. Using this selection, a total of 33 events are observed in $36 \mathrm{pb}^{-1}$ of data.

### 4.2 Event selection in the $\tau+$ lepton final state

In this channel, the event signature is based on the leptonically decaying $W$ boson $(l=e, \mu$, or $\tau$ with $e / \mu$ decays) and the presence of a hadronically-decaying $\tau$. Neutrinos in the event result in a large amount of $E_{\mathrm{T}}^{\text {miss }}$

$$
\begin{equation*}
t \bar{t} \rightarrow\left[H^{+} b\right]\left[W^{-} \bar{b}\right] \rightarrow\left[\left(\tau^{+} v\right) b\right]\left[\left(l^{-} \bar{v}\right) \bar{b}\right] \tag{3}
\end{equation*}
$$

The signal can manifest itself as an excess of $\tau$ leptons above the irreducible Standard Model background of $t \bar{t}$ production. Since at least three neutrinos are expected to be present in the final state, a full event reconstruction is not possible. The lepton originating from the $W$ decay allows for the use of a highly efficient trigger.

The baseline event selection is built around an isolated lepton trigger requirement, missing transverse energy, tagged $b$ jets, and a $\tau$ jet. It is based on the objects and definitions in Section 3 and consists of the following requirements:

1. Event preselection:
(a) event-level cleaning cuts as described in Reference [20], with further refinements;
(b) lepton trigger;
(c) exactly one trigger-matched isolated lepton with $p_{T}>20 \mathrm{GeV}$.
2. Exactly one $\tau$ jet with $p_{T}>20 \mathrm{GeV}$.
3. At least two jets with $p_{T}>20 \mathrm{GeV}$ and $|\eta|<4.9$.
4. At least one of the jets is $b$-tagged.
5. $\sum E_{\mathrm{T}}>200 \mathrm{GeV}$.
6. Selected $\tau$ jet and lepton have opposite charge.
7. $E_{\mathrm{T}}^{\text {miss }}>60 \mathrm{GeV}$.

Using this selection, a total of 11 events are observed in $37 \mathrm{pb}^{-1}$ of data.

## 5 Data-driven background estimation

Events coming from production processes such as $t \bar{t}$, single top-quark, $W+$ jets, $Z+$ jets and QCD multijets make up the dominant background to charged Higgs boson searches at the LHC. The individual contributions from many of these backgrounds can be determined in a data-driven way. Events in which electrons, muons, or jets are misidentified as $\tau$ jets are predicted using methods based on fake rates. In this note, a fake rate is understood as the number of objects ( $e, \mu$ or jet) being identified as a $\tau$ jet divided by all objects considered for $\tau$ identification (called $\tau$ jet candidates). Background events containing true $\tau$ jets are studied with the embedding method. The QCD multi-jet background is estimated in the $\tau+$ jets analysis using a data-driven control sample.

### 5.1 Events with electrons misidentified as $\tau$ jets

The $\tau$ identification has been optimized separately for a high QCD jet rejection, and for the rejection of electrons [26]. The probability that an electron is misidentified as a $\tau$ jet can be estimated from data.

### 5.1.1 Method

A technique to derive this fake rate from data is the so-called tag-and-probe method. The process $Z \rightarrow e e$ allows the selection of an unbiased and clean sample of electrons from data. While the tag electron is required to satisfy a tight electron selection, the other, if it is reconstructed as a $\tau$ jet candidate, is then used as the probe.

Only those probe $\tau$ jet candidates with exactly one associated track are considered as the rate of electrons faking 3 -track $\tau$ jets is negligible compare to the 1 -track case. The individual requirements for both the $\tau+$ jets and $\tau+$ lepton analyses are applied, this includes the electron veto and the overlap removal with electron candidates.

### 5.1.2 Results

The measured fake rates are shown in Figure 2. Within uncertainties, the fake rates modeled in Monte Carlo agree with those obtained from data.

### 5.1.3 Systematic uncertainties

Three main sources of systematic uncertainties on the electron-to- $\tau$ fake rate have been studied. The largest contribution originates from the background contamination with QCD jets (after the application of the electron veto on the probe object, QCD jets are enhanced with respect to electrons among the $\tau$ jet candidates) and gives an uncertainty of about $30 \%$. The choice of the mass window size around the $Z$ boson mass applied to the tag-and-probe objects introduces another uncertainty ( $13 \%$ ). The uncertainty of the electron energy scale (via the cut on the tag electron energy) only gives a small contribution (2\%). The total systematic uncertainty varies slighty with $p_{\mathrm{T}}$ and $\eta$ and is estimated to be $33 \%$.

Figure 2: The fake rate for probe objects passing the $\tau$ identification, the electron veto, and overlap removal with reconstructed electrons is shown parametrized in $p_{T}$ and $|\eta|$. The uncertainties indicated are statistical only.

### 5.1.4 Application to estimate the electron-to- $\tau$ fake background to the $H^{+}$selections

The electron-to- $\tau$ fake background is estimated the following way: In simulated events, any true electron matched to a $\tau$ jet candidate is labeled as an identified $\tau$ jet and the event is given a weight equal to the probability given by the fake rate measured in this section, instead of performing the usual $\tau$ identification (i.e. the $\tau$ identification part is taken from data instead of simulation). All relevant quantities ( $E_{\mathrm{T}}^{\mathrm{miss}}, \Sigma E_{T}$, $E_{\mathrm{T}}^{\mathrm{miss}}$ significance, $m_{T}$, opposite-charge requirement) are then recalculated under the hypothesis that the electron is identified as a $\tau$ jet. The baseline selections of both the $\tau+$ jets and the $\tau+$ lepton channels (with the exception of the $\tau$ log-likelihood identification requirements) are then applied and the number of events surviving is counted (summing the weights of these events). The prediction using the fake rate derived from data and the expectation from Monte Carlo are shown in Table 3.

Table 3: Application of the fake rate obtained from $Z \rightarrow e e$ events. The numbers shown are the expected number of events after the baseline $\tau+$ lepton selection (normalized to $37 \mathrm{pb}^{-1}$ ), and after the baseline $\tau+$ jets selection (normalized to $36 \mathrm{pb}^{-1}$ ), for one-track $\tau$ jets. The predictions based on the fake rate measurement (the first uncertainty is statistical and the second is systematic), as well as the Monte Carlo prediction (statistical uncertainties only), are given.

| Selection | Sample | Fake rate prediction [num. of events] | MC prediction [num. of events] |
| :--- | :--- | :--- | :--- |
| $\tau+$ jets | $t \bar{t}$ | $1.08 \pm 0.01$ (stat) $\pm 0.38$ (syst) | $1.50 \pm 0.09$ (stat) |
| $\tau+$ lepton | $t \bar{t}$ | $0.65 \pm 0.01$ (stat) $\pm 0.04$ (syst) | $0.79 \pm 0.08$ (stat) |

### 5.2 Events with muons misidentified as $\tau$ jets

The muon-to- $\tau$ fake rate has been studied in a control sample of $Z \rightarrow \mu \mu$ events, in a similar manner as the electron-to- $\tau$ fake rate described in Section 5.1. The Monte Carlo description of the muon-to- $\tau$ fake rate is found to be consistent with that in data. Since the Monte Carlo expectation is that this background is 2-3 orders of magnitude smaller than even the uncertainties of other backgrounds, it is concluded that the background due to muons misidentified as $\tau$ jets is negligible.

Figure 3: Jet-to- $\tau$ fake rates measured from $\gamma+$ jet events for 1 -track and 3-track $\tau$ jets. Statistical and systematic uncertainties are given for Monte Carlo, while the uncertainties shown for data are only statistical.

### 5.3 Events with jets misidentified as $\tau$ jets

A measurement of the probability of jets to be misidentified as $\tau$ jets is performed using $\gamma+\mathrm{jet}$ events selected from collision data. This particular control sample is selected as the jet in these events is dominantly quark-initiated (as opposed to QCD jets events, where jets are dominantly gluon-initiated) which is also the case for the background investigated in this section, i.e., $t \bar{t}$, single top-quark, and $W+$ jets. The resulting fake rate is used to predict the part of these backgrounds which is due to jet-to- $\tau$ fakes, for both the $\tau+$ jets and $\tau+$ lepton analyses.

### 5.3.1 Method

For the measurement of the jet $\rightarrow \tau$ fake rate, events are required to pass a $\gamma$ trigger. Identified $\gamma \mathrm{s}$ are required to be matched to the trigger object and pass a tight isolated photon selection. They must have $|\eta|<2.5$ and a transverse momentum of at least 25 GeV . Events are selected which have one $\gamma$ and a jet of $p_{\mathrm{T}}>20 \mathrm{GeV}$ separated by a $\Delta R$ of at least 0.7 . The fake rate is binned in number of tracks associated to the $\tau$ jet candidate and in $p_{\mathrm{T}}$. The object going into the denominator of the fake rate calculation is a $\tau$ jet candidate which must have $p_{\mathrm{T}}>20 \mathrm{GeV},|\eta|<2.5$, 1 or 3 associated tracks, and pass lepton vetoes in order to reduce lepton fakes that would otherwise contaminate the fake measurement.

Objects going into the numerator of the fake rate calculation must pass the complete $\tau$ identification as described in Section 3. They must also have between 1 and 3 associated tracks, not be within $\Delta R$ of 0.4 of any $e$ or $\mu$ passing the common object selection, and pass the cuts for reconstructed $\tau$ identification. Once measured, the fake rate can be applied to MC to test its ability to accurately measure the number of fakes and to predict fakes in data. The resulting fake rates are shown in Figure 3.

### 5.3.2 Systematic uncertainties

The systematic uncertainties considered are (the values depend slightly on $p_{T}$ ):

- Contamination of the control sample with true $\tau$ jets from $Z \rightarrow \tau \tau$ and $W \rightarrow \tau v$ (negligible).
- Contamination of the control sample with QCD multi-jet events. This is tested by investigating the effect of modifying the photon identification requirements on the measured fake rate, in particular loosening the photon isolation which increases the impurity from QCD jets in the control sample ( $\approx 10 \%$ ).
- Uncertainties of the control samples selection. This is tested by varying the selection cuts, and by splitting the control sample into a part which fulfils even tighter requirements and one which does not, and then taking the variation of the fake rate due to these changes as the uncertainty ( $\approx 15 \%$ ).
- Correlations between the tag and probe objects. This is evaluated by changing the selection requirements for the tag object and studying the impact on the fake rate $(\approx 3 \%)$.

The total systematic uncertainty is about $20 \%$ in the $p_{T}$ range of interest. The statistical uncertainty on the fake rate is a systematic uncertainty for any application of the fake rate, and grows rapidly with $p_{T}$, as shown in Figure 3.

### 5.3.3 Application to estimate the fake-jets background to the $H^{+}$selections

In simulated events, any jet matched to a $\tau$ jet candidate as defined by the denominator requirements of the fake rate detailed in Section 5.3 .1 is labeled as a $\tau$ jet (instead of performing the offline hadronic $\tau$ identification), and given a weight equal to the calculated fake rate value. In order to avoid doublecounting, the jet that corresponds to this hadronic $\tau$ is removed from the event, affecting the number of reconstructed jets, $\Sigma E_{T}$ of the event, $E_{\mathrm{T}}^{\text {miss }}$, the $E_{\mathrm{T}}^{\text {miss }}$ significance, the number of $b$-tagged jets, and the top quark reconstruction. For all events which pass the event selection after taking this into consideration, the weight is summed. The number of events predicted for collision data, together with a comparison to the prediction using Monte Carlo truth information, is shown in Table 4 both for the $\tau+$ jets and the $\tau+$ lepton baseline selection (see Section 4). Within uncertainties, the predictions agree well.

Table 4: Application of the fake rate obtained from $\gamma+$ jet events. The numbers shown are the expected number of events in collision data after the baseline $\tau+$ lepton selection (normalized to $37 \mathrm{pb}^{-1}$ ), and after the baseline $\tau+$ jets selection (normalized to $36 \mathrm{pb}^{-1}$ ). The predictions based on the fake rate measurement (statistical and systematic uncertainties), as well as the Monte Carlo prediction (statistical uncertainties), are given.

| Selection | Sample | Fake rate prediction [num. of events] | MC prediction [num. of events] |
| :--- | :--- | :--- | :--- |
| $\tau+$ jets | $t \bar{t}$ | $1.7 \pm 0.2$ (stat) $\pm 0.3$ (syst) | $1.9 \pm 0.2$ (stat) |
| $\tau+$ lepton | $t \bar{t}$ | $6.7 \pm 1.0$ (stat) $\pm 1.4$ (syst) | $6.0 \pm 0.2$ (stat) |
| $\tau+$ lepton | $W+$ jets | $0.9 \pm 0.1$ (stat) $\pm 0.2$ (syst) | $0.6 \pm 0.3$ (stat) |
| $\tau+$ lepton | Single top | $0.16 \pm 0.02$ (stat) $\pm 0.03$ (syst) | $0.12 \pm 0.02$ (stat) |
| $\tau+$ lepton | $Z+$ jets | $0.15 \pm 0.02$ (stat) $\pm 0.03$ (syst) | $0.3 \pm 0.2$ (stat) |

### 5.4 QCD Background Estimate

### 5.4.1 Method

The following method is used to estimate the QCD jets background to the $\tau+\mathrm{jets}$ analysis. In order to model the QCD background from data, an orthogonal event selection is defined which is identical to the complete $\tau+$ jets event selection, except for requiring a looser $\tau$ identification while rejecting events using the tighter $\tau$ identification used in the baseline selection.

This selection, referred to as "inverted selection" in this section, is applied to data and the shape of the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution is used as a model for the QCD background (after subtracting the contribution from the background expectation from simulation for non-QCD processes). Then, a fit is performed to the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution in data resulting from the baseline $\tau+$ jets selection (after all cuts), using two shapes:
the model extracted for the QCD background, and the sum of non-QCD processes (dominated by $t \bar{t}$, $W+$ jets) for which the shape and the relative normalization is taken from MC simulation.

The fit floats the overall normalization (to the one in data) and the QCD fraction. The underlying assumption is that the shape of the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution for QCD is the same for the baseline and the inverted selection. This is shown in Figure 4 where the two distributions are compared for collision data. The comparison is done after selection cuts $1-3$ as described in Section 4.1 have been applied, as this ensures that the distributions are QCD-dominated. In spite of the QCD-dominance, the contribution of events with true $E_{\mathrm{T}}^{\text {miss }}$, like $t \bar{t}$ and $W+$ jets, is still significant in the tail of the distribution. For this reason, their expectation from simulation has been subtracted. Only a very small number of QCD events is observed for $E_{\mathrm{T}}^{\text {miss }}>100 \mathrm{GeV}$, as expected. The remaining differences are within statistical uncertainties.

Figure 4: Distribution of $E_{\mathrm{T}}^{\text {miss }}$ for data, after subtracting the expectation from $t \bar{t}, W+\mathrm{jets}$ and single topquark simulation. The comparison is done after selection cuts 1-3 as described in Section 4.1 have been applied, as this ensures that the distributions are QCD-dominated. The error bars show the size of the data statistical uncertainties.

### 5.4.2 Results

The result of the fit is shown in Figure 5. The QCD fraction is estimated to be ( $54 \pm 19$ ) \% for the 1-track $\tau$ case. There are not enough 3-track events in data after the baseline selection, thus no separate fit is performed and instead, both the 1- and 3-track cases are fitted simultaneously. The QCD fraction is estimated to be $(57 \pm 19) \%$.

### 5.4.3 Systematic uncertainties

The dominant systematic uncertainties are:

- Using $t \bar{t}$ and $W+$ jets shape and relative normalization from Monte Carlo, dominated by uncertainties on the $t \bar{t}$ cross section: $15 \%$.
- $E_{\mathrm{T}}^{\text {miss }}$ shape difference in signal and control region: $5 \%$.

The contamination in the control region from backgrounds that were not considered is negligible. Currently, the systematic uncertainty is dominated by the statistical uncertainty of the limited size of the data set on which the fit is applied, amounting to $33 \%$. However, this component will naturally decrease as the collected integrated luminosity increases. Uncertainties related to the cross sections and shapes of other backgrounds will also decrease once they are measured with high accuracy at the LHC.

Figure 5: Fit to $E_{T}^{\text {miss }}$ after all selection cuts using two shapes: one for the QCD model and one for $t \bar{t}$ and $W+$ jets (all other backgrounds are negligible and not shown). Left: 1 -track $\tau$ jets. Right: 1 -track and 3 -track $\tau$ jets together. The error bars show the size of the data statistical uncertainties.

### 5.4.4 Application to estimate the QCD background to the $\tau+$ jets selection

The estimated QCD jets contribution to the final $m_{T}$ distribution is shown in Figure 6. All other backgrounds have $W$ bosons in the final state and their distributions drop off around the $W$ boson mass, as expected. Such behaviour is neither expected nor observed for the QCD jets background as the sources of both the $\tau$ jet and $E_{\mathrm{T}}^{\text {miss }}$ are fakes and the resulting shapes are thus not steered by a specific physics process but by instrumental effects. To probe the region with large $m_{T}$, in which a potential $H^{+}$signal resides, it is thus important to suppress the QCD jets background as much as possible. This can be done with a tighter $\tau$ identification and harder $E_{\mathrm{T}}^{\text {miss }}$ requirements once a larger data set becomes available. The estimated QCD jets contribution after all cuts is $18.8 \pm 6.2$ (stat) $\pm 3.0$ (syst) events.

Figure 6: Estimated QCD jets contribution to the $m_{T}$ distribution after all cuts of the baseline $\tau+$ jets selection. The data is shown, together with the fit for $t \bar{t}$ and $W+$ jets contributions, where the shapes have been taken from simulation. The error bars show the size of the data statistical uncertainties.

### 5.5 Embedding method

Embedding tools are used for estimating the background with true $\tau$ jets for the $\tau+$ jets analysis. The method consists of collecting a control sample containing $t \bar{t}$, single top-quark production and $W+$ jet events with muons, replacing the detector signature of the muon with a simulated $\tau$ lepton, re-reconstructing the new hybrid event, and then using these events instead of simulation for background estimation. The advantage is that the whole event (except for the $\tau$ jet) is taken directly from data, including the underlying event and pile-up, $b$-quark jets and light-quark jets.

### 5.5.1 Method

Control sample collection. To select the $\mu+$ jets control sample from data, the following event selection is used, based on the objects and definitions in Section 3:

- Event-level cleaning cuts.
- Event passed a trigger requiring the presence of a muon candidate.
- Exactly one isolated muon with $p_{T}>20 \mathrm{GeV}$.
- No electron with $p_{T}>20 \mathrm{GeV}$.
- At least three jets with $p_{T}>20 \mathrm{GeV}$.
- At least one of the jets is tagged as $b$ jet.
- A reconstructed invariant mass of two jets with $p_{T}>35 \mathrm{GeV}$ in a mass window of 20 GeV around the nominal $W$ boson mass.
- Missing transverse energy $E_{T}^{\text {miss }}>30 \mathrm{GeV}$.
- Scalar sum of the energy in the calorimeter $\Sigma E_{T}>200 \mathrm{GeV}$.

The expected and observed number of events are shown in Table 5 and agree well.
Table 5: Expected (from simulation) and observed number of events in the embedding control sample. Statistical uncertainties only.

|  | Expected |  |  |  |  | Observed |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $t \bar{t}$ | Single top-quark | $W+$ jets | QCD | Sum | Data |
| Events | $171.2 \pm 1.4$ | $11.3 \pm 0.3$ | $16.8 \pm 2.1$ | $12.4 \pm 3.2$ | $212 \pm 7$ | 219 |

The impurity from backgrounds with muons produced in $\tau$ decays, and non-isolated muons (dominantly $b \bar{b}$ and $c \bar{c}$ events) is at the level of $10 \%$ and biases the shape of embedded events as there is no physical correspondence to such embedded events. However, as is shown below, the bias is reduced as these events typically have a softer $\mu$ spectrum ( $W \rightarrow \tau \nu \rightarrow \mu \nu \nu \nu$ as compared to $W \rightarrow \mu \nu$, and muons from $B$ and $D$ meson decays) and thus mostly contribute to the low-mass tail of the $m_{T}$ distribution which is not considered.

Embedding step. After events have been selected, the actual embedding takes place. The muon in the event is selected, its vertex position and momentum are extracted. The momentum is then rescaled to account for the higher $\tau$-lepton mass, and fed into TAUOLA to produce the $\tau$-lepton decay products and generate final-state radiation. The result is propagated through the ATLAS detector simulation, followed by reconstruction.

In the next step, tracks and calorimeter cell depositions in the vicinity of the muon are replaced with those of the $\tau$-lepton decay products-in other words, the simulated $\tau$ event is embedded in the collision data event. Then the reconstruction algorithms are re-run on this hybrid event, reconstructing $\tau$ jets, leptons, missing transverse energy, and other high-level physics objects.

### 5.5.2 Application to estimate the true- $\tau$ background to the $\tau+$ jets selection

The contribution of backgrounds with true $\tau$ jets to the final $m_{T}$ distribution is estimated from this distribution for embedded events. The normalization is taken from collision data events in the region $30<m_{T}<70 \mathrm{GeV}$, where both the QCD background contribution and the signal contamination are low. The following procedure is applied:

1. Obtain the $m_{T}$ distribution after the $\tau+\mathrm{j}$ ets baseline selection from embedded events.
2. From collision data, count the number of events after applying the $\tau+$ jets selection in the $m_{T}$ distribution between $30<m_{T}<70 \mathrm{GeV}$ (after subtracting the background from fake $\tau$ jets).
3. Using this number, normalize the $m_{T}$ distribution from embedding using the ratio of events in collision data and embedded events in the region $30<m_{T}<70 \mathrm{GeV}$.

Currently, the method is statistics-limited and thus the selection applied to the embedded events is loosened compared to that given in Section 4.1: no trigger requirement is applied to the embedded samples and the $\tau$ identification is replaced by matching a $\tau$ candidate to the true $\tau$ in the event. Requirements related to the second top quark $t \rightarrow b q q$ in the event are dropped as they are not expected to influence the $m_{T}$ shape, namely the reconstruction of this hadronic top quark in a mass window and the requirement of having at least four jets in the event (loosened to three). In Figure 7, it is shown that the impact of this loosened selection on the $m_{T}$ shape, as compared to the same distribution for the baseline selection, can be taken into account by a systematic uncertainty of $20 \%$, which is less than the statistical uncertainty associated to the set of embedding events. Figure 7 also shows the $m_{T}$ distribution obtained from embedded simulation events (left) and data (right).

Figure 7: Left: Comparison of the $m_{T}$ shape in simulation for selections which have been loosened with respect to the $\tau+$ jets selection. Shown is the shape for the full selection (Baseline), and when removing the trigger, the $\tau$ identification requirement (replaced by matching a $\tau$ candidate to a true $\tau$ ), not using the top quark reconstruction requirement and only requiring a minimum of three instead of four jets (Loose). Additionally, this loosened selection is also applied to an embedded $t \bar{t}$ simulation sample (Embedded). Statistical uncertainties are shown. Right: Comparison of the $m_{T}$ shape embedded versus collision data after subtracting the contributions from fake $\tau$, as estimated in previous sections, from the data. The comparison is done after the $\tau+$ jets event selection described in Section 4.1 and after normalizing the embedding distribution to the data distribution in the range $30<m_{T}<70 \mathrm{GeV}$. Statistical and systematic uncertainties are shown.

As can be seen, the background estimate is currently limited by the statistical uncertainty due to the limited number of events in the $t \bar{t}$ control sample. In the range $70<m_{T}<210 \mathrm{GeV}, 4.7 \pm 1.3_{-1.1}^{+1.4}$ background events with true $\tau$ jets are expected and $6.3 \pm 2.5$ are observed in excess of the background predicted by the fake rate methods and the QCD fit. Within large statistical uncertainties, the background prediction and data agree well.

### 5.5.3 Systematic uncertainties

The following systematic uncertainties are associated to the background prediction:

- Differences in shapes of distributions between events with an embedded $\tau$ compared to a reference; considering Figure 7, the uncertainy is estimated to be $\pm 10 \%$. This includes the impact of the control sample selection (e.g. the muon trigger efficiency, the $\eta$ dependence of the offline muon selection) and the contamination from non-isolated muons and muons from $\tau$ decays.
- Difference in $m_{T}$ shape due to the loosening of the selection with respect to the baseline selection, as shown in Figure 7: $-20 \%$.
- Uncertainties in the subtraction of fake- $\tau$ backgrounds from data: $\pm 20 \%$.

An additional statistical uncertainty of about $30 \%$ is larger than the systematic uncertainties.

## 6 Summary of data-driven estimates

The results of the data-driven methods introduced and explained in Section 5 are summarized for each of the $\tau+$ jets and $\tau+$ lepton final state analyses, and compared to collision data.

## $6.1 \quad \tau+$ jets channel

The results of the data-driven methods in estimating the contributions of the various categories of backgrounds after the baseline selection are summarized in Table 6 and the $m_{T}$ distribution of the remaining events is shown in Figure 8. The number of events with true $\tau$ jets has been estimated with the embedding method, the jet $\rightarrow \tau$ fakes with $\gamma+$ jet control samples, the $e \rightarrow \tau$ fakes with $Z \rightarrow e e$ control samples and the QCD contribution by taking its shape from a sideband region and fitting it to the data. Both the total number of events, and the number of events with $m_{T}>70 \mathrm{GeV}$ is given. This allows for a better comparison of data and expectation as the estimate from the embedding method is fitted to data in the range $30<m_{T}<70 \mathrm{GeV}$. The uncertainties are still large, but a good agreement between estimated and observed events is seen.

Table 6: Expected number of events from data-driven estimates and as observed in data for the $\tau+$ jets channel.

|  | Expected |  |  |  | Observed |  |
| :--- | ---: | :---: | :---: | :---: | :---: | :---: |
|  | True $\tau$ jets | Jet $\rightarrow \tau$ fakes | $e \rightarrow \tau$ fakes | QCD | Sum | Data |
| All events | $10.8 \pm 3.1_{-2.4}^{+3.2}$ | $1.7 \pm 0.2 \pm 0.3$ | $1.1 \pm 0.0 \pm 0.4$ | $18.8 \pm 6.2 \pm 3.0$ | $32 \pm 9 \pm 7$ | 33 |
| $m_{T}>70 \mathrm{GeV}$ | $4.7 \pm 1.3_{-1.1}^{+1.4}$ | $1.2 \pm 0.2 \pm 0.2$ | $0.7 \pm 0.0 \pm 0.3$ | $11.3 \pm 3.7 \pm 1.7$ | $18 \pm 5 \pm 4$ | 17 |

Figure 8: The $\tau+E_{\mathrm{T}}^{\text {miss }}$ transverse mass distribution at the end of the event selection for the $\tau+\mathrm{jets}$ channel comparing the observation in collision data, and the estimates from data-driven methods. The error bars show the size of the data statistical uncertainties. The distribution of the $H^{+}$signal is given for a reference point in parameter space corresponding to $\mathrm{BR}\left(t \rightarrow b H^{+}\right) \approx 6 \%$, thus the SM-like $t \bar{t}$ background and its contribution to the $e \rightarrow \tau$ and jet $\rightarrow \tau$ fake background would be reduced correspondingly.

## $6.2 \tau+$ lepton channel

For the second final state under investigation, the results are summarized in Table 7 , and the $E_{\mathrm{T}}^{\text {miss }}$ distribution of the remaining events is shown in Figure 9. The number of events with true $\tau$ jets is taken from simulation, while the contribution of jet $\rightarrow \tau$ fakes and $e \rightarrow \tau$ fakes is estimated using $\gamma+\mathrm{jet}$ and $Z \rightarrow e e$ control samples. In this channel, the QCD jets background is negligible mostly due to the lepton and the $E_{\mathrm{T}}^{\mathrm{miss}}$ requirements. A good agreement between the estimated and the observed value is seen.

Table 7: Expected number of events from data-driven estimates and as observed in data for the $\tau+$ lepton channel. The number of events with true $\tau$ jets is taken from simulation.

|  | Expected |  |  |  | Observed |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | True $\tau$ jets | Jet $\rightarrow \tau$ fakes | $e \rightarrow \tau$ fakes | Sum | Data |
| Events | $6.9 \pm 0.3 \pm 1.4$ | $7.9 \pm 1.1 \pm 1.6$ | $0.65 \pm 0.01 \pm 0.04$ | $15.5 \pm 1.4 \pm 3.0$ | 11 |

## 7 Conclusions

Data-driven methods are used in $37 \mathrm{pb}^{-1}$ of $\sqrt{s}=7 \mathrm{TeV}$ data to estimate the number of events characterized by the presence of a $\tau$ jet, $E_{\mathrm{T}}^{\text {miss }}, b$ jets, and a hadronically or leptonically decaying $W$ boson. The events are predominantly expected to come from $t \bar{t}, W$ or $Z+$ jets, single top-quark, and QCD events and represent backgrounds to charged Higgs boson searches. Predictions of $32 \pm 9$ (stat) $\pm 7$ (syst)

Figure 9: The $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution at the end of the event selection for the $\tau+$ lepton channel comparing the observation in collision data, and the estimates from data-driven methods. The error bars show the size of the data statistical uncertainties. The distribution of the $H^{+}$signal is given for a reference point in parameter space corresponding to $\operatorname{BR}\left(t \rightarrow b H^{+}\right) \approx 6 \%$, thus the SM-like $t \bar{t}$ background and its contribution to the $e \rightarrow \tau$ and jet $\rightarrow \tau$ fake background would be reduced correspondingly.
$\left(18 \pm 5(\right.$ stat $) \pm 4$ (syst) with $\left.m_{T}>70 \mathrm{GeV}\right)$ and $15.5 \pm 1.4$ (stat) $\pm 3.0$ (syst) events are achieved in the $\tau+$ jets and $\tau+$ lepton channels, respectively. The observation of 33 events ( 17 with $m_{T}>70 \mathrm{GeV}$ ) in the $\tau+$ jets channel and 11 events in the $\tau+$ lepton channel is consistent with expectations based on these data-driven background estimation methods. The study presented here serves as a foundation for future charged Higgs boson searches in the hadronically-decaying $\tau$ final state using larger amounts of integrated luminosity.

# Update of Background Studies in the Search for the Higgs Boson in the Diphoton Channel with the ATLAS detector at $\sqrt{s}=7 \mathrm{TeV}$ 

The ATLAS collaboration

#### Abstract

This note presents an update of the study of the backgrounds in the search for the Higgs boson decaying into a pair of photons. The analysis done with $38 \mathrm{pb}^{-1}$ of $p p$ collision data collected in 2010 with the ATLAS detector at a centre-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ is complemented with $94 \mathrm{pb}^{-1}$ of data collected in 2011. The dominant background components are measured and found to be in agreement with the Standard Model predictions, both in terms of overall yield and invariant mass distribution. No excess is observed.

At this early stage of LHC operation an important question in the search for the Higgs boson in the diphoton decay channel is the relative contributions of the different background processes. The predominant background components are the irreducible prompt diphoton production, the reducible $\gamma$ jet and dijet backgrounds where one or more jets are misidentified as photons, and Drell-Yan events where both electrons are misidentified as photons. The measurement of these backgrounds is essential to accurately assess the performance of the search and to ascertain that all background processes are well modeled. This note presents an update of the study of backgrounds in the search for the Higgs boson in the $H \rightarrow \gamma \gamma$ channel, using a data sample corresponding to an integrated luminosity of $94 \mathrm{pb}^{-1}$ recorded in 2011 with the ATLAS detector at a centre-of-mass energy of 7 TeV . This luminosity estimate is based on a preliminary calibration; a $7 \%$ uncertainty is assigned in the normalization calculation. The computation of the expected backgrounds and the details of the data-driven background measurements follow closely the procedure described in [1, 2]. The two data sets of 2010 and 2011 are analyzed independently as the acceptance has changed due to the repair of faulty optical links in the calorimeter readout during the winter shutdown and because of the different running conditions.

Since the end of 2010 the LHC has been running with beams structured in bunch trains, with the number of bunches per train varying from 8 to more than 70 . The bunch spacing also varied from 150 ns in fall 2010 to 75 ns in March 2011 and down to 50 ns in April 2011. The changing beam patterns, in conjunction with the increasing beam intensities, have resulted in a variety of in-time and out-of-time pile-up conditions. An average number of interactions per bunch crossing of up to $\sim 8$ was reached. In this analysis a full Monte Carlo simulation, taking into account both the effects of in-time and out-oftime pile-up, was used. The efficiency of the photon identification and in particular that of the isolation cut are estimated using this simulation with high pile-up conditions.

The event selection is unchanged with respect to [1,2], except for the trigger thresholds where the transverse energy requirement for the two loosely selected photons has been raised from 15 GeV in 2010 to 20 GeV in 2011. Diphoton candidates are required to pass tight identification criteria, to be within the inner detector and calorimeter acceptance ( $|\eta|<2.37$ excluding $1.37<|\eta|<1.52$ ), to have transverse momenta larger than 40 GeV for the leading photon and 25 GeV for the sub-leading photon, and to have an invariant mass between 100 and 150 GeV . The photon isolation used in this analysis is calorimeter-based; it is corrected for underlying event and pile-up effects on an event-by-event basis, and for out-of-cone showering as described in [3]. Similarly to what was done in [1, 2] the Monte Carlo isolation efficiency is corrected for differences between the simulation and the data using electrons from $W$ decays collected in 2011.

The numbers of expected events for all background processes estimated for the 2011 running conditions are summarized in Table 1. The total expected background amounts to $301 \pm 72$ events. The main sources of uncertainties in these predictions are the jet fragmentation (into a photon or a leading $\pi^{0}$ ), the parton density functions and the variations of renormalization and factorization scales in the next-to-leading order predictions [1].

Altogether 291 diphoton candidate events are selected in the 2011 data, in good agreement with the overall Monte Carlo expectation. The number of prompt diphoton ( $N_{\gamma \gamma}$ ), photon-jet ( $N_{\gamma j}$ ) and dijet ( $N_{j j}$ ) events in the 2011 data sample are measured using the double sideband method described in [1, 2]. This method applies the sideband procedure of [3] to each photon sequentially. The sidebands are defined in terms of photon isolation and identification criteria using the fine-grained first sampling of the electromagnetic calorimeter. Since electrons from Drell-Yan events have a shower profile similar to that of isolated prompt photons, the $N_{\gamma \gamma}$ component estimated using the double sideband method contains most Drell-Yan dielectron events. The number of these events ( $N_{\mathrm{DY}}$ ) is independently measured, and subsequently subtracted from $N_{\gamma \gamma}$, using $Z$ decays to two electrons of which at least one is reconstructed as a photon. Systematic uncertainties in the background decomposition arise from the asymmetry between the photon and the jet transverse energies in photon-jet events, the correlations between isolation and

Table 1: Summary of the number of measured and expected prompt diphoton $\left(N_{\gamma \gamma}\right)$, Drell-Yan $\left(N_{\mathrm{DY}}\right)$, photon-plus-jet $\left(N_{\gamma j}\right)$, and dijet $\left(N_{j j}\right)$ background events with a diphoton invariant mass between 100 and 150 GeV .

|  | $N_{\gamma \gamma}$ | $N_{\mathrm{DY}}$ |
| :---: | :---: | :---: |
| Measured | $219 \pm 25$ (stat.) ${ }_{-9}^{+8}$ (syst.) | $6.7 \pm 0.3$ (stat.) $\pm 1.8$ (syst.) |
| Expected (MC) | $214 \pm 59$ | $7.1 \pm 0.5$ |
|  | $N_{\gamma j}$ | $N_{j j}$ |
| Measured (Reducible) | $59 \pm 12$ (stat.) $\pm 9$ (syst.) | $6 \pm 4$ (stat.) ${ }_{-1}^{+4}$ (syst.) |
| Expected (MC) | $77 \pm 42$ | $2.5 \pm 2.6$ |

identification variables, and the uncertainty in the contribution of diphoton events to the isolation and identification sideband regions. A summary of the main background components, estimated in the 2011 data, is given in Table 1 and illustrated in Figure 1 (a). A reasonable agreement between each measured component and its prediction is observed.

In order to reconstruct the invariant mass of the diphoton system as precisely as possible, two essential ingredients are the photon energy calibration and the reconstruction of the longitudinal position of the primary vertex of the interaction. The calibration of the reconstructed photon energy is based on precise test-beam data as well as on a simulation of the calorimeter and an accurate description of the amount of material upstream of it. This calibration scheme is further completed by an additional correction for energy scale variations as a function of pseudorapidity estimated with electrons from $Z$ decays. As in the 2010 data analysis, for events with more than one reconstructed primary vertex, the vertex associated with tracks having the largest sum of transverse momenta-squared is used to estimate the position of the hard scattering interaction. This method does not use the full ATLAS capabilities to select the primary vertex such as the ability of the calorimeter to determine the photon direction and the reconstruction of converted photons. An improvement in the $\gamma \gamma$ invariant mass resolution of about $10 \%$, in the 2011 data running conditions, compared to the data taken in 2010 [1, 2], could be achieved with a refined primary vertex reconstruction method.

The invariant mass distributions of the events selected in the 2011 data (b) and for the combined 2010 and 2011 data set corresponding to an integrated luminosity of $131 \mathrm{pb}^{-1}$ (c) are shown in Figure 1 along with the absolute background predictions. The expected full width at half maximum (FWHM) of the invariant mass distribution of a narrow resonance decaying into two photons amounts to $\sim 4.5 \mathrm{GeV}[1$, 2]. Given the bin size of 5 GeV in the histograms of Figure 1, if produced at a sufficiently high rate, such a resonance would manifest itself as an excess of events mostly in two bins with respect to their neighboring sidebands. No excess is observed, neither with the analysis criteria described in this note nor with other selections studied.

## Conclusion

The estimate of the background composition in the search for the Higgs boson in the diphoton channel has been updated using a sample of $94 \mathrm{pb}^{-1}$ of data collected in 2011. The main background components are measured and found to be in good agreement with their Standard Model predictions. No excess with respect to the expected backgrounds is observed in the diphoton invariant mass distribution.

# Search for the Higgs Boson in the Diphoton Channel with the ATLAS Detector using $209 \mathbf{~ p b}^{-1}$ of 7 TeV Data taken in 2011 

The ATLAS collaboration

#### Abstract

This note presents the result of a search for a Higgs boson decaying into a pair of photons in $p p$ collision data collected in 2011 with the ATLAS detector at a centre-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$. In the $209 \mathrm{pb}^{-1}$ of data analysed no statistically significant excess is observed. A $95 \%$ CL exclusion limit on the production cross section of a Higgs boson decaying into two photons relative to the Standard Model cross section is given.

## 1 Introduction

This note presents an update of the search for the Standard Model Higgs boson decaying to two photons. The updated search uses an integrated luminosity of $209 \mathrm{pb}^{-1}$ of $p p$ collision data collected in 2011 by the ATLAS detector [1] at a centre-of-mass energy of 7 TeV at the LHC. Techniques similar to those reported in $[2,3,4]$ are used to estimate the background composition, study the diphoton invariant mass resolution and determine the signal-related systematic uncertainties. Exclusion limits on the $H \rightarrow \gamma \gamma$ rate are derived from the study of the diphoton invariant mass distribution.

## 2 Event Selection and Reconstruction

The data sample collected in 2011 used in this analysis has two distinct LHC bunch patterns, with 75 ns and 50 ns bunch spacings. The vast majority of the data $\left(\sim 194 \mathrm{pb}^{-1}\right)$ was taken in the latter configuration. These conditions were sufficiently similar to not require a special treatment when combined as a single data set. As described in [4] an average number of interactions per bunch crossing of up to $\sim 8$ was reached. A full Monte Carlo simulation, taking into account both the effects of in-time pile-up events, occurring in the same bunch crossing as the hard scattering event, and out-of-time pile-up events, occurring in bunch crossings other than that of the hard scattering process, was used (with both the 50 ns and 75 ns configurations). In the simulation, pile-up events are added to the hard-scattering process according to a Poisson distribution. In order to accurately reproduce the changing beam conditions, the mean value of the Poisson distribution $\left(\mu_{P U}\right)$ is varied, and a reweighting procedure is applied to match the $\mu_{P U}$ distribution of the Monte Carlo to that of the data.

The 2011 data were triggered with the requirement of two photon-candidate clusters selected with loose identification criteria [5] and a transverse energy threshold of 20 GeV on both photons. The trigger efficiency for events passing all selection criteria (described below) is estimated using an independent trigger and is found to be $\sim 99 \pm 1 \%$. Event and object based data quality requirements are applied. Their impact on the signal efficiency are of the order of $\sim 1 \%$.

The kinematic event selection is unchanged with respect to [2, 3, 4]. Diphoton candidates are required to pass tight identification criteria, to be within the inner detector and calorimeter acceptance $(|\eta|<2.37$ excluding $1.37<|\eta|<1.52$ ) and to have transverse momenta larger than 40 GeV and 25 GeV for the leading and sub-leading photons respectively. In this analysis, the diphoton invariant mass range investigated is limited to candidate events with invariant masses between 100 GeV and 150 GeV . The photon identification criteria are essentially the same as those used in [4]. To cope with the higher pile-up environment two basic improvements to the analyses presented in $[2,3,4]$ are made.
(i) The additional pile-up events increase the fluctuations of the photon isolation transverse energy. The isolation requirement is thus relaxed from 3 GeV to 5 GeV . The isolation energy is the energy deposited in a $\Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}=0.4$ cone around the photon in the calorimeters, corrected for the underlying event and pile-up effects on an event-by-event basis, and for out-of-cone showering [6]. This modification resulted in an increase of $\sim 12 \%$ in isolation efficiency per photon and a small reduction in the purity of the diphoton sample from approximately $76 \%$ to $70 \%$.
(ii) Reconstructing the location of the primary vertex (PV) of the hard scattering interaction is crucial for a precise diphoton invariant mass reconstruction. In the moderate pile-up environment of the 2010 data (with an average of $\sim 2$ pile-up events per bunch crossing), the PV location was estimated using the reconstructed PV (from tracks in the inner detector) with the highest sum of the transverse momentum squared of its associated tracks. This choice is not optimal in the current higher pile-up environment. The longitudinal segmentation of the liquid-argon electromagnetic calorimeter and the fine granularity of its first sampling layer can be used to reconstruct the photon
direction, as described in more detail in [7]. The combination of the directions (also referred to as pointing direction) and positions of the two photons is used to estimate the PV location. In addition, when one or both photons are converted, the conversion tracks are also used to locate the PV. As in the case of energy scale and energy resolution, the resolution of the direction measurement is monitored using electrons from $Z$ decays. In the 2011 high pile-up conditions the improvement on the invariant mass resolution using this method amounts to $\sim 5 \%$. The signal diphoton invariant mass distribution for a Higgs boson mass hypothesis of 120 GeV is shown for both PV reconstruction methods in Figure 1. The full width at half maximum of the diphoton mass distribution is 4.1 GeV using the photon directions or conversion tracks.

Figure 1: Distributions of the reconstructed diphoton invariant mass of a simulated 120 GeV Higgs boson signal. Events are produced with a realistic simulation of the photon energy resolution, the effect out-of-time and in-time pile-up events and an inter-bunch spacing of 50 ns . The points and solid fit function correspond to the photon direction or conversion-based PV reconstruction. The triangles and dashed fit function represent the method using the PV with the highest sum of transverse momentum squared. The full width at half maximum of the invariant mass distribution is 4.1 GeV with the method using photon directions and conversion tracks.

After all selection cuts are applied, 926 diphoton candidate events are observed.
The photon identification efficiency is estimated from the Monte Carlo simulation with small shower shape corrections applied to better describe the distributions observed in 2010 data. As in [2, 3, 4], the Monte Carlo isolation efficiency is corrected from data using electrons from $Z$ decays. The smaller inefficiency due to the looser isolation cut reduces the effect of differences between the data and the Monte Carlo simulation.

Applying all selection criteria, for a Higgs boson with a mass between 110 and 140 GeV , the number of expected Standard Model Higgs boson events ranges from 3.6 to 2.5. The main production processes are all accounted for in this estimate, and they include the gluon fusion, the vector boson fusion, and the associated production with a vector boson or a pair of top quarks. Gluon fusion is both dominant and has the largest theoretical uncertainty, despite being computed at an improved next-to-next-to-leading-order level. The cross sections and $\gamma \gamma$ branching fractions used herein were computed in [8]. The uncertainty in the theoretical prediction is estimated to ${ }_{-15}^{+20} \%$ mostly from the renormalisation and factorisation scale variations and the uncertainties in the parton distribution functions [8].

The probability-density function for the signal diphoton mass is modelled by the sum of a Crystal Ball function (for the bulk of the events) and a Gaussian (to model the tails) [3]. Signal events were fully simulated at masses of $110,115,120,130$ and 140 GeV . The parameters of the signal model for Higgs boson mass hypotheses other than those fully simulated are linearly interpolated.

## 3 Background Estimation

The main background components in this analysis are the irreducible prompt diphoton production $(\gamma \gamma)$, the reducible photon-jet process ( $\gamma$-jet), the dijet (jet-jet) processes with one or more fake photons from jets fragmenting mainly into a leading $\pi^{0}$, and Drell-Yan events where both electrons are misidentified as photons. The expected abundance of these background components is indicated in Table 1. The large uncertainties in these predictions mostly arise from the jet fragmentation (into a photon or a leading $\pi^{0}$ ), the parton distribution functions and the variations of renormalisation and factorisation scales in the next-to-leading order predictions [2]. The uncertainty in the Drell-Yan prediction is from the Monte Carlo statistics only. The invariant mass distribution of the 926 candidate events selected in the data is illustrated in Figure 2 (a) along with the Monte-Carlo prediction for each background component.

Altogether the number of expected background events as estimated in [4] and corrected for the difference in the isolation cut is $866 \pm 207$, in agreement with the 926 events observed in the data.

Table 1: Number of expected and measured prompt diphoton ( $N_{\gamma \gamma}$ ), Drell-Yan ( $N_{\mathrm{DY}}$ ), photon-plus-jet $\left(N_{\gamma j}\right)$, and dijet $\left(N_{j j}\right)$ background events with a diphoton invariant mass between 100 GeV and 150 GeV .

|  | $N_{\gamma \gamma}$ | $N_{\text {DY }}$ |
| :---: | :---: | :---: |
| Expected (MC) | $602 \pm 169$ | $18 \pm 2$ (MC stat only) |
| Measured | $643 \pm 45$ (stat.) ${ }_{-71}^{+54}$ (syst.) | $23.8 \pm 0.6$ (stat.) $\pm 3.8$ (syst.) |
| $N_{\gamma j}$ | $N_{j j}$ |  |
| Expected (MC) | $238 \pm 129$ | $8 \pm 8$ |
| Measured (Reducible) | $216 \pm 23$ (stat.) ${ }_{-54}^{+32}$ (syst.) | $43 \pm 6$ (stat.) ${ }_{-18}^{+44}$ (syst.) |

A double side-band method is applied to measure these background components directly from the data as was done in [2, 3, 4]. The treatment of systematic uncertainties is extended to include variations of the base sample selection criteria of the side-band method, resulting in a non-negligible additional systematic uncertainty. The Drell-Yan component, which cannot be distinguished from the irreducible background, is estimated using $Z$ decays to electrons where one electron is misreconstructed as a photon. The results of the background studies are shown in Table 1 and summarised in Figure 2 (b). Good agreement between the data-driven background estimates and the Monte Carlo prediction is observed.

## 4 Systematic Uncertainties

The experimental systematic uncertainty on the event yield has the following main components:
(i) The uncertainty arising from the reconstruction and identification efficiencies amounts to $\pm 11 \%$ per event. It is estimated from data and Monte Carlo differences ( $\pm 5 \%$ per photon as estimated in 2010 data [3]) and the variation of pile-up conditions as a function of $\mu_{P U}$ and the two inter-bunch spacings 50 ns and 75 ns ( $\pm 2 \%$ per photon). The efficiency uncertainties between the two photons in the event are fully correlated.

Figure 2: (a) Diphoton invariant mass distributions for data and the cumulative predictions of the DrellYan (red solid), dijet (blue dotted), photon-jet (blue dashed) and diphoton (blue solid) components of the background. The two yellow bands depict the total uncertainty on the prediction and the uncertainty on the reducible background component only. (b) Measured number of events for each background component (points with error bars), compared with the corresponding Monte Carlo predictions (color bands).
(ii) The uncertainty in the isolation cut efficiency, estimated from the difference in efficiency between data and Monte Carlo found in $Z$ decays to electrons, amounts to $\pm 3 \%$ per event.
(iii) There is a $\pm 1 \%$ uncertainty on the overall event trigger efficiency.
(iv) The preliminary luminosity uncertainty for the 2011 data is $4.5 \%$. It is based on the 2010 luminosity calibration [9] which was transferred to the 2011 data by means of the liquid-argon forward calorimeter and the tile calorimeter current measurements.

The total uncertainty on the overall signal event yield from the event selection, corresponding to the first three sources $(i-i i i)$ listed above, is $\pm 11 \%$. The total experimental uncertainty on the event yield amounts to $\pm 12 \%$.

The uncertainty on the invariant mass resolution has the following main components:
(i) The uncertainty on the constant term of the cluster energy resolution is estimated from $Z$ to electrons decays. It amounts to an $\pm 11 \%$ relative uncertainty on the diphoton invariant mass resolution.
(ii) The uncertainty on the photon energy calibration arising from the extrapolation of the energy scale calibration of electrons, which is then applied to photons, is estimated using a full Monte Carlo simulation with a distorted amount of material upstream of the calorimeter. It amounts to a $\pm 6 \%$ relative uncertainty on the mass resolution.
(iii) The pile-up contributions to the cluster energies are measured in random clusters in events taken at random bunch crossings in the data and compared to the simulation under various pile-up conditions. The impact of the different pile-up contributions on the mass resolution amounts to a $\pm 3 \%$ relative uncertainty.
(iv) The uncertainty on the PV location estimate arising from differences between data and Monte Carlo in the calorimeter photon direction reconstruction is studied in $Z$ to electrons decays and its relative impact on the diphoton invariant mass resolution is $\pm 2 \%$.

The total relative uncertainty on the diphoton invariant mass resolution is $\pm 13 \%$.

## 5 Results

As seen from Figure 2 (a), no significant evidence for an excess in the invariant mass distribution is observed in the data. Using a profile likelihood estimator where the total background is modelled by an exponentially falling distribution determined by two nuisance parameters (the overall background normalisation and its exponential negative slope), and treating the systematic uncertainties on the signal yield and the mass resolution as additional nuisance parameters [3], the data are compared to background and signal-plus-background hypotheses. Within the selected mass range, $100-150 \mathrm{GeV}$, the search is restricted to Higgs boson mass hypotheses between 110 and 140 GeV for which a fit of the signal-plusbackground model to the data is performing well.

The compatibility of the selected events with the background-only hypothesis is quantified by the $1-C L_{b}$ (the probability to observe an excess larger than that observed in the data in the backgroundonly hypothesis) shown in Figure 3 (a) and reported in Table 2. A slight excess is observed at a diphoton invariant mass of $\sim 127 \mathrm{GeV}$. The $1-C L_{b}$ or corresponding $p$-value of the excess is $\sim 2 \%$. The probability for such an excess to occur anywhere in the $110-140 \mathrm{GeV}$ mass range is approximately $30 \%$.

Table 2: The expected Higgs boson signal yields, for fully simulated Higgs boson mass hypotheses with an integrated luminosity of $209 \mathrm{pb}^{-1}$ (the experimental and theoretical uncertainties are given separately). The $1-C L_{b}$ for each of these mass hypotheses and the $95 \%$ CL expected and observed PCL limits on the Higgs production cross section relative to the Standard Model cross section ( $\sigma_{95} / \sigma_{S M}$ ) are also reported. The minimum $1-C L_{b}$ reaches $\sim 2 \%$ for Higgs boson mass hypotheses around $\sim 127 \mathrm{GeV}$.

| Observed $\sigma_{95} / \sigma_{S M}$ | 5.7 | 4.2 | 4.6 | 11.7 | 4.9 |

Exclusion limits on the inclusive production cross section of a Standard Model-like Higgs boson relative to the Standard Model cross section are derived. Two interpretations of these limits are given. The first is the purely frequentist $C L_{s+b}$ derived limit for which a power constraint (PCL) is invoked when the observed limit fluctuates more than $-1 \sigma$ from the expected median limit in the backgroundonly hypothesis [10]. This Power Constraint Limit (PCL) interpretation is illustrated in Figure 3 (b). The observed limit does not fluctuate below $-1 \sigma$ from the median expected limit, the power constraint is therefore not invoked. The second, the modified frequentist approach ( $C L_{s}$ method), is illustrated in Figure 3 (c). The results using the PCL method are also summarised in Table 2. The theoretical uncertainty on the predicted Standard Model cross section is not included in the experimental limit but shown as a band around 1 in Figure 3 (b) and (c).

## Conclusion

An update of the $H \rightarrow \gamma \gamma$ analysis with the $209 \mathrm{pb}^{-1}$ of data collected early 2011 is given in this note. Improvements to the analysis were made to cope with the high pile-up environment. The background and signal studies shown in [2,3,4] are repeated here and exclusion limits for Higgs boson mass hypotheses between 110 GeV and 140 GeV are set. In this data sample, expected exclusion limits at $95 \% \mathrm{CL}$ between 6 and 7 times the Standard Model cross section are achieved. The observed excluded cross section of a Standard Model-like Higgs boson decaying into a pair of photons ranges between 4.2 and 15.8 times the

Standard Model cross section. The fluctuations of this observed limit are compatible with the expected statistical fluctuations of the background.

# Search for technihadrons in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

The ATLAS Collaboration

#### Abstract

A search for the technivector mesons $\rho_{T}$ and $\omega_{T}$ produced in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ and decaying to dielectron and dimuon final states is presented. The analysis is based on $1.08 \mathrm{fb}^{-1}\left(1.21 \mathrm{fb}^{-1}\right)$ of data for the $e e(\mu \mu)$ channel collected with the ATLAS detector at the CERN LHC. Since the $\rho_{T}$ and $\omega_{T}$ are narrow, spin 1 resonances, the search uses the limit results of the ATLAS $Z^{\prime}$ search. No evidence for a technihadron signal is observed. Within the context of the low-scale technicolor model, masses of the $\rho_{T}$ and $\omega_{T}$ from 130-480 GeV are excluded at $95 \% \mathrm{CL}$ for $\pi_{T}$ masses from $50-480 \mathrm{GeV}$.

Technicolor (TC) models use new strong dynamics to provide an alternative mechanism for breaking electroweak symmetry. In contrast to the Standard Model Higgs mechanism, TC avoids the introduction of fundamental scalar particles. Technicolor models predict new technihadron states that could be copiously produced at the LHC. The lowest mass states are the scalar technipion $\pi_{T}^{ \pm, 0}$ and the vector technirho $\rho_{T}^{ \pm, 0}$ and techniomega $\omega_{T}^{0}$. These technivector mesons can decay into a Standard Model (SM) gauge boson plus technipion $\left(\gamma \pi_{T}, W \pi_{T}\right.$ or $Z \pi_{T}$ ), pairs of SM gauge bosons ( $W Z, \gamma W$, etc.) and fermion-antifermion pairs.

A search for the $\rho_{T}$ and $\omega_{T}$ in the dilepton final state has been conducted previously by CDF and placed a lower bound on the $\rho_{T}$ and $\omega_{T}$ masses of 280 GeV [1]. A recent search by CDF [2] for technihadrons in the $W \pi_{T}$ final state excludes a region of the $m\left(\rho_{T}\right)-m\left(\pi_{T}\right)$ plane where $m\left(\rho_{T}\right)$ ranges from 180250 GeV and $m\left(\pi_{T}\right)$ from $95-145 \mathrm{GeV}$. Another recent search in the $W Z$ final state by $\mathrm{D} \emptyset[3]$ rules out the interval of $\rho_{T}$ mass from $208-408 \mathrm{GeV}$ when the $W Z$ mode is dominant, i.e. when $m\left(\rho_{T}\right)<m\left(\pi_{T}\right)+m(W)$. A similar search in the $W Z$ final state by CMS [4] excluded $\rho_{T}$ masses below 436 GeV .

Additional motivation for this search stems from the observation by CDF of an excess in the dijet mass spectrum in $W j j$ events [5]. It has led to speculation that the excess may be due to a $290 \mathrm{GeV} \rho_{T}$ that decays into a $W$ and a $160 \mathrm{GeV} \pi_{T}$ [6].

In this note a search for the technicolor vector mesons $\rho_{T}$ and $\omega_{T}$ with their subsequent decay to $\ell^{+} \ell^{-}$, where $\ell=e$ or $\mu$, is presented. The search is performed in the context of the low-scale technicolor model (LSTC) [7, 8]. In the LSTC model, it is assumed that techni-isospin is a good symmetry and therefore the isotriplet $\rho_{T}$ and isosinglet $\omega_{T}$ will be nearly degenerate in mass. For what follows, it is assumed that $m\left(\rho_{T}\right)=m\left(\omega_{T}\right)$ and therefore the signal in the dilepton mass spectrum is the sum of the $\rho_{T}$ and $\omega_{T}$ contributions. The $\omega_{T}$ branching ratio to dileptons is approximately an order of magnitude larger than for the $\rho_{T}$ so the dilepton signal is mostly due to the $\omega_{T}$. The natural width of the $\rho_{T}$ and $\omega_{T}$ resonances is very narrow, less that 1 GeV , so that the observed line shape is due to detector resolution alone. Other important LSTC parameters are the number of technicolors $N_{T C}=4$, the charges of the up (U) and down (D) type technifermions $Q_{U}=Q_{D}+1=1$, the mixing angle $\sin \chi=1 / 3$, and the vector and axial mass parameters $M_{V}=M_{A}=m\left(\rho_{T}\right)$.

Since the $\rho_{T}$ and $\omega_{T}$ are narrow, spin 1 resonances, the search methodology will be identical to that developed for the ATLAS search for the $Z^{\prime} \rightarrow \ell^{+} \ell^{-}$where $\ell=e$ or $\mu$ [9]. The same data samples, object identification and event selection criteria, backgrounds, and systematic uncertainty determination as presented in Ref. [9] were used here.

The $\rho_{T}$ and $\omega_{T}$ signal cross sections were calculated with Pythia 6.4 [10] using MRST2007 LO* parton density functions (PDF) [11]. A dilepton-mass-dependent K-factor was applied to account for higher order QCD effects [9].

To demonstrate that the $Z^{\prime} 95 \%$ CL cross section limit results may be used directly for the TC search, it is sufficient to show that the kinematics and acceptance are the same for the $Z^{\prime}$ and TC signals. Figure 1 plots the acceptance times efficiency $(A \epsilon)$ as a function of dielectron mass for the $\rho_{T} / \omega_{T}$ and $Z^{\prime}$. Figure 2 plots $A \epsilon$ for the dimuon channel. The results agree within the statistical uncertainty and therefore the $Z^{\prime}$ limits from Ref. [9] may be used unaltered for setting limits on TC.

Figure 3 shows the dielectron mass distribution from $1.08 \mathrm{fb}^{-1}$ of 2011 data along with the expected SM backgrounds and representative TC signals. Figure 4 shows the analogous plot for the dimuon channel obtained from $1.21 \mathrm{fb}^{-1}$ of 2011 data. The agreement between data and SM backgrounds is excellent and quantified in Ref. [9].

In the absence of a TC signal, limits on the cross section times dilepton branching ratio are set as a function of resonance mass. Within the context of the LSTC model, the limit on $\sigma B\left(\ell^{+} \ell^{-}\right)$is converted into a lower limit on the mass of the $\rho_{T} / \omega_{T}$. Figure 5 plots the $95 \% \mathrm{CL}$ observed and expected exclusion regions in the $m\left(\pi_{T}\right)-m\left(\rho_{T} / \omega_{T}\right)$ plane. The mass limit depends on the $\rho_{T} / \omega_{T}-\pi_{T}$ mass splitting since that determines if decay modes such as $W \pi_{T}$ or multi- $\pi_{T}$ are kinematically allowed. Masses of the $\rho_{T}$

Figure 1: Signal acceptance times efficiency as a function of dielectron mass for the $\rho_{T} / \omega_{T}$ and for the $Z^{\prime}$.

Figure 2: Signal acceptance times efficiency as a function of dimuon mass for the $\rho_{T} / \omega_{T}$ and for the $Z^{\prime}$.

Figure 3: The dielectron mass distribution after the final event selection showing the data in points and the SM backgrounds from the $Z / \gamma^{*}$, diboson, $t \bar{t}, W+$ jets, and QCD multijet processes in stacked filled histograms. Also shown in open histograms is the expected LSTC signal for several $\rho_{T} / \omega_{T}$ masses.

Figure 4: The dimuon mass distribution after the final event selection showing the data in points and the SM backgrounds from the $Z / \gamma^{*}$, diboson, $t \bar{t}$, $W+$ jets, and QCD multijet processes in stacked filled histograms. Also shown in open histograms is the expected LSTC signal for several $\rho_{T} / \omega_{T}$ masses.

Figure 5: The $95 \%$ CL excluded region as a function of the assumed $\pi_{T}$ and $\rho_{T} / \omega_{T}$ masses is shown in red. The dotted line corresponds to $m\left(\rho_{T} / \omega_{T}\right)-m\left(\pi_{T}\right)=100 \mathrm{GeV}$. The dashed line shows the expected limit with the green dashed lines showing the $\pm 1 \sigma$ bands. The hashed region where $m\left(\pi_{T}\right)>m\left(\rho_{T} / \omega_{T}\right)$ is excluded by theory. Also shown are recent results from CDF [2] and DØ [3].

Figure 6: The expected and observed $95 \%$ CL limits on $\sigma B$ as a function of mass of $\rho_{T} / \omega_{T}$ or $Z^{\prime}$ for the combination of the dielectron and dimuon channels. Also shown are the theory predictions for the LSTC model, assuming $m\left(\rho_{T} / \omega_{T}\right)-m\left(\pi_{T}\right)=100 \mathrm{GeV}$, and for the $Z^{\prime}$ models studied in Ref. [9]. The thickness of the theory curves illustrate the theoretical uncertainties, which for the $Z^{\prime}$ curves are described in Ref. [9] and for the LSTC curve are the PDF and K-factor uncertainties.
and $\omega_{T}$ from $130-480 \mathrm{GeV}$ are excluded at $95 \% \mathrm{CL}$ for $\pi_{T}$ masses from $50-480 \mathrm{GeV}$. Figure 6 plots the $95 \%$ CL observed and expected limits on $\sigma B\left(\ell^{+} \ell^{-}\right)$as a function of mass of the $\rho_{T} / \omega_{T}$ or $Z^{\prime}$ resonance. For an assumed $\rho_{T} / \omega_{T}-\pi_{T}$ mass splitting of 100 GeV , masses of the $\rho_{T}$ and $\omega_{T}$ below 470 GeV are excluded at $95 \% \mathrm{CL}$.

To conclude, a search for the technivector mesons $\rho_{T}$ and $\omega_{T}$ in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ has been presented. The search methodology is identical to that used for the ATLAS $Z^{\prime} \rightarrow e^{+} e^{-}$and $Z^{\prime} \rightarrow$ $\mu^{+} \mu^{-}$searches [9]. No evidence for a TC signal is observed in $1.08 \mathrm{fb}^{-1}\left(1.21 \mathrm{fb}^{-1}\right)$ of data for the $e e$ $(\mu \mu)$ channel. The results of Ref. [9] are used to exclude at $95 \%$ CL masses of the $\rho_{T}$ and $\omega_{T}$ from $130-480 \mathrm{GeV}$ for $\pi_{T}$ masses from $50-480 \mathrm{GeV}$.

# Search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ with the ATLAS detector 

The ATLAS collaboration

#### Abstract

The search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow$ $\ell^{+} \ell^{-} \ell^{+} \ell^{-}$, where $\ell=e, \mu$, is presented. Proton-proton collision data at $\sqrt{s}=7 \mathrm{TeV}$ recorded with the ATLAS detector and corresponding to an average integrated luminosity of $1.1 \mathrm{fb}^{-1}$ are compared to the Standard Model expectations. Upper limits on the production cross section of a Standard Model Higgs boson with a mass between 110 and 600 GeV are derived. The observed (expected) $95 \%$ confidence level upper limit on the production cross section for a Higgs boson with a mass of 200 GeV , near the most sensitive point of this search, is 2.0 (1.7) times the Standard Model prediction.

## 1 Introduction

The search for the Standard Model (SM) Higgs boson [1-3] is a major goal of the Large Hadron Collider (LHC) programme. Direct searches at the CERN LEP $e^{+} e^{-}$collider have led to a lower limit on the Higgs boson mass, $m_{H}$, of 114.4 GeV at $95 \%$ confidence level (CL) [4]. The searches at the Fermilab Tevatron $p \bar{p}$ collider have excluded at $95 \%$ CL the region $158 \mathrm{GeV}<m_{H}<173 \mathrm{GeV}$ [5]. Results from the 2010 LHC run extended the search in the region $200 \mathrm{GeV}<m_{H}<600 \mathrm{GeV}$ by excluding a SM Higgs boson with cross section larger than 5-20 times the SM prediction [6, 7].

This note presents the search by the ATLAS experiment for the SM Higgs boson in the channel $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{\prime}+\ell^{\prime-}$, where $\ell, \ell^{\prime}=e, \mu$, in the mass range from 110 to 600 GeV . Three distinct final states, $\mu \mu \mu \mu(4 \mu), e e \mu \mu(2 e 2 \mu)$, and eeeee $(4 e)$, are selected. The largest background to this search comes from the $Z Z^{(*)}$ production. For $m_{H}<180 \mathrm{GeV}$, contributions from $Z+$ jets and $t \bar{t}$ processes, where the additional leptons arise either from semi-leptonic decays of heavy flavour or light jets misidentified as leptons, are important. The proton-proton collision data were recorded with the ATLAS detector at the LHC at $\sqrt{s}=7 \mathrm{TeV}$ and correspond to an average integrated luminosity of $1.1 \mathrm{fb}^{-1}$ [8]. The previously published ATLAS results in this channel [6] are improved by using about 27 times more integrated luminosity.

## 2 The ATLAS Detector

The ATLAS detector [9] is a multipurpose particle physics apparatus with forward-backward symmetric cylindrical geometry ${ }^{1}$. The inner tracking detector (ID) consists of a silicon pixel detector, a silicon microstrip detector, and a transition radiation tracker. The ID is surrounded by a thin superconducting solenoid providing a 2 T magnetic field. A high-granularity lead-liquid-Argon (LAr) sampling calorimeter measures the energy and the position of electromagnetic showers. An iron-scintillator tile calorimeter provides hadronic coverage in the central rapidity range. The end-cap and forward rapidity regions are instrumented with LAr calorimetry for both electromagnetic and hadronic measurements. The muon spectrometer (MS) surrounds the calorimeters and consists of three large superconducting toroids, each with eight coils, a system of precision tracking chambers, and detectors for triggering. A three-level trigger system selects events to be recorded for offline analysis.

## 3 Data and Monte Carlo Samples

The accumulated data are subjected to quality requirements ensuring that the relevant detector components are operational. The average integrated luminosity of $1.1 \mathrm{fb}^{-1}$ corresponds to $1.21 \mathrm{fb}^{-1}, 1.07 \mathrm{fb}^{-1}$, and $1.07 \mathrm{fb}^{-1}$ for the $4 \mu, 2 e 2 \mu$, and $4 e$ final states respectively.

The $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ signal is modelled in the range 110 to 600 GeV using the powheg Monte Carlo (MC) event generator [10, 11], which calculates separately the gluon and vector-boson fusion production mechanisms of the Higgs boson with matrix elements up to next-to-leading order (NLO). The Higgs boson $p_{\mathrm{T}}$-spectrum is reweighted to the calculation of ref. [12], correseponding to QCD corrections up to next-to-leading order and QCD soft-gluon resummations up next-to-next-to-leading log. POWHEG is interfaced to PYTHIA [13] for showering and hadronization, which in turn is interfaced to PHOTOS [14] for QED radiative corrections in the final-state and to TAUOLA [15,16] for the simulation of $\tau$ decays. The

[^62]Higgs boson $p_{\mathrm{T}}$ spectrum is reweighted to the calculation of Ref. [12], corresponding to QCD corrections up to next-to-leading order and QCD soft-gluon resummations up next-to-next-to-leading log.

The cross sections for Higgs boson production, the corresponding branching fractions, as well as their uncertainties, are compiled in Ref. [17]. They correspond to next-to-next-to-leading order (NNLO) in QCD for the gluon fusion [18-23] and vector boson fusion [24]. In addition, QCD soft-gluon resummations up to next-to-next-to-leading $\log$ (NNLL) are available for the gluon fusion process [25], while the NLO electroweak (EW) corrections are applied to both the gluon fusion [26,27] and vector boson fusion [28,29]. The Higgs boson decay branching ratio to the four-lepton final state is predicted by PROPHECY4F [30,31], including the complete NLO QCD+EW corrections, including all interference effects and leading two-loop heavy Higgs boson corrections to the four-fermion width. Table 1 gives the production cross-sections for the $H \rightarrow 4 \ell(\ell=e, \mu)$ for typical Higgs boson masses.

Table 1: Higgs boson production cross-sections for both gluon and vector-boson fusion processes in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$. The cross-sections include the branching ratio of $H \rightarrow 4 \ell, \ell=e, \mu$.

| $m_{H}(\mathrm{GeV})$ | 130 | 150 | 200 | 240 | 300 | 400 | 500 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\sigma \cdot \mathrm{BR}(H \rightarrow 4 \ell)(\mathrm{fb})$ | 2.87 | 4.38 | 6.77 | 5.35 | 3.75 | 2.66 | 1.11 |

The $Z Z^{(*)}$ background is generated using PYTHIA, taking into account $Z-\gamma$ interference. For the inclusive total cross section and the shape of the $m_{Z Z^{(*)}}$ spectrum the MCFM [32,33] prediction is used, including both quark-antiquark annihilation at QCD NLO and gluon fusion. Inclusive $Z$ boson and $Z b \bar{b}$ processes are modelled using ALPGEN [34], removing overlaps between the two samples. More specifically, $b \bar{b}$ pairs with separation $\Delta R=\sqrt{\Delta \phi^{2}+\Delta \eta^{2}} \geq 0.4$ between the jets are taken from the matrix-element calculation, while for $\Delta R<0.4$ the parton-shower jets are used. The total inclusive cross section for $Z$ boson production is normalized to the QCD NNLO prediction by FEWZ [35, 36], while $Z b \bar{b}$ is normalized to the MCFM prediction [32,33]. Finally, the $t \bar{t}$ background is modelled using MC @ NLO [37] and is normalized to the approximate NNLO cross section calculated using HATHOR [38]. Both ALPGEN and MC@NLO are interfaced to HERWIG [39] for parton shower hadronization and to JIMMY [40] for the underlying event simulations.

All generated events undergo a full detector simulation performed using GEANT4 [41, 42].
As a result of the intensity increase of LHC an average number of five interactions per bunch crossing has been measured in data. In order to adequately take into account the impact of pileup on lepton reconstruction efficiency and isolation, these effects have been included in all ATLAS simulations.

## 4 Physics Object Identification and Event Selection

The data were collected using single-lepton triggers with thresholds on transverse energy, $\mathrm{E}_{T}$, of 20 GeV for electrons and on transverse momentum, $p_{\mathrm{T}}$, of 18 GeV for muons. Both triggers are more than $99.5 \%$ efficient for events passing the selection described below.

Electron candidates consist of clusters of energy deposited in the electromagnetic calorimeter associated to inner detector tracks. The electrons must satisfy the ATLAS "medium" electron criteria that require the shower profiles to be consistent with those expected from an electromagnetic shower shape and a well reconstructed ID charged track pointing to the corresponding clusters [43].

Muon candidates are reconstructed by matching inner detector tracks with either full or partial tracks in the muon spectrometer [44-46]. For the former case, the two independent momentum measurements are combined, while for the latter case the muon spectrometer provides only the muon identification
information. To reject cosmic rays, tracks are required to be consistent with having originated from the primary vertex, defined as the reconstructed vertex with the highest $\sum p_{\mathrm{T}}^{2}$ of associated tracks.

Leptons from Higgs boson decays are expected to be isolated and to originate from a common vertex. Track and calorimeter isolation as well as transverse impact parameter significance requirements are therefore applied to further reduce the $Z+$ jets and $t \bar{t}$ contributions. The sum of $p_{\mathrm{T}}$ of tracks within $\Delta R<0.20$ from the lepton divided by the lepton $p_{\mathrm{T}}$ is required to be less than 0.15 , while the sum $E_{\mathrm{T}}$ of the calorimeter cells within $\Delta R<0.20$ around the lepton divided by the lepton $p_{\mathrm{T}}$ is required to be less than 0.30 . In the case of electrons, the calorimeter cells corresponding to the electromagnetic shower are subtracted from the cone. The cut on the impact parameter significance is tuned to guarantee more than $95 \%$ efficiency for an isolated lepton. The selection efficiency of the isolation and impact parameter requirements has been studied using data both for isolated leptons, with $Z \rightarrow \ell \ell$ events, and non-isolated leptons from semi-leptonic heavy flavour decays, with heavy-flavour enriched dijet sample, and found to be well described by the simulation.

Higgs boson candidates are formed by selecting two same-flavour, opposite-sign isolated lepton pairs in an event. Each lepton must satisfy $p_{\mathrm{T}}>7 \mathrm{GeV}$ and be measured in the pseudorapidity range $|\eta|<$ 2.47 for electrons and $|\eta|<2.5$ for muons. For the transition region between the barrel and the end-cap calorimeters $1.37<\eta<1.52$, the electron $p_{\mathrm{T}}$ threshold is increased to 15 GeV . At least two leptons must have $p_{\mathrm{T}}>20 \mathrm{GeV}$. The leptons are required to be well separated from each other, $\Delta R>0.1$. The invariant mass of the lepton pair closest to the nominal $Z$ boson mass $\left(m_{Z}\right)$ is denoted by $m_{12}$. It is required that $\left|m_{Z}-m_{12}\right|<15 \mathrm{GeV}$. The invariant mass of the remaining lepton pair, $m_{34}$, is required to be greater than a threshold depending on the reconstructed four lepton mass, $m_{4 \ell}$, as summarized in Table 2. The final discriminating variable is $m_{4 \ell}$, where the Higgs boson production would appear as a clustering of events on top of the background.

Table 2: Summary of thresholds applied to $m_{34}$ for reference values of $m_{4 \ell}$. For other $m_{4 \ell}$ values, the selection requirement is obtained with linear interpolation.

| $m_{4 \ell}(\mathrm{GeV})$ | $\leq 120$ | 130 | 140 | 150 | 160 | 165 | 180 | 190 | $\geq 200$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| threshold $(\mathrm{GeV})$ | 15 | 20 | 25 | 30 | 30 | 35 | 40 | 50 | 60 |

## 5 Background Estimation

The dominant $Z Z^{(*)}$ background is estimated using MC simulation. Generated events are required to pass the complete analysis selection and the final rate is normalized to the integrated luminosity.

The $t \bar{t}$ background is also estimated using MC simulation. Comparing data to MC predictions in a control sample of opposite sign electron-muon pairs consistent with the $Z$ boson mass and with one or two additional leptons, verifies that the $t \bar{t}$ background is small with respect to the dominant $Z Z^{(*)}$ process and under control.

The $Z+j$ jets background is normalized on a data control sample. The control sample is formed by selecting events with a pair of same-flavour, opposite-sign isolated leptons consistent with the $Z$ boson mass, $\left|m_{Z}-m_{12}\right|<15 \mathrm{GeV}$, and a second same-flavour, opposite-sign lepton pair where only kinematic, but no isolation or impact parameter, requirements are applied. At this stage, the dominant background source depends on the flavour of the second lepton pair: $Z b \bar{b}$ production dominates the final states with a second muon-pair and $Z+$ light jets the final states with a second electron-pair. In Fig. 1 distributions of the number of additionnal muons in events with a reconstructed $Z \rightarrow \ell \ell$ decay and of their transverse momentum are compared with MC expectations. The small contributions from $t \bar{t}, Z Z^{(*)}$, and muons

Figure 1: (a) Multiplicity with $p_{T}>7 \mathrm{GeV}$ and (b) $p_{T}$ distribution of additional muons in events with a reconstructed $Z \rightarrow \ell \ell$ decay, $\left|m_{Z}-m_{12}\right|<15 \mathrm{GeV}$, before and after the subtraction of muons originating from light quarks and $Z Z, W Z$ and $t \bar{t}$ decays. The Monte Carlo expectation for the heavy flavour component, $Q$, is also presented. The quoted uncertainties include both statistical and systematic effects.
from in-flight $\pi$ and $K$ decays are subtracted. The yield of the background, which is found to be in good agreement with expectation, is extrapolated to the signal region by means of the MC simulation.

## 6 Systematic Uncertainties

Uncertainties on lepton reconstruction and identification efficiency, momentum resolution and momentum scale are constrained using the accumulated samples of $W / Z$ bosons and $J / \psi$ decays. The muon efficiency uncertainty results in an acceptance uncertainty on the signal and the irreducible background which is uniform over the mass range of interest and amounts to $1.7 \%(1.2 \%)$ for the $4 \mu(2 e 2 \mu)$ channel. The electron efficiency for the $4 e(2 e 2 \mu)$ channel results in an acceptance uncertainty of $3 \%(2 \%)$ at $m_{4 \ell}=600 \mathrm{GeV}$ and reaches $15 \%(6 \%)$ at $m_{4 \ell}=110 \mathrm{GeV}$ for the $4 e(2 e 2 \mu)$ channel.

A conservative theoretical uncertainty of $15 \%$ is assigned to the $Z Z^{(*)}$ background contribution [47]. The $Z+$ jets and $Z b \bar{b}$ contributions to the four lepton final state are evaluated on data. A systematic uncertainty between $20 \%$ and $40 \%$ is assigned on the normalization to account for the statistical uncertainty in the control sample and the extrapolation to the signal region. The uncertainty on the $t \bar{t}$ cross section is found to be $10 \%$ by adding linearly the contributions from variations of the scale and of the parton distribution functions.

The theoretical uncertainties on the Higgs boson production cross section are 15-20\% for the gluon fusion process and $3-9 \%$ for the vector-boson fusion process [17], depending on the Higgs boson mass ${ }^{2}$. These errors are composed of uncertainties in QCD scale and parton distribution functions [49-52]. An additional $2 \%$ uncertainty is added to the signal selection efficiency due to the modelling of the signal kinematics. This is evaluated by comparing signal samples generated with PYTHIA instead of POWHEG.

[^63]Table 3: The expected number of signal and background events, with their systematic uncertainty, separated into "Low mass" ( $m_{4 \ell}<180 \mathrm{GeV}$ ) and "High mass" ( $m_{4 \ell} \geq 180 \mathrm{GeV}$ ) regions. The observed number of events is also presented.

|  | $\mu \mu \mu \mu$ |  | ee $\mu \mu$ |  | eeee |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Low mass | High mass | Low mass | High mass | Low mass | High mass |
| $Z Z^{(*)}$ | $0.84 \pm 0.13$ | $4.5 \pm 0.7$ | $0.80 \pm 0.12$ | $5.6 \pm 0.8$ | $0.33 \pm 0.07$ | $2.1 \pm 0.3$ |
| $Z, Z b \bar{b}$, and $t \bar{t}$ | $0.03 \pm 0.01$ | $0.01 \pm 0.01$ | $0.15 \pm 0.06$ | $0.08 \pm 0.03$ | $0.12 \pm 0.05$ | $0.07 \pm 0.03$ |
| Total Background | $0.87 \pm 0.13$ | $4.5 \pm 0.7$ | $0.95 \pm 0.13$ | $5.7 \pm 0.8$ | $0.45 \pm 0.09$ | $2.2 \pm 0.3$ |
| Data | 1 | 9 | 1 | 5 | 0 | 2 |
| $m_{H}=130 \mathrm{GeV}$ | $0.21 \pm 0.03$ |  | $0.21 \pm 0.03$ |  | $0.07 \pm 0.01$ |  |
| $m_{H}=150 \mathrm{GeV}$ | $0.50 \pm 0.08$ |  | $0.50 \pm 0.08$ |  | $0.18 \pm 0.03$ |  |
| $m_{H}=200 \mathrm{GeV}$ |  | $1.18 \pm 0.17$ |  | $1.40 \pm 0.20$ |  | $0.50 \pm 0.07$ |
| $m_{H}=240 \mathrm{GeV}$ |  | $0.90 \pm 0.13$ |  | $1.16 \pm 0.17$ | $0.46 \pm 0.07$ |  |
| $m_{H}=300 \mathrm{GeV}$ |  | $0.60 \pm 0.09$ |  | $0.85 \pm 0.12$ | $0.33 \pm 0.05$ |  |
| $m_{H}=400 \mathrm{GeV}$ |  | $0.44 \pm 0.07$ |  | $0.64 \pm 0.10$ | $0.27 \pm 0.04$ |  |
| $m_{H}=600 \mathrm{GeV}$ |  | $0.08 \pm 0.01$ |  | $0.12 \pm 0.02$ |  | $0.05 \pm 0.01$ |

The overall uncertainty for the total integrated luminosity is $3.7 \%$ [8].

## 7 Results

Table 3 shows the number of events observed in each final state, separately for $m_{4 \ell}<180 \mathrm{GeV}$ and $m_{4 \ell} \geq 180 \mathrm{GeV}$, compared with the expectations for background. The expected signal yields for various $m_{H}$ values are also presented. In total 18 candidate events are selected by the analysis: ten $4 \mu$, six $2 e 2 \mu$, and two $4 e$ events. In the same mass range 14.6 events are expected from the described background processes. The mass spectra for $m_{12}, m_{34}$, and $m_{4 \ell}$ are shown in Fig. 2, while the kinematic distributions of the leptons are presented in Fig. 3 and Fig. 4. The selected events have been examined visually and no reconstruction issues were identified. Typical event displays are presented in Figs. 5, 6, 7. In Fig. 8, the $m_{4 \ell}$ distribution is shown along with the expected background and the expected signal for several $m_{H}$ hypotheses.

Upper limits are set on the Higgs boson cross section at $95 \% \mathrm{CL}$, using the $C L_{s}$ modified frequentist formalism [53] with the profile likelihood test statistic [54]. Figure 9 shows the expected and observed exclusions as a function of $m_{H}$ and Table 4 summarizes the numerical values for selected $m_{H}$ points. The consistency with the background-only hypothesis is quantified using the $p$-value, the probability that a background-only experiment will fluctuate more than a given observation. The most significant deviation from the background-only hypothesis is observed at $m_{H}=246 \mathrm{GeV}$ with a $p$-value of $3 \%$. This calculation does not account for the look-elsewhere effect.

## 8 Summary

The search for the decay $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ in the data accumulated by the ATLAS detector corresponding to $1.1 \mathrm{fb}^{-1}$ has been presented. No significant excess of candidates is observed in the mass range between 110 and 600 GeV with respect to the expected SM background. The observed (expected) 95\% CL upper

Figure 2: Invariant mass distributions (a) $m_{12}$, (b) $m_{34}$, and (c) $m_{4 \ell}$ for the selected candidates. All plots show comparisons with background expectation from the dominant $Z Z^{*}$ and the sum of $t \bar{t}, Z b \bar{b}$ and $Z+j e t s$ processes. Error bars represent $68.3 \%$ central confidence intervals.

Figure 3: $p_{T}$ distribution (a) and $\eta$ distribution (b) for the leptons of the 18 candidates surviving the selection criteria. The corresponding shapes for the expected background contributions are also shown.
limit on the Higgs boson production cross section, in units of the SM rate, is 2.0 (1.7) at $m_{H}=200 \mathrm{GeV}$, which is the most sensitive point of this search.

Figure 4: Scatter plot of $m_{12}$ and $m_{34}$ for the 18 candidates surviving the selection criteria. The corresponding shape for the total expected background contribution is also shown.

Figure 5: Event display of a $4 e$ candidate event with $m_{4 l}=270.1 \mathrm{GeV}$. The masses of the lepton pairs are 85.0 and 111.3 GeV respectively.

Figure 6: Event display of a $4 \mu$ candidate event with $m_{4 l}=143.5 \mathrm{GeV}$. The masses of the lepton pairs are 90.6 and 47.4 GeV respectively.

Figure 7: Event display of a $2 e 2 \mu$ candidate event with $m_{4 l}=209.7 \mathrm{GeV}$. The masses of the lepton pairs are 85.9 and 85.5 GeV respectively.

Figure 8: $m_{4 \ell}$ distribution of the selected candidates, compared to the background expectation. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown. The resolution of the reconstructed Higgs mass is dominated by experimental performances at low $m_{H}$ values and by the natural Higgs boson width at high $m_{H}$.

Table 4: Observed and median expected 95\% CL upper limit on the SM Higgs boson production cross section, in multiples of the SM rate, as a function of the Higgs boson mass in GeV , obtained with $C L_{s}$.

| Mass (GeV) | Observed | Expected |
| :---: | :---: | :---: |
| 130 | 7.9 | 6.5 |
| 150 | 2.9 | 2.7 |
| 200 | 2.0 | 1.7 |
| 240 | 3.2 | 2.1 |
| 300 | 2.2 | 2.6 |
| 400 | 2.5 | 2.9 |
| 600 | 27.6 | 16.3 |

Figure 9: Expected (dashed) and observed (full line) 95\% CL upper limit on the SM Higgs boson production cross section as a function of the Higgs boson mass, expressed in multiples of the SM rate. Figures (a),(b),(c), (d) are different presentations of the same result.

# Search for Charged Higgs Bosons in the $\tau+$ jets Final State in $t \bar{t}$ Decays with $1.03 \mathrm{fb}^{-1}$ of $p p$ Collision Data Recorded at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS Experiment 

The ATLAS Collaboration

#### Abstract

This note presents the results of a search for charged Higgs bosons, $H^{ \pm}$, in $1.03 \mathrm{fb}^{-1}$ of proton-proton collision data recorded at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS experiment at the LHC using the $\tau+$ jets channel in $t \bar{t}$ decays with a hadronically decaying $\tau$ lepton in the final state. The data agree with the Standard Model expectation leading to a limit on the product of branching ratios $\mathrm{BR}\left(t \rightarrow b H^{ \pm}\right) \times \mathrm{BR}\left(H^{ \pm} \rightarrow \tau v\right)$ of $0.03-0.10$ for $H^{ \pm}$masses in the range $90 \mathrm{GeV}<m_{H^{ \pm}}<160 \mathrm{GeV}$. In the context of the Minimal Supersymmetric Standard Model values of $\tan \beta$ larger than $22-30$ are excluded in the mass range $90 \mathrm{GeV}<m_{H^{ \pm}}<140 \mathrm{GeV}$.

## 1 Introduction

The charged Higgs boson is predicted by many non-minimal Higgs scenarios [1, 2], such as models containing Higgs triplets and Two-Higgs-Doublet Models (2HDM) [3]. The observation of charged Higgs bosons ${ }^{1}, H^{ \pm}$, would indicate physics beyond the Standard Model (SM). The analysis in this note considers the type II-2HDM [3], which is also the Higgs sector of the Minimal Supersymmetric Standard Model (MSSM) [4]. For charged Higgs boson masses, $m_{H^{+}}$, smaller than the top quark mass, $m_{t}$, the dominant production mode at the LHC for $H^{+}$is through top quark decay via $t \rightarrow H^{+} b$. The dominant source of top quarks at the LHC is through $t \bar{t}$ production; the cross section for charged Higgs boson production from top quark decays in single-top events is much smaller and not considered here. For $\tan \beta>3$, where $\tan \beta$ is the ratio of the vacuum expectation values of the two Higgs doublets, charged Higgs bosons decay mainly via $H^{+} \rightarrow \tau v$ [5]. Recent limits on light charged Higgs boson production come from the Tevatron [6], where the observed upper limit on $\operatorname{BR}\left(t \rightarrow H^{+} b\right)$ assuming $\operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)=1$ is 0.17 for $m_{H^{+}}=120 \mathrm{GeV}$. Direct searches at LEP [7] give a lower limit of $m_{H^{+}} \simeq 90 \mathrm{GeV}$ for $\operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)=1$. Preliminary results for charged Higgs boson searches in top quark decays have recently been made public by the CMS experiment [8].

This note describes the search for charged Higgs bosons in $t \bar{t}$ events in the topology shown in Fig. 1, for the case where both the $\tau$ lepton and the $W$ decay hadronically ( $\tau+\mathrm{jets}$ channel).

The $H^{+}$search uses proton-proton collision data collected with the ATLAS experiment [9] at the LHC at a center-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ in 2011. The total integrated luminosity amounts to $1.03 \mathrm{fb}^{-1}$.

The background processes that enter these searches include the production of $t \bar{t}$, single-top, $W+$ jets, $Z / \gamma^{*}+$ jets, and multi-jet events where there is either a true $\tau$ lepton, or another object misidentified as a hadronically decaying $\tau$. In this note, all significant backgrounds, i.e. events with correctly identified hadronically decaying $\tau$ leptons (hereafter referred to as $\tau$ jets), or with jets or electrons misreconstructed as $\tau$ jets, are estimated using data-driven methods.

Figure 1: Example for a leading-order Feynman diagram for the production of a charged Higgs boson through gluon fusion in $t \bar{t}$ decays.

## 2 Physics processes and their cross sections

All relevant backgrounds are estimated using data-driven techniques. However, for backgrounds with intrinsic missing transverse energy and objects misidentified as $\tau$ jets, simulation is used to model any aspects not related to the probability of the object to be misidentified as a $\tau$ jet. For backgrounds without

[^64]intrinsic $E_{\mathrm{T}}^{\text {miss }}$ (multi-jet background), simulation is used to subtract the electroweak and $t \bar{t}$ contribution in the control region. Simulation is also used for comparison with the results of the data-driven estimates.

The Monte Carlo (MC) simulation of $t \bar{t}$ and single-top events is based on MC@NLO [10] using HERWIG [11] for the hadronization process and JIMMY [12] for simulating multi-parton interactions. Overlap between $t \bar{t}$ and single-top final states is taken into account [13]. A $t \bar{t}$ production cross section of 165 pb [14] obtained from approximate NNLO calculations [15] is used (both for SM $t \bar{t}$ decays and decays via a charged Higgs boson). The MC@NLO cross sections are used for single-top production. Throughout this note, a top quark mass of 172.5 GeV is assumed.

ALPGEN [16] is used for the generation of $W+$ jets and $Z / \gamma^{*}+$ jets events with up to five partons from the hard matrix element, again together with HERWIG/JIMMY. The ALPGEN cross sections are rescaled by a factor $1.20(W)$ and $1.25\left(Z / \gamma^{*}\right)$ to match NNLO calculations [17]. The $H^{+}$signal events are generated with PYTHIA [18], using TAUOLA [19] for $\tau$ lepton decays and PHOTOS [20] for photon radiation off charged leptons. Event generators are tuned to describe ATLAS data, and the parameter sets AMBT1 [21] and AUET1 [22] are used for this purpose for events hadronized with Pythia, and with HERWIG/JIMMY, respectively.

Table 1: Simulated events used in this study. The $W / Z+$ jets as well as the $s$ - and $t$-channel single-top events are only simulated for decays involving leptons ( $\ell$ denotes $e, \mu$, or $\tau$ ), and the cross section given includes this branching ratio. The NLO+NNLL cross section is used for $t \bar{t}$, NLO for single-top, and NNLO for $W / Z+$ jets. The $H^{+}$sample uses $m_{H^{+}}=130 \mathrm{GeV}, \operatorname{BR}\left(t \rightarrow b H^{+}\right)=0.1$ and $\operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$ is assumed to be 1 .

| Process | Generator | Cross section [pb] |
| :--- | :--- | ---: |
| $t \bar{t}$ with $\geq 1 \ell$ | MC@NLO | 89.4 |
| single-top $(s, t, W t$ channel $)$ | MC@NLO | $21.4,1.41,14.6$ |
| $W \rightarrow \ell v+$ jets | ALPGEN | $3.1 \cdot 10^{4}$ |
| $Z / \gamma^{*} \rightarrow \ell \ell+$ jets | ALPGEN | $3.2 \cdot 10^{3}$ |
| $t \bar{t} \rightarrow b H^{ \pm} b W$ with $H^{ \pm} \rightarrow \tau v$ | PYTHIA | 29.6 |

All events are propagated through a detailed GEANT4 [23, 24] simulation of the ATLAS detector and reconstructed by the same algorithms as the data. Cross sections and simulated event samples are summarized in Table 1.

## 3 Object reconstruction

A description of the ATLAS detector can be found elsewhere [9]. In this section, the criteria used to identify and reconstruct physics objects such as leptons or jets are described.

Data quality: For both the $H^{+}$event selection and the data-driven background estimates, the following requirements are applied [25]: The sub-detectors relevant to the analyses have been operational, the LHC delivered stable beams, and there are no jets in the event consistent with coming from instrumental effects such as coherent noise in the electromagnetic calorimeter, or non-collision backgrounds. To further reject non-collision backgrounds, only events with a reconstructed primary vertex with at least five associated tracks are considered.

Jets: Jets are reconstructed with the anti- $k_{t}$ algorithm [26,27] with a size parameter value of $R=0.4$. The jet finder uses three-dimensional noise-suppressed clusters [28] in the calorimeter, reconstructed at
the electromagnetic (EM) energy scale. Jets are then calibrated to the hadronic energy scale with Monte-Carlo-based correction factors which depend on their transverse momentum ( $p_{\mathrm{T}}$ ) and pseudorapidity $(\eta)$. The jet energy scale uncertainty is estimated to be $(2.5-14) \%$, depending on $p_{\mathrm{T}}$ and $\eta$, with methods described in Ref. [29] but based on a larger data set. Jets considered in this analysis are required to have $p_{\mathrm{T}}>20 \mathrm{GeV}$ and $|\eta|<2.5$.
$\boldsymbol{b}$ jets: To identify jets initiated by $b$ quarks, a combination of a 3D-impact-parameter-based discriminant and a secondary-vertex-tagger [30] with an identification efficiency of about $60 \%$ for $b$ jets with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $t \bar{t}$ events is applied.
$\boldsymbol{\tau}$ jets: For the reconstruction of $\tau$ jets, all anti- $k_{t}$ jets in the calorimeter with $E_{\mathrm{T}}>10 \mathrm{GeV}$ are considered as $\tau$ candidates [31]. A dedicated algorithm is used to reject electrons (called tight electron veto). Only candidates with 1 or 3 associated tracks reconstructed in the inner detector are considered. Hadronic $\tau$ decays are identified using a likelihood quality criterion (corresponding to an efficiency of about $30 \%$ for $\tau$ leptons with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $Z \rightarrow \tau \tau$ events, and a rejection factor of about 100-1000 for quarkand gluon-initiated jets, depending on $p_{\mathrm{T}}, \eta$, and the number of associated tracks). For this analysis, they are required to have a visible $p_{\mathrm{T}}>20 \mathrm{GeV}$ and to be within $|\eta|<2.3$. In some control regions, a loose $\tau$ identification is used instead; this corresponds to an efficiency of $60 \%$, and a jet rejection of about 10 , depending on $p_{\mathrm{T}}$ and $\eta$.

Electrons: Electrons are reconstructed by matching clustered energy deposits in the electromagnetic calorimeter to tracks reconstructed in the inner detector [32]. They are required to meet quality requirements based on the expected shower shape of electrons [33]. Electrons are required to have $E_{\mathrm{T}}>20 \mathrm{GeV}$, and be isolated (defined by requiring less than 3.5 GeV of transverse energy - after corrections for pileup and leakage - in a cone of $\Delta R=0.2$ around the electron ${ }^{2}$, excluding the electron itself). Electrons are required to be in the fiducial volume of the detector, $|\eta|<2.47$. Electrons in the transition region $1.37<|\eta|<1.52$ are excluded.

Muons: Muon candidates are required to have a match of an inner detector track with a track reconstructed in the muon spectrometer [34]. Candidates are required to have $p_{\mathrm{T}}>10 \mathrm{GeV}$ and $|\eta|<2.5$. Only isolated muons are accepted by requiring that in a cone of $\Delta R=0.3$ around the muon (excluding the muon itself), both the energy deposited in the calorimeters and the momentum of all inner detector tracks total less than 4 GeV of transverse energy.

Missing transverse energy, transverse energy sum: The reconstructed missing transverse energy, $E_{\mathrm{T}}^{\text {miss }}$, is based on the energy deposited in the calorimeter and the momentum of tracks identified as associated to muons. Only noise-suppressed clusters of cells are used, and corrections for unclustered cells are applied. The contribution of the calorimeter cells is calibrated differently depending on which object they are associated to. For all jets, the same hadronic calibration scheme as for jet reconstruction is used while electrons are calibrated at the electromagnetic energy scale [35].

The transverse energy sum, $\sum E_{\mathrm{T}}$, is defined as the sum of the transverse energy of all the objects which have been reconstructed as detailed in this section, including missing transverse energy.

[^65]Overlap removal: When candidates selected using the above criteria overlap geometrically with one another (within $\Delta R<0.2$ ), this conflict is resolved by only selecting one candidate in the following order of priority: muon, electron, $\tau$ jet, or jet.

General systematic uncertainties The main detector-related systematic uncertainties are listed in Table 2. These are mostly related to identification efficiencies and the energy/momentum resolution and scale of the physics objects described above. Uncertainties on trigger efficiency, luminosity, cross sections and acceptance are also listed.

To assess the impact of most sources of systematic uncertainty on the result of the analysis, selection cuts for each analysis are re-applied after shifting a particular parameter by its $\pm 1$ standard deviation uncertainty. The luminosity and the trigger uncertainty with respect to the offline efficiency serve directly as scale factors on the event yield.

Table 2: Systematic uncertainties. Uncertainties on the $t \bar{t}$ cross section include variations of the parton density functions (pdf) and of the factorization and renormalisation scale. A scale factor is the ratio of efficiencies in data and simulation, and is here denoted as "SF". The difference in acceptance for $t \bar{t}$ events at LO and NLO is used as systematic uncertainty on the signal acceptance.

| Quantity | Uncertainty |
| :--- | :--- |
| Luminosity [36] | $\pm 3.7 \%$ |
| Jet energy resolution (JER) | $\pm(10-30) \%$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| Jet energy scale (JES) | $\pm(2.5-14) \%$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $E_{\mathrm{T}}^{\text {miss }}$ | Uncertainty due to scale/resolution uncertainties (e.g. JES); |
|  | additional $10 \%$ of pile-up-related uncertainty |
| $b$-tagging efficiency SF unc. | $\pm(0.05-0.15)$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $b$-tagging mistag rate | $\pm(0.16-0.39)$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $b$ jets JES uncertainty | an additional $\pm 2.5 \%$ on top of the standard JES |
| $\tau$ identification efficiency | $\pm(8.5-9.9) \%$, depending on $p_{\mathrm{T}}$ |
| $\tau$ energy scale | $\pm(4.5-6.5) \%$, depending on $p_{\mathrm{T}}, \eta$, number of associated tracks |
| $\tau$ electron mis-id correction factors | $\pm(23-100) \%$, depending on $\eta$; for one-prong only |
| $\tau+E_{\mathrm{T}}^{\text {miss trigger }}$ | $\pm 9 \%$ |
| $e$ reco. efficiency SF | $\pm(0.7-1.8) \%$, depending on $\eta$ |
| $e$ identification efficiency SF | $\pm(2.2-3.8) \%$, depending on $E_{\mathrm{T}}$ and $\eta$ |
| $e$ energy scale | $\pm(0.3-1.8) \%$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $e$ energy resolution | $\pm(0.5-2.4) \%$ (additional constant term), depending on $p_{\mathrm{T}}$ and $\eta$ |
| $\mu$ reco. efficiency SF | $\pm(0.25-0.55) \%$, depending on the data-taking period |
| $\mu$ momentum scale and resolution | $\pm(0.4-0.7) \%$, depending on $\eta$ |
| Initial/final state radiation modelling | $-16 \% /+19 \%(t \bar{\tau}$ signal and background) |
| Acceptance | $\pm 4 \%$ (background), $\pm 10 \%$ (signal) |
| $t \bar{t}$ cross section | $165_{-9}^{+4}($ scale $)+7($ pdf $)$ pb |

## 4 Event selection

This study describes the search for a charged Higgs boson in the topology

$$
\begin{equation*}
t \bar{t} \rightarrow\left[H^{+} b\right]\left[W^{-} \bar{b}\right] \rightarrow\left[\left(\tau_{h a d}^{+}+v\right) b\right]\left[\left(q \bar{q}^{\prime}\right) \bar{b}\right] \tag{1}
\end{equation*}
$$

where both the $W$ boson and the $\tau$ lepton decay hadronically. This topology has the advantage that the $W$ boson can be fully reconstructed, the $H^{+}$candidate can be reconstructed in the transverse plane, and
the branching ratio of the $W$ boson decay to quarks is larger than that to leptons; but it needs to be distinguished from a large multi-jet background.

The following selection cuts are applied, based on the reconstructed physics objects described in Section 3:

1. Event preselection:
(a) Data quality cuts.
(b) $E_{\mathrm{T}}^{\text {miss }}$ plus tau trigger $[37,38]$, with a threshold of 29 GeV on the $\tau$ object, of 35 GeV on $E_{\mathrm{T}}^{\text {miss }}$, and no muon corrections on $E_{\mathrm{T}}^{\text {miss }}$. The signal efficiency is about $70 \%$, depending on $m_{H^{+}}$.
(c) At least 4 jets (excluding $\tau$ jets) with $p_{\mathrm{T}}>20 \mathrm{GeV}$ and $|\eta|<2.5$.
2. A $\tau$ jet with $p_{\mathrm{T}}^{\tau}>35 \mathrm{GeV}$ within $|\eta|<2.3$ is required. This $\tau$ jet must be matched to the $\tau$ trigger object within $\Delta R<0.1$. Events with a second identified $\tau$ jet with $p_{\mathrm{T}}^{\tau}>20 \mathrm{GeV}$ are vetoed.
3. Events are vetoed if any identified electrons $\left(E_{\mathrm{T}}>20 \mathrm{GeV}\right)$ or muons $\left(p_{\mathrm{T}}>10 \mathrm{GeV}\right)$ are present.
4. The missing transverse energy $E_{\mathrm{T}}^{\mathrm{miss}}$ is required to be larger than 40 GeV .
5. Events with large reconstructed $E_{\mathrm{T}}^{\mathrm{miss}}$ due to the limited resolution of the energy measurement are rejected with a cut on the ratio $\frac{E_{\mathrm{T}}^{\text {miss }}}{0.5 \cdot \sqrt{\sum E_{\mathrm{T}}}}>8 \mathrm{GeV}^{1 / 2}$, using the $\sum E_{\mathrm{T}}$ definition described in Section 3. Considering the minimum $\sum E_{\mathrm{T}}$ required to pass all other selection cuts, this also corresponds to raising the cut on $E_{\mathrm{T}}^{\text {miss }}$ to about 50 GeV .
6. At least one $b$-tagged jet is required.
7. Topologies consistent with a top decay are identified by requiring that the $q q b$ candidate with the highest $p_{\mathrm{T}}^{q q b}$ value must satisfy $m(q q b) \in[120,240] \mathrm{GeV}$.

For events passing the above selection cuts the transverse mass, $m_{\mathrm{T}}$, is defined as

$$
\begin{equation*}
m_{\mathrm{T}}=\sqrt{2 p_{\mathrm{T}}^{\tau} E_{\mathrm{T}}^{\mathrm{miss}}(1-\cos \Delta \phi)} \tag{2}
\end{equation*}
$$

where $\Delta \phi$ is the azimuthal angle between the $\tau$ jet and the missing energy direction. This final discriminating variable is related to the $W$ boson mass in the $W \rightarrow \tau v$ background case, and the $H^{+}$mass for the signal hypothesis.

At the end of the selection cut flow, after applying data-driven methods as detailed in the sections that follow, $37 \pm 7$ background events are expected for $m_{\mathrm{T}}>40 \mathrm{GeV}$. Of those, $21 \pm 5$ events are expected with a correctly identified $\tau$ jet; about 2 events each for the case where an electron or a jet have been misidentified as a hadronically decaying $\tau$ lepton in a $t \bar{t}$ or electroweak background process. The multijet contribution is expected to be $12 \pm 5$ events. A potential signal yield depends on the charged Higgs boson mass and the branching ratio $t \rightarrow b H^{+}$; for example, 70 events are expected for $m_{H^{+}}=130 \mathrm{GeV}$ and $\operatorname{BR}\left(t \rightarrow b H^{+}\right)=0.1$.

## 5 Data-driven background estimation

The main source of background events to charged Higgs boson searches at the LHC are those coming from production processes such as $t \bar{t}$, multi-jet, single top-quark, and $W+$ jets, in this order of relevance. The individual contributions from these backgrounds are determined in a data-driven way. They can
be divided into two categories: backgrounds with intrinsic $E_{\mathrm{T}}^{\text {miss }}$ from $W$ decays, and backgrounds with $E_{\mathrm{T}}^{\text {miss }}$ caused by detector effects (multi-jet events). For the first category, the contribution from events in which electrons or jets are misidentified as $\tau$ jets are predicted using appropriate control samples while events with correctly identified $\tau$ jets are studied with the embedding method. The multi-jet background can be estimated using the shape of its $E_{\mathrm{T}}^{\text {miss }}$ distribution in a suitable control region.

### 5.1 Methods based on measuring misidentification probabilities

The background from events where an electron or a jet is misidentified as a hadronically decaying $\tau$ lepton is estimated in a data-driven procedure from suitable control samples. The probability for an electron or jet to be misidentified as a $\tau$ jet is defined as
misidentification probability $=\frac{\text { number of } \tau \text { candidates passing event selection, } \tau \text { ID and electron veto }}{\text { number of } \tau \text { candidates passing event selection }}$.

### 5.1.1 Electron-to- $\tau$ misidentification probability with a tag-and-probe method

The Method A tag-and-probe method on $Z / \gamma^{*}$ events in collision data is used to measure the misidentification probability of electrons. The result is compared to simulation, and the ratio of the misidentification probability as measured in data to that determined in simulation is called a scale factor. This factor is then used to correct the description of the electron-to- $\tau$ misidentification probability in simulation. The method used is identical to that described in [39] though based on a larger data set. The process $Z / \gamma^{*} \rightarrow e e$ allows the selection of a clean sample of electrons from data. An electron trigger with a threshold on the electron $E_{\mathrm{T}}$ of 20 GeV is used. The tag electron is required to have a $p_{\mathrm{T}}>30 \mathrm{GeV}$ and to be located in the central region $(|\eta|<2.47)$ of the detector (but outside the transition region between the barrel and the end-cap, $1.37<|\eta|<1.52$ ). It must be isolated (the sum of the momenta of tracks in a cone of $\Delta R=0.4$ around the electron is required to be less than $6 \%$ of the electron momentum) and must pass tight electron identification criteria [33]. Furthermore, a match within $\Delta R=0.1$ to the trigger electron is required. The probe electron is considered for further analysis if it is reconstructed as a $\tau$ jet candidate with $p_{\mathrm{T}}>20 \mathrm{GeV}$ with exactly one associated track. The probability of electrons to be misidentified as 3-track $\tau$ jets is negligible. The pair with the highest scalar $E_{\mathrm{T}}$ sum is chosen from all possible $e-\tau$ pairs that are separated by $\Delta R>0.4$. Additionally, the tag and the probe objects are required to have opposite electric charges. Events with $E_{\mathrm{T}}^{\text {miss }}>20 \mathrm{GeV}$ are discarded to reduce the background contamination from $W \rightarrow e v$ decays, and the invariant mass of the $e-\tau$ pair is required to be between 80 and 100 GeV .

The selected probe sample of $\tau$ jet candidates then contains electrons originating from $Z$ bosons with a purity (estimated from simulation) of about $99 \%$. The main backgrounds are multi-jet events, $W \rightarrow e v$, and $Z / \gamma^{*} \rightarrow \tau \tau$, in that order. The multi-jet background is estimated using a two-dimensional sideband subtraction method [39], the electroweak backgrounds using simulation.

Results The misidentification probabilities (as defined in Eq. 3) are extracted for the $\tau$ candidates which pass the $\tau$ selection (including overlap removal with electron candidates) and the electron veto criteria as used in the $H^{+}$selection. In the denominator, the probe objects are not required to pass the $\tau$ jet identification, whereas the numerator contains the number of events with the probe objects both passing the identification and not being discarded by the electron veto. The results for the scale factor and misidentification probability are shown in Table 3 for the different calorimeter regions. Only the scale factors are used in the following. No significant dependence of the scale factor on the $p_{\mathrm{T}}$ of the $\tau$ lepton candidate is observed.

Application of the method to estimate the $e \rightarrow \tau$ misidentification background The misidentification probability from this study is applied by scaling simulated events in which the selected reconstructed $\tau$ jet originates from a true electron. The scale factor used is given by the ratio of the misidentification probability in data to that in Monte Carlo.

Table 3: Scale factors and measured $e \rightarrow \tau$ misidentification probabilities for $\tau$ candidates with $E_{\mathrm{T}}>20$ GeV in the barrel $(0<|\eta|<1.37)$, transition $(1.37<|\eta|<1.52)$ and end-cap $(1.52<|\eta|<2.5)$ regions passing the $\tau$ identification and a tight electron veto, for a $\tau$ identification efficiency of about $30 \%$. The scale factors are given with statistical and systematic uncertainties combined.

| Region | Scale factor | Misidentification probability (data) |
| :--- | ---: | ---: |
| $0<\|\eta\|<1.37$ | $1.1 \pm 0.3$ | $0.0028 \pm 0.0006$ |
| $1.37<\|\eta\|<1.52$ | $1.0 \pm 1.0$ | $0.0005 \pm 0.0004$ |
| $1.52<\|\eta\|<2.5$ | $1.6 \pm 0.5$ | $0.009 \pm 0.003$ |

Systematic uncertainties Five main sources of systematic uncertainties on the electron- $\tau$ jet misidentification probability are studied. The systematic uncertainty due to the subtraction of multi-jet and electroweak backgrounds is at the level of only $1 \%$, but can reach up to $25 \%$ in the transition region. Ideally, the measurement should be independent of the tag selection. To test any potential correlation, this selection has been varied (using medium electron identification criteria instead of tight ones in order to study the bias of only selecting very well-reconstructed tag electrons), leading to an estimate of a systematic uncertainty of $10 \%$. Other systematic uncertainties are negligible in comparison. The choice of the mass window size around $m_{Z}$ applied to the tag-and-probe objects which could result in a bias by only studying objects with well-reconstructed momentum and the uncertainty of the electron energy scale (via the cut on the tag electron energy) only give a small contribution. The total uncertainties on the scale factors (combining the statistical and systematic uncertainties of the measurement) are $24 \%$ in the barrel, $29 \%$ in the end-caps, and $100 \%$ in the transition region. Except for the end-cap, they are dominated by the statistical uncertainties.

In total, the expected contribution of events with electrons misidentified as $\tau$ jets in the signal region is about 2 events which is about $5 \%$ of the expected background. Thus reducing the relatively large uncertainties would only lead to a minor improvement of the $H^{+}$sensitivity.

### 5.1.2 Jet-to- $\tau$ misidentification probability from photon+jets

To study the probability for jets to be misidentified as hadronically decaying $\tau$ leptons, a $\gamma$-jet control sample is used. Like jets from the hard process in the dominant $H^{+}$background $t \bar{t}$, jets in this control sample originate predominantly from quarks as opposed to gluons. A measurement of the probability for a jet to be misidentified as a hadronically decaying $\tau$ lepton is performed using $1.03 \mathrm{fb}^{-1}$ of data and is used to predict the yield of jet-to- $\tau$ misidentification events from the most important SM backgrounds with intrinsic $E_{\mathrm{T}}^{\text {miss }}$. The main difference between $t \bar{t}$ and $\gamma$-jet events is the different fraction of $b$ jets which is smaller in $\gamma$-jet events. However, the probability for a $b$ jet to be misidentified as a $\tau$ jet is smaller than the corresponding probability for a light-quark jet: The average track multiplicity of $b$ jets is higher, and variables which measure the mass of the $\tau$ candidate allow a good discrimination. Hence using the $\gamma$-jet misidentification probability leads to a higher background estimate and is thus conservative.

Figure 2: Jet $\rightarrow \tau$ misidentification probability measured from $\gamma$-jet events for jets with 1 or 3 associated tracks as a function of $p_{\mathrm{T}}$ and $\eta$. The error bars indicate the size of the statistical uncertainties.

The Method Events are required to pass a single-photon trigger (with an $E_{\mathrm{T}}$ threshold of 15,20 or 40 GeV ). The photon candidate must be isolated (less than 6 GeV of $E_{\mathrm{T}}$ deposited in a $\Delta R=0.2$ cone around the photon), is required to match a trigger object, pass the photon selection [40], and have either zero or two associated tracks to include photon conversions. The photon candidate must have $|\eta|<2.37$, not be located in the transition region, and must have a transverse energy of at least 15 GeV . The selected $\gamma$-jet sample consists of events with one photon candidate and a jet with $p_{\mathrm{T}} \geq 20 \mathrm{GeV}$, separated in $\phi$ by at least 2.84 radians. The difference in transverse energy between the jet and the photon must be less than half of the total transverse energy of the photon. Any additional jets are required to have less than $20 \%$ of the photon transverse energy.

The misidentification probability is measured as a function of both $p_{\mathrm{T}}$ and $\eta$. The denominator of the calculated misidentification probability is the number of events with a $\tau$ candidate (i.e. no $\tau$ ID applied) with $p_{\mathrm{T}}$ greater than 20 GeV and $|\eta|<2.3$, which passes an electron veto. The misidentification probability is evaluated separately for the case of candidates with 1 or 3 associated tracks. Among all jets with $E_{\mathrm{T}}>20 \mathrm{GeV}$ and $|\eta|<2.3$, the fraction of light-quark jets which are considered as such $\tau$ candidates is about $27 \%$. The numerator in the calculated misidentification probability consists of events with objects which pass the full $\tau$ identification. They must not be within $\Delta R=0.2$ of any $e$ or $\mu$. The measured misidentification probabilities are shown in Fig. 2.

Systematic uncertainties The dominant systematic uncertainties on the misidentification probability are (the ranges given on each systematic uncertainty show the variation with the $p_{\mathrm{T}}$ and $\eta$ of the $\tau$ candidate):

- Contamination of the control sample with true $\tau$ jets from $Z \rightarrow \tau \tau$ and $W \rightarrow \tau v$ events, evaluated using simulation: $(1-3) \%$.
- Contamination of the control sample with multi-jet events which have a larger gluon-initiated jet fraction than $\gamma$-jet events. The associated systematic uncertainty is evaluated by modifying the photon ID requirements, in particular loosening the photon isolation which increases the impurity from multi-jet events in the control sample: $(5-9) \%$.
- Contamination of the control sample by three-jet events. The associated systematic uncertainty is evaluated by varying the selection cuts (vetoing events with additional jets with less than 0.1 of the
photon momentum), and by splitting the control sample in a part which fulfills even tighter requirements and one which does not, and then taking the variation of the misidentification probability due to these changes as the uncertainty: $(11-17) \%$.
- The measurement of the misidentification probability on the probe object is assumed to be uncorrelated from the selection of the tag object. To evaluate uncertainties from a violation of this assumption, correlations between the tag and the probe objects are studied by changing the requirements on the tag object (requiring a photon with a looser quality criterion) and studying the impact on the measurement of the misidentification probability on the probe object: $(7-14) \%$.

Additionally, the statistical uncertainty of the measurement of the misidentification probability enters as uncertainty on any application of the misidentification probability. The total systematic uncertainty is about $(15-24) \%$, depending on $p_{\mathrm{T}}$ and $\eta$. The systematic uncertainties on the misidentification probability are propagated into the background prediction for the baseline selection and enter the statistical evaluation as shape uncertainties.

Application to estimate the jet $\rightarrow \tau$ misidentification background To predict the background in $\mathrm{H}^{+}$ searches, the measured jet $\rightarrow \tau$ misidentification probability is applied to simulated $t \bar{t}$, single-top, and $W+$ jets events. These events are required to pass the full event selection except for the $\tau$ identification. For these events, $\tau$ candidates fulfilling the same requirements as in the misidentification probability definition which do not overlap with a true $\tau$ lepton are identified. Out of the remaining $\tau$ candidates, each one is considered to be potentially misidentified as a $\tau$ jet separately. The identified jet that corresponds to the $\tau$ candidate is removed from the event, affecting the number of reconstructed jets, the $E_{\mathrm{T}}^{\text {miss }}$ significance of the event, and the number of $b$-tagged jets. If, after taking this into consideration, the event still passes the selection, then the event is counted as background event with a weight given by the misidentification probability corresponding to the $p_{\mathrm{T}}$ and the $\eta$ of the $\tau$ candidate. The predicted number of events from the $t \bar{t}$ sample, together with a comparison to the MC prediction using truth information, is shown in Table 4. All other jet $\rightarrow \tau$ misidentification backgrounds with intrinsic $E_{\mathrm{T}}^{\text {miss }}$ are at least two orders of magnitude smaller than $t \bar{t}$.

Table 4: Application of the misidentification probability obtained from $\gamma$-jet events. The numbers shown are the expected number of events in collision data after the $H^{+}$selection. The prediction based on the misidentification probability measurement (statistical and systematic uncertainties), as well as the MC prediction (statistical uncertainties), are given.

| Sample | Data-driven prediction [number of events] | MC prediction [number of events] |
| :--- | :--- | :--- |
| $t \bar{t}$ | $2.8 \pm 1.0($ stat $) \pm 0.5($ syst $)$ | $3.8 \pm 0.6($ stat $)$ |

### 5.2 Multi-jet background estimate

As the uncertainties on the multi-jet expectation are large, it is necessary to avoid using any multi-jet simulation to estimate this background. Thus an approach different from estimating the jet $\rightarrow \tau$ misidentification contribution in events with intrinsic $E_{\mathrm{T}}^{\text {miss }}$, as described in the previous section, is chosen.

The Method The multi-jet background is estimated by fitting its $E_{\mathrm{T}}^{\text {miss }}$ shape (and the $E_{\mathrm{T}}^{\text {miss }}$ shape of other backgrounds) to data. In order to study this shape in a data-driven way, a control region is defined
where the $\tau$ identification and $b$-tagging requirements are inverted. The $\tau$ candidates must pass a loose $\tau$ identification but fail the tight $\tau$ identification used in the baseline selection. In addition, the event is required not to contain any $b$-tagged jets and therefore also the requirement on the $q q b$ mass (selection cut 7) is removed.

Assuming that the shapes of the $E_{\mathrm{T}}^{\text {miss }}$ and $m_{\mathrm{T}}$ distributions are the same in the control sample and signal regions (see Fig. 3 for a comparison early in the selection cut flow), the shape of the $E_{\mathrm{T}}^{\text {miss }}$ distribution is used to model the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution for the multi-jet background (after subtracting the background from other processes). The $E_{\mathrm{T}}^{\text {miss }}$ distribution measured in data (for the baseline selection) is then fitted using two shapes: this multi-jet model, and the sum of other processes (dominated by $t \bar{t}, W+\mathrm{jets}$ ) for which the shape and the relative normalisation are taken from MC simulation. The free parameters in the fit are the overall normalisation (to the one in data) and the multi-jet fraction.

Figure 3: Distribution of $E_{\mathrm{T}}^{\text {miss }}$, after subtracting the expectation from $t \bar{t}, W+\mathrm{jets}$, and single-top simulation; compared are the distributions after requirement 3 of the baseline selection as detailed in Section 4, with the exception that in the control region, the $\tau$ selection and the $b$-tagging requirements have been inverted. The shaded area indicates the size of the statistical uncertainties.

Systematic uncertainties The dominant systematic uncertainties are:

- The uncertainty on the assumption that the $E_{\mathrm{T}}^{\mathrm{miss}}$ shape is identical in the signal and control regions. This is studied by varying the number of entries in each bin separately within the maximum differences observed early in the selection cut flow (a factor of 0.5 and 2.0) and redoing the fit. Then, the largest downwards and upwards fluctuations are used as systematic uncertainty. This leads to an uncertainty on the multi-jet fraction of $-13 \% /+25 \%$.
- The uncertainty on the $t \bar{t}$ and $W+$ jets shapes and relative normalisation from Monte Carlo is dominated by uncertainties on the $t \bar{t}$ cross section. The scaling of the $t \bar{t}$ Monte Carlo is varied according to these uncertainties, leading to an uncertainty on the multi-jet fraction of $2.4 \%$.
- The uncertainty from backgrounds other than $t \bar{t}$ and $W+$ jets in the control region is found to be negligible.

The uncertainty on the multi-jet fraction is dominated by the statistical uncertainty of the data set on which the fit is performed.

Result of the data-driven estimate of the multi-jet background The multi-jet fraction is estimated to be $(23 \pm 10) \%$ using the fit to the $E_{\mathrm{T}}^{\text {miss }}$ distribution shown in Fig. 4. The $m_{\mathrm{T}}$ distribution for the same
events is shown in Fig. 5. Except for the multi-jet background, all other processes have $W$ bosons in the final state and their distributions drop off around the $W$ boson mass, as expected. Such behavior is neither expected nor observed for the multi-jet background as resulting shapes are mainly caused by detector effects. To probe the region with large $m_{\mathrm{T}}$, in which a potential $H^{+}$signal resides, it is thus important to suppress the multi-jet background as much as possible.

Figure 4: Multi-jet estimate: A fit to the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution in data after all selection cuts using two shapes (one for the multi-jet model, and one for all other background processes, dominated by $t \bar{t}$ and $W+$ jets) is shown. The multi-jet fraction estimated after all selection cuts is $(23 \pm 10) \%$.

Figure 5: Contribution of multi-jet events to the $m_{\mathrm{T}}$ distribution after all cuts of the $H^{+}$selection. The multi-jet fraction is estimated using the fit to the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution shown in Fig. 4.

### 5.3 Embedding method

Complementary to the methods based on misidentification probability, an embedding method is used for estimating the background from true $\tau$ jets, described below. The method consists of collecting a control sample of $t \bar{t}$, single-top, and $W+$ jets events with a muon in data, and replacing the detector signature of this muon with that of a simulated $\tau$ lepton. The reconstruction is re-applied to the new hybrid
events which are then used to estimate the background to the $H^{+}$selection. The advantage is that the whole event (except for the $\tau$ jet) is taken directly from data, including the underlying event and pile-up, missing energy, $b$-quark jets and light-quark jets. The method has been validated in $\tau+$ jets events using early ATLAS data [41].

### 5.3.1 The Method

Control sample selection To select the $t \bar{t}$-like $\mu+$ jets control sample from data, the following event selection is used:

- Event triggered by a single muon trigger ( $p_{\mathrm{T}}$ threshold of 18 GeV ),
- data quality cuts as described in Section 3,
- exactly one isolated muon with $p_{\mathrm{T}}>25 \mathrm{GeV}$,
- no isolated electron with $p_{\mathrm{T}}>20 \mathrm{GeV}$,
- at least four jets with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $|\eta|<2.5$,
- at least one of the jets is $b$-tagged (nominal efficiency of $65 \%$ ),
- missing transverse energy $E_{\mathrm{T}}^{\text {miss }}>30 \mathrm{GeV}$,
- scalar sum of energy of reconstructed objects $\sum E_{\mathrm{T}}>200 \mathrm{GeV}$.

This selection is looser than the selection defined in Section 4 in order not to bias the control sample. This also applies to the $\tau$ jet which carries the momentum of the selected muon minus the momentum of the neutrino in the $\tau$ lepton decay and its $p_{\mathrm{T}}$ is required to be larger than 35 GeV in the $H^{+}$selection. The impurity from the background with muons produced in $\tau$ decays, and non-isolated muons (dominantly $b \bar{b}$ and $c \bar{c}$ events) is at the level of $10 \%$ and biases the shape of embedded events. However, the bias is greatly reduced as these events are much less likely to pass the $H^{+}$selection.

Embedding step After events have been selected, the actual embedding step takes place. The muon in the event is selected and its vertex position and momentum are extracted. The momentum is then rescaled to account for the higher $\tau$ lepton mass and fed into TAUOLA to produce the $\tau$ lepton decay products and generate final state radiation. The result is propagated through ATLAS detector simulation, followed by reconstruction. In the next step, tracks, calorimeter deposits and segments in the muon spectrometer in the vicinity of the muon are replaced with those of the simulated $\tau$ lepton decay products.

Comparison of embedding method versus simulation To test the method, the embedded data events are compared to simulated $t \bar{t}$ events (hereafter referred to as 'reference') in which the $\tau$ lepton comes directly from simulation of the whole event, and is not added via the embedding method. To make sure the set of events is comparable, both for the embedded and the reference events, a reconstructed $\tau$ candidate which is matched to a true $\tau$ lepton is required (this can be performed using embedded events, as the $\tau$ part of the event is taken from simulation).

A comparison of distributions of variables relevant to this analysis is shown in Fig. 6. A good agreement is observed within the statistical uncertainties.

Figure 6: Validation plots for the embedding method used to estimate the background with true $\tau$ jets. Embedded data is compared to $t \bar{\tau}$ simulation after applying the $H^{+}$selection. The $\tau$ likelihood (TauLLH), the $\tau$ transverse momentum, the missing transverse energy, and the top quark transverse momentum on the $t \rightarrow b q q$ side are shown. The plots are normalized to unit area. The shaded area indicates the size of the statistical uncertainties on the MC simulation.

### 5.3.2 Application to estimate the true- $\tau$ background

The contribution of backgrounds with true $\tau$ jets to the final $m_{\mathrm{T}}$ distribution is estimated from this distribution for embedded events. The normalisation is taken from collision data events in the region $0-40 \mathrm{GeV}$ of this distribution, where any signal contamination would be low for the expected range of sensitivity $\left(\operatorname{BR}\left(t \rightarrow b H^{+} \approx 5 \%\right)\right)$. Such a contamination is dealt with in the limit-setting process by subtracting the expected signal from the observed data before normalizing the shape to the region $m_{\mathrm{T}}<40 \mathrm{GeV}$. This is done when evaluating the signal+background hypothesis and takes the tested $\mathrm{BR}\left(t \rightarrow b H^{+}\right)$into account. Effectively, this brings the signal+background expectation closer to the background-only expectation.

The following procedure is applied:

1. Apply the $\tau+$ jets event selection to embedded events to obtain the $m_{\mathrm{T}}$ shape.
2. From collision data, count the number of events in the $m_{\mathrm{T}}$ distribution between $0-40 \mathrm{GeV}$ after subtracting the background from objects misidentified as $\tau$ jets.
3. Using this number, normalize the $m_{\mathrm{T}}$ distribution from embedded events using the ratio of events in collision data and embedded data.

For technical reasons, the trigger simulation cannot be re-run for embedded events. As the number of events entering the embedding control sample and passing the whole event selection is still relatively small, the event selection applied to the embedded events is modified by requiring a $\tau$ identified using loose criteria. This can be done because the $m_{\mathrm{T}}$ distribution is normalized to data and, as Fig. 7 (left) shows, the looser cuts do not bias the shape significantly.

The result is shown in Fig. 7 (right). As can be seen, the uncertainty of the background estimate is currently limited by the statistical uncertainty due to the limited number of events in the $t \bar{t}$ control sample. In the range $40<m_{\mathrm{T}}<300 \mathrm{GeV}$, there are $21 \pm 5$ background events with true $\tau$ jets expected where the uncertainty is due to the limited number of events in the control sample, and of the data in the region to which the shape is normalized to. In data, 26 events are observed after subtracting the background predicted by the misidentification probability methods and the multi-jet estimate. Within statistical uncertainties, the background prediction and data agree well.

### 5.3.3 Systematic uncertainties

The following systematic uncertainties are associated with the background prediction:

- To study the effect of additional multi-jet background on the embedding and the control sample selection itself, the $\mu$ isolation requirement is varied. To study a potential bias introduced by the embedding method parameters chosen, alternative values are used for the inner and outer cone size in which calorimeter cell depositions are replaced or added. To account for the fact that a small amount of pile-up-related activity can be present in the calorimeter cells removed in a cone around the muon, the effect of only removing half of this energy before adding the $\tau$ jet is studied. This results in a systematic uncertainty of $7 \%$ on the background normalisation.
- The systematic uncertainty due to the difference in the $m_{\mathrm{T}}$ shape as a consequence of loosening the selection with respect to the $H^{+}$selection, as shown in Fig. 7, results in a $8 \%$ uncertainty on the background normalisation, and a shift of about 2 GeV in the $m_{\mathrm{T}}$ distribution.
- The impact of the incomplete treatment of the $\tau$ polarisation in embedded events results in an uncertainty on the $m_{\mathrm{T}}$ shape which is estimated by comparing bin by bin the difference in the number of events for simulated $t \bar{t}$ events with and without correct treatment of the $\tau$ polarisation.

Figure 7: Left: Comparison of the $m_{\mathrm{T}}$ shape for simulation and for embedded events (with loose $\tau$ identification) used to estimate the background with true $\tau$ jets. The distribution from simulation is shown both after the $H^{+}$baseline selection and after the same selection but without trigger requirement and loose $\tau$ identification. All distributions are normalized to unit area. Right: Comparison of the $m_{\mathrm{T}}$ shape for embedded events versus collision data. The prediction using the embedding method is stacked on top of the expected backgrounds with objects misidentified as $\tau$ jets: MC expectation for $t \bar{t}$ and electroweak processes, and the data-driven estimate for multi-jet events. The comparison is done after the $H^{+}$event selection and after normalizing the $m_{\mathrm{T}}$ distribution of embedded events to the data distribution in the range $0-40 \mathrm{GeV}$. The gray area indicates the size of the statistical and systematic uncertainties of the embedding method estimate.

This results in an uncertainty on the normalisation of $15 \%$, and the $m_{\mathrm{T}}$ distribution is shifted by about 7 GeV which corresponds to $14 \%$ of the average $m_{\mathrm{T}}$.

- The impact on the $m_{\mathrm{T}}$ distribution due to the uncertainty on the $\tau$ energy scale (Table 2 ) is evaluated, leading to a normalisation uncertainty of $+4 /-2 \%$, and a shift in the $m_{\mathrm{T}}$ distribution by $\pm 1 \mathrm{GeV}$.

The statistical uncertainty of the estimate is $8 \%$ due to the limited size of the control sample, and additionally $20 \%$ due to the normalisation to data (allowing data to fluctuate within one standard deviation for $m_{\mathrm{T}}<40 \mathrm{GeV}$ ). The numbers above are only indicative, for the limit calculation the full shape uncertainty is used.

## 6 Results

The results of the data-driven methods in estimating the contributions of the various categories of backgrounds after the baseline selection are summarized in Table 5, and the $m_{\mathrm{T}}$ distribution of the remaining events is shown in Fig. 8. The total systematic uncertainty on the background prediction is about $30 \%$ but can reach up to $70 \%$ for $m_{\mathrm{T}}>100 \mathrm{GeV}$. For the signal, the total systematic uncertainty on the yield is about $40 \%$ with a small dependence on $m_{H^{+}}$. The number of events with true $\tau$ jets has been estimated with the embedding method, the jet $\rightarrow \tau$ misidentification events with intrinsic $E_{\mathrm{T}}^{\text {miss }}$ with $\gamma+\mathrm{jets}$ control samples, the $e \rightarrow \tau$ misidentification events with $Z / \gamma^{*} \rightarrow e e$ control samples, and the multi-jet contribution by taking its shape from a sideband region and fitting it to the data. The number of events with $m_{\mathrm{T}}>40 \mathrm{GeV}$ is given which allows for a better comparison of data and expectation as the estimate from the embedding method is normalized to data in the range $m_{\mathrm{T}}<40 \mathrm{GeV}$. A good agreement between the estimated and the observed number of events is seen.

Table 5: Expected number of events from data-driven estimates with $m_{\mathrm{T}}>40 \mathrm{GeV}$, and as observed in data. Only statistical uncertainties are given.

|  | Events with/from |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | true $\tau$ jets | jet $\rightarrow \tau$ mis-id | $e \rightarrow \tau$ mis-id | multi-jet | expected (sum) | data |
| $m_{\mathrm{T}}>40 \mathrm{GeV}$ | $21 \pm 5$ | $2.4 \pm 0.7$ | $1.9 \pm 0.2$ | $12 \pm 5$ | $37 \pm 7$ | 43 |

Using data-driven background estimates, no statistically significant excess of events is observed in $1.03 \mathrm{fb}^{-1}$ of collision data. Exclusion limits are set on the branching ratio $t \rightarrow b H^{+}$, and in the $m_{H^{+}}-\tan \beta$ plane, by rejecting the signal hypothesis at the $95 \%$ confidence level applying the $\mathrm{CL}_{s}$ procedure [42, 43]. A profile likelihood ratio [44] is used with the $m_{\mathrm{T}}$ distribution as the discriminating variable. The statistical analysis is based on a binned likelihood function for the $m_{\mathrm{T}}$ distribution. Systematic uncertainties in shape and normalisation are incorporated via nuisance parameters and the one-sided profile likelihood ratio, $\tilde{q}_{\mu}$, is used as a test statistic. The final limits are based on the asymptotic distribution of the test statistic [44].

The resulting exclusion limit is shown in Fig. 9 in terms of $\operatorname{BR}\left(t \rightarrow H^{+} b\right) \times \operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$. Figure 10 shows the upper limit in the context of the $m_{h}^{\max }$ scenario of the MSSM [45] in the $m_{H^{+-}} \tan \beta$ plane. No exclusion limit is shown for charged Higgs boson masses close to 160 GeV as no reliable calculations for $\mathrm{BR}\left(t \rightarrow H^{+} b\right)$ exist for $\tan \beta$ values in the range of interest. The following relative uncertainties on $\mathrm{BR}\left(t \rightarrow b H^{+}\right)$are considered [46]: 5\% for one-loop electro-weak corrections missing in the calculations, $2 \%$ for missing two-loop QCD corrections, and about $1 \%$ (depending on $\tan \beta$ ) $\Delta_{b^{-}}$ induced uncertainties (where $\Delta_{b}$ is a correction factor to the running bottom quark mass [47]). These

Figure 8: The $m_{\mathrm{T}}$ distribution after event selection. The observation in collision data, and the estimates from data-driven methods are compared. The distribution of the $H^{+}$signal is given for a reference point in parameter space corresponding to $\mathrm{BR}\left(t \rightarrow b H^{+}\right)=10 \%$, thus the SM-like $t \bar{t}$ background is reduced correspondingly.
uncertainties are added linearly. This result constitutes a significant improvement compared to existing limits provided by the Tevatron experiments [6] over the whole investigated mass range, but in particular for charged Higgs boson masses close to the top quark mass.

## 7 Conclusions

Charged Higgs bosons are searched for in the decay mode $t \rightarrow b H^{+}, H^{+} \rightarrow \tau v$, with hadronically decaying $\tau$ leptons, using $t \bar{t}$ events reconstructed in a total of $1.03 \mathrm{fb}^{-1}$ of $\sqrt{s}=7 \mathrm{TeV} p p$ collision data recorded with the ATLAS experiment. Data-driven methods, employed to estimate the number of background events characterized by the presence of a $\tau$ jet, $E_{\mathrm{T}}^{\text {miss }}, b$ jets, and a hadronically decaying $W$ boson, predict $37 \pm 7$ (stat) events with $m_{\mathrm{T}}>40 \mathrm{GeV}$. A total of 43 such events are observed which is consistent with the prediction. The $\mathrm{CL}_{s}$ procedure is used to derive $95 \%$ CL exclusion limits. Values of the product of branching ratios, $\mathrm{BR}\left(t \rightarrow b H^{+}\right) \times \mathrm{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$, larger than $0.03-0.10$ have been excluded in the $H^{+}$mass range $90-160 \mathrm{GeV}$, significantly extending limits from other experiments. Interpreted in the context of the $m_{h}^{\max }$ scenario of the MSSM, values of $\tan \beta$ above $22-30$ (depending on $m_{H^{+}}$) can be excluded in the mass range $90 \mathrm{GeV}<m_{H^{ \pm}}<140 \mathrm{GeV}$.

## A Limit figure with PCL

Figure 11: Expected and observed $95 \%$ CL exclusion limits for charged Higgs boson production from top quark decays as a function of $m_{H^{+}}$in terms of $\mathrm{BR}\left(t \rightarrow H^{+} b\right) \times \mathrm{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$ using the $\mathrm{CL}_{s}$ procedure. Power-Constrained limits (PCL) [48] with a $50 \%$ power constraint are shown as well. For comparison, the best limit provided by the Tevatron experiments is shown [6].

## ATLAS NOTE

ATLAS-CONF-2011-161

December 11, 2011

# Search for the Standard Model Higgs boson in the diphoton decay channel with $4.9 \mathbf{f b}^{-1}$ of ATLAS data at $\sqrt{s}=7 \mathbf{~ T e V}$ 

The ATLAS collaboration

#### Abstract

This note presents a search for the Standard Model Higgs boson in the diphoton decay channel in proton-proton collisions at a centre-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ using data corresponding to an integrated luminosity of $4.9 \mathrm{fb}^{-1}$ collected with the ATLAS detector at the LHC. Over the diphoton mass range $110-150 \mathrm{GeV}$ the maximum deviation from the background-only expectation is observed at 126 GeV with a local significance of 2.8 standard deviations. Taking the look-elsewhere effect into account, the significance is 1.5 standard deviations. The expected cross section exclusion at $95 \%$ confidence level varies between 1.6 and 2.9 times the Standard Model cross section over the mass range 110150 GeV . The observed exclusions lie between 0.9 and 4.0 times the Standard Model cross section, and a Standard Model Higgs boson is excluded at $95 \%$ confidence level in the mass range of $114-115 \mathrm{GeV}$ and $135-136 \mathrm{GeV}$.

## 1 Introduction

The low mass region, in which the Standard Model (SM) Higgs boson [1-3] is not yet excluded, is constrained from below at 114.4 GeV by the LEP experiments [4] and from above at 141 GeV by the ATLAS and CMS experiments [5]. The diphoton decay mode is one of the most important channels in the search for the Higgs boson in this region. This note presents the search for the Higgs boson in the diphoton decay channel with an integrated luminosity of $4.9 \mathrm{fb}^{-1}$, corresponding to the total protonproton collision data sample recorded with the ATLAS detector [6] in 2011 at a centre-of-mass energy of 7 TeV . The general analysis strategy closely follows the one described in Ref. [7], but some refinements have been introduced to the categorization of events, as described below.

This note is organized as follows. The photon reconstruction and event selection are described in Section 2. The event categorization is illustrated in Section 3, and the signal and background modelling are discussed in Section 4. The systematic uncertainties are summarized in Section 5. The statistical methods and the results of the search are presented in Section 6. Conclusions are given in Section 7.

## 2 Photon Reconstruction, Event Selection and Sample Composition

### 2.1 Photon Reconstruction and Event Selection

The data used in this analysis were recorded using a diphoton trigger with a threshold on the transverse energy $E_{\mathrm{T}}$ on each photon of 20 GeV , seeded by a trigger that required two clusters in the electromagnetic calorimeter with $E_{\mathrm{T}}>12$ or 14 GeV , depending on the data-taking period. The trigger has an efficiency of approximately $99 \%$ for the signal after the final offline event selection. After applying data quality requirements on the recorded data sample, the total integrated luminosity of the data set used in this analysis amounts to $4.9 \mathrm{fb}^{-1}$.

Events are required to contain at least one primary vertex with at least three associated tracks, where the transverse momentum, $p_{\mathrm{T}}$, of each track is required to be larger than 0.4 GeV . Photons are reconstructed both in the converted and unconverted topologies. In both cases, photon candidates are seeded by energy clusters in the electromagnetic calorimeter with $E_{\mathrm{T}}>2.5 \mathrm{GeV}$. In the case of converted photon candidates, tracks reconstructed in the inner detector are matched to these calorimeter clusters. The photon energy is calibrated based on detailed Monte Carlo (MC) simulations, separately for converted and unconverted photons [8]. A correction, dependent on pseudorapidity and typically of the order of $\pm 1 \%$, is applied to the photon calibrated energy, as obtained from studies using $Z \rightarrow e e$ decays in data [9]. Photons are reconstructed in the fiducial region defined by the pseudorapidity ${ }^{1}|\eta|<2.37$, excluding the calorimeter barrel/endcap transition region, $1.37<|\eta|<1.52$.

The $E_{\mathrm{T}}$ of the leading (subleading) photon candidate must exceed 40 GeV ( 25 GeV ). MC simulation studies [8] have shown that this requirement leads to an optimal sensitivity in the mass region of interest. Both candidates are required to pass tight identification criteria based on shower shape variables and on the energy leakage into the hadronic calorimeter [10]. The tight photon identification efficiency ranges typically from $65 \%$ to $95 \%$ for $E_{\mathrm{T}}=25-80 \mathrm{GeV}$. These two photon candidates are required to be isolated by having at most 5 GeV energy deposited in the calorimeter in a cone of $\Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}=0.4$ around the candidate excluding the photon energy itself. The isolation variable is corrected for lateral shower leakage and ambient energy from pileup, as explained in Ref. [11]. The isolation cut efficiency for the diphoton candidate is $\approx 87 \%$ for the Higgs boson signal. If the reconstructed photon is a conversion, it is rejected if it has a track reconstructed in a region of the inner detector where the module traversed

[^66]in the innermost pixel layer is one of the $\approx 3.5 \%$ which are inactive, to reduce the contamination from misidentified electrons

The angle between the two selected photons is determined from the interaction vertex position and the photon impact points in the calorimeter. For converted photons with tracks having a precise measurement in the $z$ direction, the vertex position is estimated from the intercept of the line joining the reconstructed conversion position and the calorimeter impact point with the beam line. For all other photons, the vertex position is estimated from the shower position measurements in the first and second layers of the calorimeter which can be used to calculate the photon direction. Finally, the independent vertex position measurements from both photons are combined also taking into account the average beam spot position in $z$. For photons reconstructed in the endcap region, a correction is applied to the $z$ coordinate of the vertex position estimated from the photon in order to compensate for a difference between data and MC simulation. This correction is determined as a function of $\eta$ from electrons in $Z \rightarrow e e$ decays.

The diphoton invariant mass distribution ( $m_{\gamma \gamma}$ ) is shown in Figure 1 (top) for the 22489 events passing the selection in the mass region $100 \mathrm{GeV}<m_{\gamma \gamma}<160 \mathrm{GeV}$. The sum of the background-only fits in different categories described in Sections 3 and 4, as well as the signal expectation for a SM Higgs boson with mass equal to 120 GeV , are also shown. Details of the background and signal models are given in Section 4. Figure 1 (bottom) shows the residual of the data with respect to the sum of the backgroundonly fits as a function of $m_{\gamma \gamma}$.

Figure 1: Invariant mass distribution for the inclusive data sample, overlaid with the sum of the background-only fits in different categories described in Sections 3 and 4 and the signal expectation for a mass hypothesis of 120 GeV corresponding to the SM cross section. The figure below displays the residual of the data with respect to the background-only fit sum.

### 2.2 Sample Composition

The composition of the inclusive sample, after the selection described above, is studied using different data-driven techniques. The estimates obtained with these methods, however, are not used in the limit calculation described in Section 6.

The background to a potential Higgs boson signal is expected to be mainly composed of the diphoton processes $(\gamma \gamma)$ together with events where either of the photon candidates come from misidentified jets (fake photons), mainly through fragmentation into $\pi^{0}(\gamma j$ and $j j)$. A very small fraction of the background is due to misidentified electrons.

A double two-dimensional sideband method is used to extrapolate the jet backgrounds from control regions into the signal region by classifying the leading and subleading photon candidates into those passing or failing the isolation and tight identification cuts [7]. Events with diphotons from possible Higgs boson decays and misidentified Drell-Yan (DY) events (see discussion below), as well as prompt diphoton production events, are classified as $\gamma \gamma$ events. The estimation of each composition is performed in each bin of the $m_{\gamma \gamma}$ distribution. By construction, the sum of the components in each bin of the $m_{\gamma \gamma}$ distribution amounts exactly to the number of events in that bin. Systematic uncertainties arise mainly from variations of the control samples and a MC-based estimation of the diphoton event fraction in the regions dominated by jets.

The Drell-Yan background is studied separately by selecting $Z \rightarrow e e$ decays in data where either one or both electrons pass the photon selection. In this way an $e \rightarrow \gamma$ misidentification rate is obtained and the number of $Z \rightarrow e e$ events where both electrons are misidentified as photons is estimated.

The sample composition in bins of $m_{\gamma \gamma}$ is shown in Figure 2. The composition of the entire sample is summarized in Table 1. The diphoton purity is estimated to be $(71 \pm 5) \%$ in the full data sample, and consistent values are found in subsamples with different amounts of pileup. The event fractions of each component estimated with MC simulations are consistent with these data-driven results.

The sample composition is also studied with other two data-driven methods. The first one is a twodimensional fit method fitting simultaneously the isolation distributions of leading and subleading photon candidates with templates obtained from control samples [12]. The second method measures the rate of jets which are misidentified as photons in $W(\rightarrow e v)+\mathrm{jets}$ events and extrapolates the fake photon backgrounds into the signal region using a two-dimensional sideband technique. All methods give compatible results.

Table 1: Composition of the selected inclusive sample obtained from the measurement using the data as described in Section 2.2. The first uncertainty is statistical and the second systematic. Only the total uncertainty is quoted for the relative fractions.

| Composition | $\gamma \gamma$ | $\gamma j$ | $j j$ | Drell-Yan |
| :--- | :---: | :---: | :---: | :---: |
| Events | $16000 \pm 200 \pm 1100$ | $5230 \pm 130 \pm 880$ | $1130 \pm 50 \pm 600$ | $165 \pm 2 \pm 8$ |
| Relative fraction | $(71 \pm 5) \%$ | $(23 \pm 4) \%$ | $(5 \pm 3) \%$ | $(0.7 \pm 0.1) \%$ |

## 3 Event Categorization

In the previous analysis [7] events were divided according to the photon reconstruction topologies (converted, unconverted) and $\eta$ direction in five categories with different signal-to-background ratios and invariant mass resolutions:

Figure 2: Composition of the inclusive data sample as a function of $m_{\gamma \gamma}$, extracted from the double twodimensional sideband method after the inclusive event selection. The various components are stacked on top of each other. The error bars correspond to the statistical uncertainties on each component separately. The gray bands show the overall uncertainty on each component.

- Unconverted central: both photons are unconverted and located in the central part of the barrel calorimeter $(|\eta|<0.75)$. This is the category with the best invariant mass resolution;
- Unconverted rest: both photons are unconverted and at least one photon does not lie in the central part of the barrel calorimeter;
- Converted central: at least one photon is converted and both photons are found in the central part of the barrel calorimeter;
- Converted transition: at least one photon is converted and at least one photon is located near the transition between barrel and endcap calorimeter $(1.3<|\eta|<1.75)$. Given the larger amount of material in this region, the energy resolution, in particular for converted photons, can be significantly degraded;
- Converted rest: all other events with at least one converted photon.

With the increased data set corresponding to $4.9 \mathrm{fb}^{-1}$ it is possible to further split some of the categories to optimize the sensitivity to a potential Higgs boson signal. This analysis therefore introduces a new diphoton observable, $p_{\mathrm{Tt}}$, which is defined as the component of $\vec{p}_{\mathrm{T}}^{\gamma \gamma}$ transverse to the diphoton thrust axis [13, 14], as shown in Figure 3.

Figure 3: Sketch of the $p_{\mathrm{Tt}}$ definition.

The diphoton thrust axis, $\widehat{t}$, is defined as:

$$
\widehat{t}=\frac{\vec{p}_{\mathrm{T}}^{\gamma_{1}}-\vec{p}_{\mathrm{T}}^{\gamma_{2}}}{\left|\vec{p}_{\mathrm{T}}^{\gamma_{1}}-\vec{p}_{\mathrm{T}}^{\gamma_{2}}\right|}
$$

where the $\vec{p}_{T}^{\gamma_{1}}$ and $\vec{p}_{\mathrm{T}}^{\gamma_{2}}$ are the transverse momenta of the two selected photons. The transverse momentum of the diphoton system, $p_{\mathrm{T}}^{\gamma \gamma}$, is given by:

$$
\vec{p}_{\mathrm{T}}^{\gamma \gamma}=\vec{p}_{\mathrm{T}}^{\gamma_{1}}+\vec{p}_{\mathrm{T}}^{\gamma_{2}}
$$

The $p_{\mathrm{Tt}}$ is then calculated as follows:

$$
\begin{aligned}
\vec{p}_{\mathrm{Tt}} & =\vec{p}_{\mathrm{T}}^{\gamma \gamma}-\left(\vec{p}_{\mathrm{T}}^{\gamma \gamma} \cdot \widehat{t}\right) \cdot \widehat{t} \\
p_{\mathrm{Tt}} & =\left|\vec{p}_{\mathrm{T}}^{\gamma \gamma} \times \widehat{t}\right|
\end{aligned}
$$

Four of the aforementioned five categories are split into a low $p_{\mathrm{Tt}}$ category and a high $p_{\mathrm{Tt}}$ category, separated at $p_{\mathrm{Tt}}=40 \mathrm{GeV}$. The categorization based on the $p_{\mathrm{Tt}}$ variable leads to a better sensitivity for the Higgs boson signal than one based on $p_{\mathrm{T}}^{\gamma \gamma}$ due to the resolution of $p_{\mathrm{Tt}}$ being better than that of $p_{\mathrm{T}}^{\gamma \gamma}$. Moreover, the shape of the $m_{\gamma \gamma}$ distribution based on the $p_{\mathrm{Tt}}$ categorization can be better described with an exponential shape, which is not the case for the $p_{\mathrm{T}}^{\gamma \gamma}$ categorization. By introducing these $p_{\mathrm{Tt}}$ categories, the expected sensitivity of the analysis is improved by $5-10 \%$ depending on the hypothesized Higgs boson mass. The number of data events in each of the nine categories are shown in Table 2.

Table 2: The number of events found in $4.9 \mathrm{fb}^{-1}$ of data for the nine categories.

| Category | Conversion and $\eta$ | $p_{\mathrm{Tt}}$ cut | Number of data events |
| :---: | :--- | :---: | :---: |
| CP1 | Unconverted central | $p_{\mathrm{Tt}} \leq 40 \mathrm{GeV}$ | 1763 |
| CP2 | Unconverted central | $p_{\mathrm{Tt}}>40 \mathrm{GeV}$ | 235 |
| CP3 | Unconverted rest | $p_{\mathrm{Tt}} \leq 40 \mathrm{GeV}$ | 6234 |
| CP4 | Unconverted rest | $p_{\mathrm{Tt}}>40 \mathrm{GeV}$ | 1006 |
| CP5 | Converted central | $p_{\mathrm{Tt}} \leq 40 \mathrm{GeV}$ | 1318 |
| CP6 | Converted central | $p_{\mathrm{Tt}}>40 \mathrm{GeV}$ | 184 |
| CP7 | Converted rest | $p_{\mathrm{Tt}} \leq 40 \mathrm{GeV}$ | 7311 |
| CP8 | Converted rest | $p_{\mathrm{Tt}}>40 \mathrm{GeV}$ | 1072 |
| CP9 | Converted transition | No cut | 3366 |
| Total |  |  | 22489 |

## 4 Signal and Background Modelling

### 4.1 Signal Model

The Higgs boson signal is studied using MC samples which are then passed through a full detector simulation [15] using Geant 4 [16]. POWHEG [17] is used for gluon fusion and vector boson fusion (VBF) production, interfaced with PYTHIA [18] for showering and hadronization. PYTHIA is used to
generate the associated Higgs boson production modes ( $\mathrm{WH}, \mathrm{ZH}$ and ttH ). Pileup effects are simulated by overlaying each MC event with a variable number of MC inelastic proton-proton collisions [19], taking into account both in-time and out-of-time pileup and the LHC bunch train structure. The predicted signal is normalised using NNLO cross section predictions for the gluon fusion [20-23], VBF [24] and W/Z associated production [25]. The cross section of the teth process is known at NLO [26]. The branching ratio of a Higgs boson decaying to two photons is taken from Refs. [27, 28].

Signal samples are produced in 5 GeV steps of Higgs boson mass between 110 GeV and 150 GeV , and the following corrections are applied to these samples to match, as closely as possible, the conditions found in the data:

- The shower shape variables used in the photon identification are shifted to better resemble the corresponding distributions in the data [10]. The photon identification efficiency was cross-checked in data measurements using electrons in $Z \rightarrow e e$ and photons in $Z \rightarrow \ell \ell(\ell=e, \mu)$. Where simple shifts of the shower shape variables are insufficient to reproduce the data results, additional MC reweighing is used.
- The photon energy is smeared to account for small differences in resolution between data and simulation observed in studies of data $Z \rightarrow e e$ events [7];
- The MC samples are reweighted to reproduce the average number of interactions per bunch crossing observed in the data. The average number is approximately 6 until the end of August and then approximately 12 until the end of the proton-proton collision data-taking in 2011;
- The signal samples were produced with a longitudinal beam spot distribution corresponding to a Gaussian with width $\sigma_{z} \sim 7.5 \mathrm{~cm}$, which is larger than that observed in the data ( $\sigma_{z} \sim 6 \mathrm{~cm}$ ). The MC samples are therefore reweighted to correct for this difference;
- The MC signal yields are rescaled by the data-to-MC ratio for the isolation cut efficiency, as determined from $Z \rightarrow e e$ events. The shift evaluated from the isolation distribution of electrons between data and MC simulation is applied to the isolation variable of photons in the Higgs boson signal MC samples. This gives a $4.4 \%$ reduction in the expected signal yield;
- The MC samples for the gluon fusion process are reweighted to take into account the expected destructive interference between the $g g \rightarrow \gamma \gamma$ continuum background and the $g g \rightarrow H \rightarrow \gamma \gamma$ process [29]. The correction depends on the Higgs mass and the $\eta$ of the photons and is in the range 2-5\%;
- Events from the gluon fusion process are reweighted so that the distribution of the Higgs boson $p_{\mathrm{T}}$ matches that obtained from the HqT calculation [30].

The expected number of signal events for any given value of $m_{H}$ is obtained by a 3rd order polynomial fit to the signal yields extracted from the simulated samples. The number of expected signal events in each category is given in Table 3. The signal shapes as a function of $m_{\gamma \gamma}$ in each category are obtained from a simultaneous fit to the $m_{\gamma \gamma}$ distributions for all the generated Higgs boson mass points using the sum of a Crystal Ball (CB) function [31] and a wide but small amplitude Gaussian component describing the tails. The CB function is defined as:

$$
N \cdot \begin{cases}e^{-t^{2} / 2} & \text { if } t>-\alpha_{\mathrm{CB}}, \\ \left(\frac{n_{\mathrm{CB}}}{\alpha_{\mathrm{CB}}}\right)^{n_{\mathrm{CB}}} \cdot e^{-\alpha_{\mathrm{CB}}^{2} / 2} \cdot\left(\frac{n_{\mathrm{CB}}}{\alpha_{\mathrm{CB}}}-\alpha_{\mathrm{CB}}-t\right)^{-n_{\mathrm{CB}}} & \text { otherwise }\end{cases}
$$

where $t=\left(m_{\gamma \gamma}-m_{H}-\delta_{\mathrm{m}_{\mathrm{H}}}\right) / \sigma_{\mathrm{CB}}, N$ is a normalization parameter, $\delta_{\mathrm{m}_{\mathrm{H}}}$ is a category dependent offset, $\sigma_{\mathrm{CB}}$ represents the diphoton invariant mass resolution, and $n_{\mathrm{CB}}$ and $\alpha_{\mathrm{CB}}$ parametrize the non-Gaussian

Table 3: Expected Higgs boson signal yields after full event selection in $4.9 \mathrm{fb}^{-1}$ integrated over a mass range of $100-160 \mathrm{GeV}$ for various values of $m_{H}$ in each category and the sum.

| $m_{H}[\mathrm{GeV}]$ | 110 | 115 | 120 | 125 | 130 | 135 | 140 | 145 | 150 |

tail. The variables $\delta_{\mathrm{m}_{\mathrm{H}}}, \sigma_{\mathrm{CB}}$ and $\alpha_{\mathrm{CB}}$ of the CB function depend linearly on the Higgs boson mass. The mean and $\sigma$ of the additional Gaussian function are constrained to the value of $m_{H}+\delta_{\mathrm{m}_{\mathrm{H}}}$ and $\kappa \cdot \sigma_{\mathrm{CB}}$. The variables $\delta_{\mathrm{m}_{\mathrm{H}}}, \sigma_{\mathrm{CB}}, \alpha_{\mathrm{CB}}$ and $\kappa$ and a fraction of the component of the CB function are determined with the simultaneous fit fixing $n_{\mathrm{CB}}$ to be 10 . The core component of the mass resolution, $\sigma_{\mathrm{CB}}$, ranges from 1.4 GeV in the "Unconverted Central" categories to 2.3 GeV in the "Converted Transition" category over the full mass range that is studied. The effect of the pileup on the mass resolution is negligible.

The result of the simultaneous fit for events selected with the inclusive analysis (i.e. without categorization) for a mass hypothesis of 120 GeV is displayed in Figure 4. Table 4 summarizes the mass resolution, $\sigma_{\mathrm{CB}}$ and full width half-maximum ( FWHM ), the expected number of signal events, the estimated number of background events in each category as determined from the data (Section 4.2), and their ratio in the mass window of $\pm 1.4 \sigma_{\mathrm{CB}}$, for a Higgs signal of $m_{H}=120 \mathrm{GeV}$.

### 4.2 Background Model

The background is estimated from the data by fitting the diphoton mass spectrum in the whole range of $100-160 \mathrm{GeV}$ with a single exponential function. Such a function was found to describe all the categories very well, as obtained from studies using large samples of diphoton events produced by the RESBOS [32] and DIPHOX [33] MC generators. Figures 5 and 6 show the invariant mass spectra reconstructed in data and the results of the unbinned maximum likelihood fit under the background-only hypothesis for the nine categories.

The systematic uncertainty on the background modelling is assigned by estimating, for each category, the potential difference between the true background shape and the single exponential function which could fake a signal-like signature. This is obtained from MC by calculating the difference between the mass distributions of the events generated with RESBOS and DIPHOX and the result of the exponential fit to these distributions. The maximum difference integrated over a window of 4 GeV normalised to the total event count in each category is assigned as uncertainty (Table 5). Other functional forms, including $2^{\text {nd }}$ order Bernstein polynomials and double exponential functions, were fitted to the data and compared to the exponential fit. The uncertainties arising from these comparisons were found to be of similar size to the MC-based estimate.

Figure 4: Reconstructed inclusive invariant mass distribution for a simulated signal of $m_{H}=120 \mathrm{GeV}$. The result of the simultaneous fit to all Higgs boson mass points is superimposed. The core component of the mass resolution, $\sigma_{\mathrm{CB}}$, is 1.7 GeV and the FWHM of the distribution is 4.0 GeV .

Table 4: The mass resolution of Higgs signal events ( $\sigma_{\mathrm{CB}}$ and FWHM), the expected number of signal events ( $N_{\mathrm{sig}}$ ), the estimated number of background events ( $N_{\mathrm{BG}}$ ) from data, and their ratio $\left(N_{\text {sig }} / N_{\mathrm{BG}}\right)$ in the mass window of $\pm 1.4 \sigma_{\mathrm{CB}}$ for $m_{H}=120 \mathrm{GeV}$ corresponding to an integrated luminosity of $4.9 \mathrm{fb}^{-1}$.

| Category | $\sigma_{\mathrm{CB}}[\mathrm{GeV}]$ | FWHM [GeV] | $N_{\text {sig }}$ | $N_{\text {BG }}$ | $N_{\text {sig }} / N_{\text {BG }}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |

## 5 Systematic Uncertainties

Systematic uncertainties affecting the extraction of a possible signal from the diphoton invariant mass distribution related to the modelling of the signal itself can be classified into three types: uncertainties

Figure 5: Diphoton invariant mass distributions for the data (points with error bars) for the four "unconverted" categories (CP1-CP4). For each plot the line shows the result of the exponential fit.
on the predicted yield, uncertainties on the signal invariant mass resolution and uncertainties on event migration between categories.

The uncertainties on the predicted signal yield are the following:

- $\mathrm{A} \pm 11 \%$ uncertainty from the photon reconstruction and identification. This is estimated by comparing the MC-based efficiencies with those extrapolated from measurement of electrons from $W / Z$-boson decays, and with the direct measurements of photons in $Z \rightarrow \ell \ell \gamma(\ell=e, \mu)$ decays which only cover the $E_{\mathrm{T}}$ range $25-60 \mathrm{GeV}$. The impact of possible additional material in front of the calorimeter, as estimated with MC simulations, is also included;
- A $\pm 4 \%$ uncertainty from the effect of the pileup on the photon reconstruction and identification efficiency. This is estimated by looking at the variation of the tight photon identification efficiency as a function of the average number of interactions per bunch crossing;
- The effect of the photon energy scale uncertainty $(\approx 0.5 \%)$ was found be to small $(0.3 \%)$, and is therefore neglected;
- A $\pm 5 \%$ uncertainty on the isolation cut efficiency. This is estimated from the difference between the isolation cut efficiency in data and MC simulation using $Z \rightarrow e e$ events;
- $\mathrm{A} \pm 1 \%$ uncertainty on the trigger efficiency. This comes from the uncertainty in the measurement of the trigger efficiency for diphoton candidates using control triggers, and from possible differ-

Figure 6: Diphoton invariant mass distributions for the data (points with error bars) for the five "converted" categories (CP5-CP9). For each plot the line shows the result of the exponential fit.
ences, evaluated with MC samples, between the trigger efficiency for photons from Higgs boson decays and for photons from all diphoton candidates;

- $\mathrm{A}+15 \% /-11 \%$ uncertainty on the signal cross section [27]. This is evaluated by varying the renormalization and factorization scales and using different parton distributions (PDF) [34] in the gluon fusion process, which has the largest uncertainty compared to other processes and dominates in all the categories ( $95 \%$ for low $p_{\mathrm{Tt}}$ and $80 \%$ for low $p_{\mathrm{Tt}}$ ). The same uncertainty is applied to signal samples produced with other processes;
- $\mathrm{A} \pm 1 \%$ uncertainty on the signal acceptance from the modelling of the Higgs boson $p_{\mathrm{T}}$, which is estimated by comparing the predictions of the HqT [30] and RESBOS [35] programs;
- A $\pm 3.9 \%$ overall uncertainty on the total integrated luminosity in the full 2011 data set, as extrapolated from Ref. [36].

The uncertainties on the mass resolution arise from the following:

- A $\pm 12 \%$ uncertainty from the calorimeter energy resolution. This results from the uncertainty on the sampling term, which is estimated to be $\pm 10 \%$, and from the uncertainty on the constant term, which is estimated to be $\left(1.2_{-0.6}^{+0.5}\right) \%$ for the barrel and $(1.8 \pm 0.6) \%$ for the endcap calorimeter using $Z \rightarrow e e$ events [9];
- A $\pm 6 \%$ uncertainty arising from the extrapolation of the electron energy calibration to that for photons. This extrapolation, obtained from MC studies, is affected by the imperfect knowledge of the material in front of the active part of the calorimeter. The effect of this imperfect knowledge on the mass resolution is evaluated using simulations with a different amount of material in front of the calorimeter.
- A $\pm 3 \%$ uncertainty from the effect of the pileup on the energy resolution. Pileup fluctuations contributing to the cluster energy measurement were checked using reconstructed clusters in randomlytriggered bunch crossings, selected in proportion to the instantaneous luminosity in the data [7];
- $\mathrm{A} \pm 1 \%$ uncertainty from the photon angle measurement on the mass resolution. This was studied in $Z \rightarrow e e$ events comparing track-based with calorimeter-based direction measurements [7].

The uncertainties on the event migration between categories arise from the following:

- $\mathrm{A} \pm 8 \%$ migration of events from the high $p_{\mathrm{Tt}}$ categories to the low $p_{\mathrm{Tt}}$ categories. This is estimated from gluon fusion Higgs boson signal MC events by varying the renormalization, factorization and resummation scales and PDF choices for the modelling of the $p_{\mathrm{T}}^{\gamma \gamma}$ spectrum in the Hq T program. The same uncertainty is applied to signal samples produced with other processes. The effect of photon energy scale uncertainty on this migration is small $(0.5 \%)$ and is neglected;
- $\mathrm{A} \pm 4.5 \%$ migration of events from the unconverted categories to the converted categories. The impact of pileup and additional material in front of the calorimeter is estimated from MC samples with different pileup and material configurations.

The systematic uncertainties on the expected signal are summarized in Table 6. Systematic uncertainties on the event yield and the mass resolution are taken as fully correlated between different categories, while those on the event migration are anti-correlated between the high and low $p_{\mathrm{Tt}}$ categories and between the unconverted and converted categories. Systematic uncertainties on the background modelling yield between $\pm 0.1$ and $\pm 5.6$ events depending on the category (Table 5). These uncertainties are treated as uncorrelated between categories except for those that share the same $\eta$ and $p_{\mathrm{Tt}}$ classification but different conversion status.

## 6 Results

The statistical interpretation of the data follows the procedure described in Ref. [5] which adopts a modified frequentist approach $\left(C L_{S}\right)$ [37] for setting the limit and a frequentist approach to calculate the $p_{0}$-value. The combined likelihood function is constructed from the likelihood functions of the nine categories, and the systematic uncertainties are incorporated by introducing 31 nuisance parameters with

Table 6: Summary of systematic uncertainties on the expected signal.

| Type and source | Uncertainty |
| :--- | :---: |
| Event yield |  |
| Photon reconstruction and identification | $\pm 11 \%$ |
| Effect of pileup on photon identification | $\pm 4 \%$ |
| Isolation cut efficiency | $\pm 5 \%$ |
| Trigger efficiency | $\pm 1 \%$ |
| Higgs boson cross section | $+15 \% /-11 \%$ |
| Higgs boson $p_{\mathrm{T}}$ modeling | $\pm 1 \%$ |
| Luminosity | $\pm 3.9 \%$ |
| Mass resolution |  |
| Calorimeter energy resolution | $\pm 12 \%$ |
| Photon energy calibration | $\pm 6 \%$ |
| Effect of pileup on energy resolution | $\pm 3 \%$ |
| Photon angular resolution | $\pm 1 \%$ |
| Migration |  |

Gaussian constraints. Asymptotic formulae [38] were used to derive the limit and $p_{0}$-values, and pseudoexperiments were generated to confirm the validity of this procedure.

The $p_{0}$-value, used to quantify the probability of seeing an excess at least as large as this in the background-only hypothesis, is evaluated for Higgs boson mass hypotheses between 110 GeV and 150 GeV in steps of 1 GeV . The expected and observed $p_{0}$-values are shown in Figure 7. The expected $p_{0}$-value is evaluated assuming a SM Higgs boson signal plus background for a given hypothesized Higgs boson mass. The minimal observed $p_{0}$-value is $0.27 \%$ and is found for a mass hypothesis of $m_{H}=126 \mathrm{GeV}$. This $p_{0}$-value corresponds to 2.8 standard deviations. The probability of such an excess appearing anywhere in the mass range investigated due to a background fluctuation, accounting for the look-elsewhere effect, is estimated to be approximately $7 \%$ and it reduces the observed significance to 1.5 standard deviations. This was determined using the prescription described in Ref. [39]. As cross checks, the observed $p_{0}$-values were reevaluated using alternate background models, including the $2^{\text {nd }}$ order Bernstein polynomials. Also, the uncertainties on the background modelling due to the use of a single exponential (Table 5) were set to zero or doubled. Furthermore, a photon energy scale uncertainty of $\approx 0.5 \%$ was introduced into the likelihood fits. All of these checks gave observed $p_{0}$-values which are similar to the quoted result. The largest change in the observed significance at $m_{H}=126 \mathrm{GeV}$ was 0.16 standard deviations.

The $95 \%$ confidence level (CL) limits on the ratio of the inclusive production cross section of a SMlike Higgs boson relative to the SM cross section are also derived as shown in Figure 8. The expected limits vary between 1.6 and 1.8 times the predicted SM cross section in the mass range $115-130 \mathrm{GeV}$, and between 1.6 and 2.9 times the SM cross section over the full mass range that is studied. The observed limits are set between 0.9 and 4.0 times the SM cross section over the full mass range. A SM Higgs boson in the mass ranges $114-115 \mathrm{GeV}$ and $135-136 \mathrm{GeV}$ is excluded. The numerical values of the limits and $p_{0}$-values in steps of 1 GeV are listed in Table 7.

Figure 7: The observed and expected $p_{0}$-value as a function of the hypothesized Higgs boson mass without taking the look-elsewhere effect into account. The dotted-dashed lines indicate the corresponding significance.

## 7 Conclusions

A search for the SM Higgs boson in the diphoton decay channel has been performed using data corresponding to an integrated luminosity of $4.9 \mathrm{fb}^{-1}$ recorded by the ATLAS experiment in 2011. Over the diphoton mass range $110-150 \mathrm{GeV}$ the maximum deviation from the background-only expectation is observed at 126 GeV with a local significance of 2.8 standard deviations. Taking the look-elsewhere effect into account, the significance is 1.5 standard deviations. The expected cross section exclusion at $95 \%$ confidence level varies between 1.6 and 1.8 times the SM cross section in the mass range $115-130 \mathrm{GeV}$, and between 1.6 and 2.9 over the full mass range that is studied. The observed exclusions are set between 0.9 and 4.0 times the SM cross section over the full mass range. A SM Higgs boson is excluded at $95 \%$ CL in the mass ranges of $114-115 \mathrm{GeV}$ and $135-136 \mathrm{GeV}$.

Figure 8: The observed and expected $95 \%$ confidence level limits, normalised to the SM Higgs boson cross sections, as a function of the hypothesized Higgs boson mass.

Table 7: The expected and observed limits, normalised to the Higgs boson cross section as predicted by the SM, and the observed and expected (for a SM Higgs boson) $p_{0}$-values.

## Appendix: Auxiliary public plots

Figure 9: The reconstructed diphoton mass in simulated $H \rightarrow \gamma \gamma$ events using the fit with the sum of a Crystal Ball function plus a Gaussian for the inclusive event selection. In the left plot, the method explained in Section 2.1 ("Calo/Conv pointing") is used to determine the vertex position. Four different results are shown corresponding to four different pile-up conditions. The number of average interactions per bunch crossing is denoted by $\mu$. On the right, the fit results using the vertex determined with "Calo/Conv pointing" method is compared to two other methods to deduce the angle between the photons. The truth vertex gives the best possible result by using MC truth information to deduce the correct primary vertex. In the $\Sigma p_{T}^{2}$ method the primary vertex is chosen as the one with the largest sum of the $p_{T}^{2}$ of the tracks associated to it. The improvement of the mass resolution by using the "Calo/Conv pointing" method instead of the $\Sigma p_{T}^{2}$ method amounts to $5-20 \%$, depending on the pile-up conditions.

Figure 10: Background components in the inclusive analysis extracted by the double two-dimensional sideband method for two data taking periods. The first period taken with LHC beam optics parameter $\beta^{*}=1.5 \mathrm{~m}$ corresponds to an integrated luminosity of $2.1 \mathrm{fb}^{-1}$ and on average 6 interactions per bunch crossing. The later period taken with $\beta^{*}=1.0 \mathrm{~m}$ corresponds to $2.8 \mathrm{fb}^{-1}$ and 12 interactions per bunch crossing on average. The statistical uncertainty is negligible small comparing to the systematic uncertainty.

Figure 11: Comparison of the number of background events for each component predicted using theory and MC simulation to the results of the data-driven data decomposition using the double two-dimensional sideband method. This is an update of the results in Ref. [1] using the full 2011 data sample.

Figure 12: The observed and expected local $p_{0}$-value as a function of $m_{H}$ for three different background models without taking the look-elsewhere effect into account. The black solid line is the result described in detail in this note, using single exponential functions in all categories. In the Hybrid model the high $p_{\mathrm{Tt}}$ categories are fitted with the $2^{\text {nd }}$ order Bernstein polynomials, the other categories with the single exponential. In the model Bernstein all categories are fitted with the Bernstein function. The $p_{0}$-values near the minima at 126 GeV are very similar in all cases: $p_{0}=0.38 \%$ using the Hybrid model, and $p_{0}=0.25 \%$ using the Bernestein function.

Figure 13: Event display of a candidate diphoton event where both photon candidates are unconverted. The event number is 86694500 and it was recorded during run 191426. The leading photon has $E_{\mathrm{T}}=64.2 \mathrm{GeV}$ and $\eta=-0.34$. The subleading photon has $E_{\mathrm{T}}=61.4 \mathrm{GeV}$ and $\eta=-0.61$. The measured diphoton mass is 126.6 GeV . The $p_{\mathrm{T}}$ and $p_{\mathrm{Tt}}$ of the diphoton are 6.1 GeV and 5.4 GeV , respectively. Only reconstructed tracks with $p_{\mathrm{T}}>1 \mathrm{GeV}$, hits in the pixel and SCT layers and TRT hits with a high threshold are shown.

Figure 14: Event display of a candidate diphoton event where the leading (subleading) photon candidate is unconverted (converted). The event number is 19448322 and it was recorded during run 191190. The leading photon has $E_{\mathrm{T}}=66.8 \mathrm{GeV}$ and $\eta=-0.27$. The subleading photon has $E_{\mathrm{T}}=56.9 \mathrm{GeV}$ and $\eta=-$ 0.67. The measured diphoton mass is 125.8 GeV . The $p_{\mathrm{T}}$ and $p_{\mathrm{Tt}}$ of the diphoton are 10.4 GeV and 3.1 GeV , respectively. The conversion radius of the subleading photon is measured to be 8.1 cm . Only reconstructed tracks with $p_{\mathrm{T}}>1 \mathrm{GeV}$, hits in the pixel and SCT layers and TRT hits with a high threshold are shown.

Figure 15: Close-up view in the transverse plane of the converted photon candidate shown in Figure 14 (run number $=191190$, event number $=19448322$ ). Only reconstructed tracks with $p_{\mathrm{T}}>2 \mathrm{GeV}$ and $|\eta|<1.4$ are shown, and only the hits in the pixel, SCT and TRT layers with $-1<|\eta|<0$ are shown. Starting from the primary vertex (shown as a large magenta dot on the left), the photon conversion vertex (brown dot) can be seen at a radius of 8.1 cm , followed by the pixel hits (magenta dots), SCT clusters (green segments) and TRT hits (blue dots for normal $\mathrm{d} E / \mathrm{d} x$ hits and red dots for hits above the high threshold required for transition radiation). The electron track (blue line) has $p_{\mathrm{T}}=56.1 \mathrm{GeV}$ and matches well with the electromagnetic cluster (shown in yellow at the outer radius). The positron track has $p_{\mathrm{T}}=4.0 \mathrm{GeV}$ and a fraction of its energy actually lies outside the main cluster.

Figure 16: Close-up view in the transverse plane of the longitudinal shower profile in the barrel electromagnetic calorimeter of the converted photon candidate shown in Figure 14 (run number $=191190$, event number $=19448322$ ). The layers of the EM calorimeter are shown as green boxes with sizes representing their real dimensions and with heights proportional to the energy deposited (normalised differently for each layer for viewing purposes). The two electrons from the photon conversions encounter first the presampler layer (which provides an estimate of the energy lost by bremsstrahlung in front of the active calorimeter), then the strip layer, which is fine-grained in $\eta$ and provides good $\gamma / \pi^{0}$ rejection, and finally the second layer where most of the energy is deposited. The conversion is quite asymmetric and the showers initiated by the two electrons appear in different strip-layer modules (in $\phi$ ) but line up very well with each other in $\eta$, as expected for such an electron pair.

## ATLAS NOTE

ATLAS-CONF-2011-162

# Search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ with $4.8 \mathbf{f b}^{-1}$ of pp collisions at $\sqrt{s}=7 \mathrm{TeV}$ 

The ATLAS collaboration

#### Abstract

A search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z^{(*)} \rightarrow$ $\ell^{+} \ell^{-} \ell^{\prime}+\ell^{\prime}-$, where $\ell, \ell^{\prime}=e, \mu$, is presented. Proton-proton collision data at $\sqrt{s}=7 \mathrm{TeV}$ recorded with the ATLAS detector and corresponding to an average integrated luminosity of $4.8 \mathrm{fb}^{-1}$ are compared to the Standard Model background expectations. Upper limits on the production cross section of a Standard Model Higgs boson with a mass between 110 GeV and 600 GeV are derived. The Standard Model Higgs boson is excluded at $95 \%$ confidence level in the mass ranges $135 \mathrm{GeV}-156 \mathrm{GeV}, 181 \mathrm{GeV}-234 \mathrm{GeV}$ and $255 \mathrm{GeV}-415 \mathrm{GeV}$. The largest deviations from the background expectation are observed for $m_{H}=125 \mathrm{GeV}$ with a $p_{0}$-value of $1.8 \%, m_{H}=244 \mathrm{GeV}$ with a $p_{0}$-value of $1.1 \%$ and $m_{H}=500 \mathrm{GeV}$ with a $p_{0}$-value of $1.4 \%$. Once the look-elsewhere effect is considered, none of these excesses is significant by itself.

## 1 Introduction

The search for the Standard Model (SM) Higgs boson [1-3] is a major goal of the Large Hadron Collider (LHC) programme. Direct searches at the CERN LEP $e^{+} e^{-}$collider excluded at $95 \%$ confidence level (CL) the production of a SM Higgs with $m_{H}<114.4 \mathrm{GeV}$ [4]. The searches at the Fermilab Tevatron $p \bar{p}$ collider have excluded at $95 \%$ CL the region $156 \mathrm{GeV}<m_{H}<177 \mathrm{GeV}$ [5]. At the LHC, the latest results of the ATLAS SM Higgs searches [6] based on data collected during the early part of the 2011 LHC run exclude the Higgs boson mass ( $m_{H}$ ) ranges $146-230 \mathrm{GeV}, 256-282 \mathrm{GeV}$ and $296-459 \mathrm{GeV}$ at $95 \%$ CL, while for CMS the corresponding excluded ranges are $145-216 \mathrm{GeV}, 226-288 \mathrm{GeV}$ and $310-400 \mathrm{GeV}$ [7]. A preliminary combination of $1.0-2.3 \mathrm{fb}^{-1}$ of LHC data per experiment exclude the SM Higgs in the region $141 \mathrm{GeV}<m_{H}<476 \mathrm{GeV}$ at $95 \%$ CL [8].

In ATLAS several final states are used to search for the SM Higgs boson [9-17]. The search for the SM Higgs through the decay $H \rightarrow \mathrm{ZZ}^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{\prime}+\ell^{\prime-}$, where $\ell, \ell^{\prime}=e, \mu$ provides good sensitivity in a wide mass range. The results of the previous search in this channel, with $2.1 \mathrm{fb}^{-1}$ [10], showed exclusion in three mass regions between 191 GeV and 224 GeV . This note presents an update of the ATLAS search for a SM Higgs boson in this channel for the mass range from 110 GeV to $600 \mathrm{GeV}^{1}$. Three distinct final states, $\mu \mu \mu \mu(4 \mu), e e \mu \mu(2 e 2 \mu)$, and eeee ( $4 e$ ), are selected. The largest background to this search comes from continuum $Z Z^{(*)}$ production. For $m_{H}<180 \mathrm{GeV}$, contributions from $Z+$ jets and $t \bar{t}$ processes, where the additional charged leptons arise either from decays of hadrons with heavy ( $b$ and $c$-quark) flavour content or from light-flavour-jets misidentified as leptons, are important. The $p p$ collision data were recorded with the ATLAS detector at the LHC at $\sqrt{s}=7 \mathrm{TeV}$ and correspond to an average integrated luminosity of $4.8 \mathrm{fb}^{-1}$ [18], more than twice that of Ref. [10]. With respect to Ref. [10] the electron identification has been refined to improve efficiency. The electron tracks have been refitted using the Gaussian Sum Filter [19,20] which corrects for energy losses due to bremsstrahlung, offering more accurate track parameter measurements. Moreover, the muon momentum resolution has improved due to improved alignment of the inner detector and muon spectrometer.

## 2 The ATLAS Detector

The ATLAS detector [21] is a multi-purpose particle physics apparatus with forward-backward symmetric cylindrical geometry ${ }^{2}$. The inner tracking detector (ID) consists of a silicon pixel detector, a silicon microstrip detector, and a transition radiation tracker. The ID is surrounded by a thin superconducting solenoid providing a 2 T magnetic field. A high-granularity lead-liquid argon (LAr) sampling calorimeter measures the energy and the position of electromagnetic showers. An iron-scintillator tile calorimeter provides hadronic coverage in the central rapidity range. The end-cap and forward rapidity regions are instrumented with LAr calorimetry for both electromagnetic and hadronic measurements. The muon spectrometer (MS) surrounds the calorimeters and consists of three large superconducting toroids, each with eight coils, a system of precision tracking chambers, and detectors for triggering. A three-level trigger system selects events to be recorded for offline analysis.

[^67]
## 3 Data and Simulation Samples

The accumulated data are subjected to quality requirements ensuring that the relevant detector components were operating normally. The resulting average integrated luminosity of $4.8 \mathrm{fb}^{-1}$ corresponds to $4.81 \mathrm{fb}^{-1}, 4.81 \mathrm{fb}^{-1}$ and $4.91 \mathrm{fb}^{-1}$ for the $4 \mu, 2 e 2 \mu$ and $4 e$ final states, respectively.

The $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ signal is modelled using the POWHEG Monte Carlo (MC) event generator [22, 23], which calculates separately the gluon and vector-boson fusion production mechanisms with matrix elements up to next-to-leading order (NLO). The Higgs boson transverse momentum, $p_{\mathrm{T}}$, spectrum in the gluon fusion process is reweighted to the calculation of Ref. [24], providing QCD corrections up to next-to-leading order and QCD soft-gluon resummations up to next-to-next-to-leading log (NNLL). POWHEG is interfaced to PYTHIA [25] for showering and hadronization, which in turn is interfaced to PHOTOS [26] for QED radiative corrections in the final state and to TAUOLA [27, 28] for the simulation of $\tau$ decays. For the Higgs boson associated production with a $W$ or a $Z$ boson, PYtHIA is used.

The cross sections for Higgs boson production, the corresponding branching fractions, as well as their uncertainties [29], are derived to next-to-next-to-leading order (NNLO) in QCD for the gluon fusion [30-35], vector-boson fusion [36] and the associated production with a $W$ or $Z$ boson [37] processes. In addition, QCD soft-gluon resummations up to NNLL are available for the gluon fusion process [38], while the NLO electroweak (EW) corrections are applied to the gluon fusion [39, 40], the vector-boson fusion [41, 42] and the associated production with a $W$ or $Z$ boson [43] processes. These cross section calculations do not take into account the width of the Higgs boson, which is implemented through a Breit-Wigner line shape applied at the event generator level. Recent studies [44-46] have indicated that effects related to off-shell Higgs boson production and interference with other SM processes may become sizeable at the highest masses $\left(m_{H}>400 \mathrm{GeV}\right)$ considered in this search. In the absence of a full calculation, a conservative estimate of the possible size of such effects was included as a signal normalization systematic uncertainty following a parameterization as a function of $m_{H}: 150 \% \times\left(m_{H}[\mathrm{TeV}]\right)^{3}$, for $m_{H} \geq 300 \mathrm{GeV}$ [47]. The Higgs boson decay branching ratio to the four-lepton final state is predicted by PROPHECY4F [48,49], which includes the complete NLO QCD+EW corrections, interference effects between identical final state fermions and leading two-loop heavy Higgs boson corrections to the fourfermion width. Table 1 gives the production cross sections and branching ratios for $H \rightarrow 4 \ell$ for several Higgs boson masses.

Table 1: Higgs boson production cross sections for gluon fusion, vector-boson fusion and associated production with a $W$ or $Z$ boson in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$. The quoted uncertainties correspond to the total theoretical systematic uncertainty. The branching ratio of $H \rightarrow 4 \ell$, with $\ell=e, \mu$, is reported in the last column.

The $Z Z^{(*)}$ continuum background is generated using PYTHIA, taking into account $Z-\gamma$ interference. For the inclusive total cross section and the shape of the $m_{Z Z(*)}$ spectrum, the MCFM [50,51] prediction is used, which includes both quark-antiquark annihilation at QCD NLO and gluon fusion. The inclusive
$Z$ boson production, $Z+$ jets, is modelled using ALPGEN [52] and is divided into $Z+$ light-flavour-jets, which includes also $Z c \bar{c}$ at the massless $c$-quark approximation and $Z b \bar{b}$ from parton showers, and $Z b \bar{b}$ using massive matrix elements. The overlaps between the two samples are removed. Specifically, $b \bar{b}$ pairs with separation $\Delta R=\sqrt{(\Delta \phi)^{2}+(\Delta \eta)^{2}} \geq 0.4$ between the $b$-quarks are taken from the matrixelement calculation, whereas for $\Delta R<0.4$ the parton-shower $b \bar{b}$ pairs are taken. PYTHIA is also used as a cross-check of the ALPGEN results. In this search the $Z+$ jets background is normalized using data control samples, but for comparisons the QCD NNLO FEWZ [53,54] and the MCFM [50,51] cross section calculations are used for the inclusive $Z$ boson and $Z b \bar{b}$ production, respectively. The $t \bar{t}$ background is modelled using MC@NLO [55] and is normalized to the approximate NNLO cross section calculated using HATHOR [56]. Both ALPGEN and MC@NLO are interfaced to HERWIG [57] for parton shower hadronization and to JIMMY [58] for the underlying event simulations.

All generated events undergo a full detector simulation performed using GEANT4 [59, 60]. Additional $p p$ interactions in the same bunch crossing (pile-up) are included in the simulation. The MC samples are reweighted to reproduce the observed distribution of the mean number of interactions per bunch crossing in the data.

## 4 Physics Object Identification and Event Selection

The data considered in this analysis were selected using single-lepton triggers. The trigger threshold on the transverse energy, $E_{\mathrm{T}}$, of electrons was $20-22 \mathrm{GeV}$ depending on the LHC instantaneous luminosity, while for muons the $p_{\mathrm{T}}$ threshold was 18 GeV . Both triggers are more than $99.5 \%$ efficient for events passing the offline selection described below.

Electron candidates consist of clusters of energy deposited in the electromagnetic calorimeter associated to ID tracks. The electron candidates must satisfy a set of identification criteria [61], which require the shower profiles to be consistent with those expected for electromagnetic showers and a well reconstructed ID track pointing to the corresponding cluster. The electron transverse momentum is computed from the cluster energy and the track direction at the interaction point.

Muon candidates are reconstructed by matching ID tracks with either full or partial tracks in the MS $[62,63]$. For the former case, the two independent momentum measurements are combined, whereas for the latter case the momentum is measured using the ID information only, with the MS providing muon identification. To reject cosmic rays, muon tracks are required to have a transverse impact parameter with respect to the primary vertex, defined as the reconstructed vertex with the highest $\sum p_{\mathrm{T}}^{2}$ of associated tracks among the reconstructed vertices with at least three associated tracks, of less than 1 mm .

Leptons from Higgs boson decays are expected to be isolated and to originate from the primary vertex. The longitudinal impact parameter of the leptons is required to be within 10 mm from the primary vertex. Track and calorimeter isolation requirements, together with requirements on the transverse impact parameter significance of the lepton, are applied to further reduce the $Z+$ jets and $t \bar{t}$ background contributions. The transverse impact parameter significance of the lepton is defined as its impact parameter in the transverse plane with respect to the primary vertex, divided by the corresponding uncertainty.

The sum of the $p_{\mathrm{T}}$ of tracks within $\Delta R<0.2$ of the lepton divided by the lepton $p_{\mathrm{T}}$ is required to be less than 0.15 , while the sum of the $E_{\mathrm{T}}$ of the calorimeter cells within $\Delta R<0.2$ around the lepton divided by the lepton $p_{\mathrm{T}}$ is required to be less than 0.3 . The track of the lepton candidate and the energies of cells associated to it are excluded from the calculation of the isolation energy. For the calorimeter isolation of electrons, in particular, the transverse energies in the $5 \times 7$ electromagnetic calorimeter cells around the cluster barycenter are excluded [61]. To reduce the impact of pile-up, the tracks included in the $p_{\mathrm{T}}$ sum for track isolation must be associated with the primary vertex, and the transverse energy included in the $E_{\mathrm{T}}$ sum for calorimeter isolation is corrected by subtracting an average offset as a function of the number
of reconstructed vertices in the event. In events with four-lepton invariant mass below 190 GeV , the transverse impact parameter significance for the two lowest $p_{\mathrm{T}}$ leptons in the quadruplet is required to be less than 3.5 and 6 for muons and electrons respectively. The selection efficiency of the isolation and impact parameter requirements has been studied using data both for isolated leptons, with $Z \rightarrow \ell \ell$ decays, and non-isolated leptons from semi-leptonic $b$ and $c$-quark decays in a heavy-flavour enriched dijet sample. Good agreement is observed between data and simulation.

Higgs boson candidates are searched for by selecting two same-flavour, opposite-sign isolated lepton pairs in an event. Each lepton must satisfy $p_{\mathrm{T}}>7 \mathrm{GeV}$ and be measured in the pseudorapidity range $|\eta|<2.47$ for electrons and $|\eta|<2.7$ for muons. At least two leptons in the quadruplet must have $p_{\mathrm{T}}>20 \mathrm{GeV}$. The leptons are required to be well-separated from each other with $\Delta R>0.1$. The invariant mass of the lepton pair closest to the nominal $Z$ boson mass $\left(m_{Z}\right)$ is denoted $m_{12}$ and it is required that $\left|m_{Z}-m_{12}\right|<15 \mathrm{GeV}$. The invariant mass of the remaining, lepton pair, $m_{34}$, is required to be lower than 115 GeV and greater than a threshold depending on the reconstructed four-lepton mass, $m_{4 \ell}$, as summarized in Table 2. The final discriminating variable is $m_{4 \ell}$, where the Higgs boson production would appear as a clustering of events. In Fig. 1 the invariant mass distributions for the $4 \mu$ and $4 e$ channels are presented for a simulated signal sample with $m_{H}=130 \mathrm{GeV}$. The width of the reconstructed Higgs boson mass distribution is dominated by experimental resolution at low $m_{H}$ values, while at high $m_{H}$ the reconstructed width is dominated by the natural width of the Higgs boson with a full-width at half-maximum of approximately 35 GeV at $m_{H}=400 \mathrm{GeV}$.

Table 2: Thresholds applied to $m_{34}$ for reference values of $m_{4 \ell}$ (see text). For other $m_{4 \ell}$ values, the selection requirement is obtained via linear interpolation.

| $m_{4 \ell}(\mathrm{GeV})$ | $\leq 120$ | 130 | 140 | 150 | 160 | 165 | 180 | 190 | $\geq 200$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| threshold $(\mathrm{GeV})$ | 15 | 20 | 25 | 30 | 30 | 35 | 40 | 50 | 60 |

## 5 Background Estimation

The composition of the background is verified in a control region defined by the analysis selection, but without applying the charge, isolation and impact parameter requirements on the second lepton pair. The $m_{34}$ distributions in this control sample are presented in Fig. 2. For large values of $m_{34}$ the $Z Z$ background dominates, while for low values of $m_{34}$ the dominant background source depends on the flavour of the second lepton pair. In final states with a ee second pair, the $Z+$ light-flavour-jets background is dominant, while the $Z b \bar{b}$ production dominates the final states with a $\mu \mu$ second pair. The normalization of the $t \bar{t}$ background, which also contributes substantially in the latter final state, is verified using a control region with opposite-sign electron-muon pairs consistent with the $Z$ boson mass and two additional same-flavour leptons. The $Z Z^{(*)}$ background is normalized using MC, while the $Z+$ jets is normalized using data. The observed background rate, which is found to be in good agreement with expectation, is extrapolated to the signal region by means of the MC simulation.

## 6 Systematic Uncertainties

Uncertainties on lepton reconstruction and identification efficiency, and on the momentum resolution and momentum scale are determined using samples of $W, Z$ and $J / \psi$ decays. The muon efficiency uncertainty results in an acceptance uncertainty on the signal and the irreducible background which is uniform over the mass range of interest and amounts to $0.22 \%(0.16 \%)$ for the $4 \mu(2 e 2 \mu)$ channel. The

Figure 1: Invariant mass distributions for simulated (a) $H \rightarrow Z Z^{(*)} \rightarrow 4 \mu$ (b) $H \rightarrow Z Z^{(*)} \rightarrow 4 e$ for $m_{H}=$ 130 GeV . The fraction of events outside the $\pm 2 \sigma$ region is found to be $15 \%$ for $4 \mu$ and $18 \%$ for $4 e$ for $m_{H}=130 \mathrm{GeV}$.

Figure 2: Invariant mass distribution of the second lepton pair:(a) $\mu \mu$ and (b) $e e$. The kinematic selections of the analysis have been applied. Isolation requirements have been applied on the first lepton pair. No charge requirements were applied to the second lepton pair.
uncertainty on the electron efficiency results in an acceptance uncertainty of $2.3 \%$ ( $1.6 \%$ ) for the $4 e$ $(2 e 2 \mu)$ channel at $m_{4 \ell}=600 \mathrm{GeV}$ and reaching $8.0 \%(4.1 \%)$ at $m_{4 \ell}=110 \mathrm{GeV}$. The effect of the muon momentum resolution and scale uncertainty is found to be small. For electrons the energy resolution uncertainty is relatively small, while the uncertainty on $m_{4 \ell}$ due to the electron energy scale uncertainty
is estimated to be $0.6 \%(0.3 \%)$ for the $4 e(2 e 2 \mu)$ channel. Fitting energy scales to the data can cause fluctuations to align, so to be conservative the energy scale uncertainty is neglected when combining results in the current analysis.

A conservative theoretical uncertainty of $15 \%$ is assigned to the $Z^{(*)}$ background contribution [64]. The $Z+$ light-flavour-jets and $Z b \bar{b}$ backgrounds are evaluated using data. A systematic uncertainty of $45 \%$ and $40 \%$, respectively, is assigned on their normalization to account for the statistical uncertainty in the control sample and the MC-based extrapolation to the signal region. The theoretical uncertainties on the $t \bar{t}$ cross-section, approximately $10 \%$ [56], are included. The additional uncertainty in the $t \bar{t}$ selection efficiency, estimated to be $10 \%$, is negligible in comparison with the errors on the larger backgrounds.

The theoretical uncertainties on the Higgs boson production cross section are 15-20\% for the gluon fusion process, $3-9 \%$ for the vector-boson fusion and $3-4 \%$ for the associated production $(\mathrm{WH} / \mathrm{ZH})$ process [29], depending on the Higgs boson mass. They include uncertainties on the QCD scale and on the parton distribution functions [65-68]. An additional $2 \%$ uncertainty is added to the signal selection efficiency due to the modelling of the signal kinematics. This is evaluated by comparing signal samples generated with PYTHIA and the default POWHEG samples.

The overall uncertainty on the integrated luminosity for the complete 2011 dataset is $3.9 \%$, based on the calibration described in Ref. [18] with an additional uncertainty for the extrapolation to the later data-taking period with higher instantaneous luminosity.

## 7 Results

The number of events observed in each final state, evaluated separately for $m_{4 \ell}<180 \mathrm{GeV}$ and $m_{4 \ell} \geq$ 180 GeV , are compared with the expectations for background and signal for various $m_{H}$ hypotheses in Table 3. In total 71 candidate events are selected by the analysis: $244 \mu, 302 e 2 \mu$, and $174 e$ events, while in the same mass range $62 \pm 9$ events are expected from the background processes; $18.6 \pm 2.84 \mu$, $29.7 \pm 4.52 e 2 \mu$ and $13.4 \pm 2.04 e$. The $m_{12}$ and $m_{34}$ mass spectra are shown in Fig. 3. The $m_{4 \ell}$ distribution for the total background and several signal hypotheses is compared to the data in Fig. 4. In Fig. 5, the $p_{\mathrm{T}}$ and $\eta$ distributions of the leptons of the selected candidates are provided.

Upper limits are set on the Higgs boson production cross section at $95 \%$ CL, using the $C L_{s}$ modified frequentist formalism [69] with the profile likelihood test statistic [70]. The test statistic is evaluated with a maximum likelihood fit of signal and background models to the observed $m_{4 \ell}$ distribution. Figure 6 shows the expected and observed $95 \%$ CL cross section upper limits as a function of $m_{H}$ and Table 4 summarizes the numerical values for selected $m_{H}$ points. The SM Higgs boson is excluded at $95 \%$ CL in the mass ranges $135 \mathrm{GeV}-156 \mathrm{GeV}, 181 \mathrm{GeV}-234 \mathrm{GeV}$ and $255 \mathrm{GeV}-415 \mathrm{GeV}$. The expected exclusion ranges are $137 \mathrm{GeV}-158 \mathrm{GeV}$ and $185 \mathrm{GeV}-400 \mathrm{GeV}$.

The $p_{0}$-value is the probability of upward fluctuations in the background as high as or higher than the excesses observed in data. The consistency of the observed results with the background-only hypothesis expressed as $p_{0}$-values is shown in Fig. 7 over the full mass range of the analysis. The most significant deviations from the background-only hypothesis are observed for $m_{H}=125 \mathrm{GeV}$ with a local $p_{0}$-value of $1.8 \%(2.1 \sigma), m_{H}=244 \mathrm{GeV}$ with a local $p_{0}$-value of $1.1 \%(2.3 \sigma)$ and $m_{H}=500 \mathrm{GeV}$ with a $p_{0}-$ value of $1.4 \%(2.2 \sigma)$. These values do not account for the so-called look-elsewhere effect, taking into account that such an excess (or larger) can appear anywhere in the search range as a result of an upward fluctuation of the background.

For an estimate of the look-elsewhere effect, similarly to Ref. [8], the method of Ref. [71] is used. When considering the complete mass range of this search, the global $p_{0}$-value for all the three excesses becomes more than $50 \%$. In particular for the excess at $m_{H}=125 \mathrm{GeV}$, if the mass range is (a posteriori) constrained to the lowest mass region not excluded at $99 \%$ by the recent LHC combined Higgs search results [8] ( $m_{H}<146 \mathrm{GeV}$ ), the global $p_{0}$-value becomes of $O(30 \%)$. From these it is concluded that,

Figure 3: Invariant mass distributions (a) $m_{12}$ and (b) $m_{34}$ for the selected candidates. The data (dots) are compared to the background expectations from the dominant $Z Z^{(*)}$ process and the sum of $t \bar{t}, Z b \bar{b}$ and $Z+$ light-flavour-jets processes. Error bars represent $68.3 \%$ central confidence intervals.
once the look-elsewhere effect is considered, none of the observed local excesses is significant by itself.

Figure 4: $m_{4 \ell}$ distribution of the selected candidates, compared to the background expecation. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown. The resolution of the reconstructed Higgs mass is dominated by detector resolution at low $m_{H}$ values and by the Higgs boson width at high $m_{H}$.

Figure 5: (a) $p_{\mathrm{T}}$ distribution and (b) $\eta$ distribution for the leptons of the 71 candidates surviving the selection criteria. The expected background distributions are also shown. Error bars represent $68.3 \%$ central confidence intervals.

## 8 Summary

A search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ based on $4.8 \mathrm{fb}^{-1}$ of data recorded by the ATLAS detector at $\sqrt{s}=7 \mathrm{TeV}$ during the 2011 run has been presented. The SM

Figure 6: The expected (dashed) and observed (full line) $95 \%$ CL upper limits on the Higgs boson production cross section as a function of the Higgs boson mass, divided by the expected SM Higgs boson cross section. The green and yellow bands indicate the expected sensitivity with $\pm 1 \sigma$ and $\pm 2 \sigma$ fluctuations, respectively.

Table 4: Median expected and observed 95\% CL upper limits on the Higgs boson production cross section for several Higgs boson masses, divided by the expected SM Higgs boson cross section.

Higgs boson is excluded at $95 \%$ confidence level in the mass ranges $135 \mathrm{GeV}-156 \mathrm{GeV}, 181 \mathrm{GeV}-$ 234 GeV and $255 \mathrm{GeV}-415 \mathrm{GeV}$. The largest deviations from the background expectation are observed for $m_{H}=125 \mathrm{GeV}$ with a $p_{0}$-value of $1.8 \%, m_{H}=244 \mathrm{GeV}$ with a $p_{0}$-value of $1.1 \%$ and $m_{H}=500 \mathrm{GeV}$ with a $p_{0}$-value of $1.4 \%$. Once the look-elsewhere effect is considered, none of these excesses is significant by itself.

Figure 7: The consistency of the observed results with the background-only hypothesis expressed as $p_{0}$ values is shown. The dashed line shows the median expected significance in the hypothesis of a Standard Model Higgs boson production. The two horizontal dashed lines indicate the $p_{0}$-values corresponding to local significances of $2 \sigma$ and $3 \sigma$. In (a) the full mass range is presented, while in (b) the low mass range is presented.

## A Additional Plots

Figure 8: Multiplicity of additional muons with $p_{T}>7 \mathrm{GeV}$ in events with a reconstructed $Z \rightarrow \ell \ell$ decay before and after the subtraction of muons originating from light quarks and $Z Z, W Z$ and $t \bar{t}$ decays. For the cases with two additional muons, their invariant mass is required to be less than 72 GeV . The MC expectation for the heavy flavour component, $Q$, is also presented. The uncertainties shown include both statistical and systematic effects.

Figure 9: Invariant mass distribution of the first lepton pair:(a) $\mu \mu$ and (b) $e e$. The kinematic selections of the analysis have been applied. Isolation requirements have been applied on the first lepton pair. No charge requirements were applied to the second lepton pair.

Figure 10: Event displays of a $4 \mu$ candidate event with $m_{4 \ell}=124.6 \mathrm{GeV}$. The masses of the lepton pairs are 89.7 GeV and 24.6 GeV .

Figure 11: Event displays of a $2 e 2 \mu$ candidate event with $m_{4 \ell}=124.3 \mathrm{GeV}$. The masses of the lepton pairs are 76.8 and 45.7 GeV .

Figure 12: Event display of a $2 \mu 2 e$ candidate event with $m_{4 \ell}=123.6 \mathrm{GeV}$. The masses of the lepton pairs are 89.3 and 30.0 GeV .

## ATLAS NOTE

ATLAS-CONF-2012-007
March 1, 2012

# Search for high-mass dilepton resonances with $5 \mathbf{f b}^{-1}$ of $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS experiment 

The ATLAS Collaboration

#### Abstract

This note reports on a search for narrow high-mass resonances decaying into dilepton final states. The data, recorded by the ATLAS experiment in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ at the Large Hadron Collider, correspond to a total integrated luminosity of $4.9(5.0) \mathrm{fb}^{-1}$ in the $e^{+} e^{-}\left(\mu^{+} \mu^{-}\right)$channel. No statistically significant excess above the Standard Model expectation is observed, and upper limits are set at the $95 \%$ confidence level on the cross section times branching fraction of $Z^{\prime}$ resonances and Randall-Sundrum gravitons decaying into dileptons as a function of the resonance mass. A lower limit of 2.21 TeV on the mass of the Sequential Standard Model $Z^{\prime}$ boson is set. A Randall-Sundrum graviton with coupling $k / \bar{M}_{\mathrm{Pl}}=0.1$ is excluded at $95 \%$ confidence level for masses below 2.16 TeV .

## 1 Introduction

This note describes a search for narrow high-mass resonances decaying into $e^{+} e^{-}$or $\mu^{+} \mu^{-}$pairs using $7 \mathrm{TeV} p p$ collision data recorded with the ATLAS detector [1] at the Large Hadron Collider (LHC). Such resonances, which are predicted by several extensions of the Standard Model (SM), include new heavy spin-1 neutral gauge bosons such as $Z^{\prime}[2,3,4]$ and $Z^{*}$ [5], techni-mesons $[6,7,8]$, as well as spin-2 Randall-Sundrum gravitons, $G^{*}$ [9].

The benchmark models considered for the $Z^{\prime}$ are the Sequential Standard Model (SSM) [3], with the same couplings to fermions as the $Z$ boson, and the $\mathrm{E}_{6}$ Grand Unified symmetry group [2], broken into $\operatorname{SU}(5)$ and two additional $\mathrm{U}(1)$ groups, leading to new neutral gauge fields $\psi$ and $\chi$. The particles associated with the additional fields can mix in a linear combination to form the $Z^{\prime}$ candidate: $Z^{\prime}\left(\theta_{E_{6}}\right)=$ $Z_{\psi}^{\prime} \cos \theta_{E_{6}}+Z_{\chi}^{\prime} \sin \theta_{E_{6}}$, where $\theta_{E_{6}}$ is the mixing angle between the two gauge bosons. The pattern of spontaneous symmetry breaking and the value of $\theta_{E_{6}}$ determine the $Z^{\prime}$ couplings to fermions; six choices of $\theta_{E_{6}}[2,3]$ lead to the specific $Z^{\prime}$ states named $Z_{\psi}^{\prime}, Z_{N}^{\prime}, Z_{\eta}^{\prime}, Z_{I}^{\prime}, Z_{S}^{\prime}$ and $Z_{\chi}^{\prime}$.

Other models predict additional spatial dimensions as a possible explanation for the gap between the electroweak symmetry breaking scale and the gravitational energy scale. The Randall-Sundrum (RS) model [9] predicts excited Kaluza-Klein modes of the graviton, which appear as spin-2 resonances. These modes have a narrow intrinsic width when $k / \bar{M}_{\mathrm{Pl}}<0.1$, where $k$ is the spacetime curvature in the extra dimension, and $\bar{M}_{\mathrm{Pl}}=M_{\mathrm{Pl}} / \sqrt{8 \pi}$ is the reduced Planck scale.

Previous searches have set direct and indirect constraints on the mass of the $Z^{\prime}$ and $G^{*}$ resonances [10, 11]. The Tevatron experiments [12, 13] excluded a $Z_{\text {SSM }}^{\prime}$ with a mass lower than 1.071 TeV [13]. Recent measurements by the ATLAS and CMS collaborations based on $1 \mathrm{fb}^{-1}$ of data excluded a $Z_{\text {SSM }}^{\prime}$ with a mass lower than 1.83 TeV [14] and 1.94 TeV [15], respectively. In addition, indirect constraints from LEP [16, 17, 18, 19] have set a limit of 1.787 TeV [11] on the $Z_{\text {SSM }}^{\prime}$. Constraints on the mass of the RS graviton have been set by the ATLAS [14, 20], CMS [15, 21], CDF [22] and D0 [23] collaborations. Assuming $k / \bar{M}_{\mathrm{Pl}}=0.1, \mathrm{CDF}$ and D 0 excluded graviton masses below 1.058 TeV and 1.050 TeV respectively, with the dielectron and diphoton channels combined; CMS excluded masses below 1.84 TeV with the diphoton channel only using $2 \mathrm{fb}^{-1}$ of data, and masses below 1.78 TeV with the dielectron plus dimuon channels using $1 \mathrm{fb}^{-1}$ of data; the ATLAS lower limit was 1.95 TeV with the combination of the dielectron and dimuon channels (using $1 \mathrm{fb}^{-1}$ of data) and of the diphoton channel (using $2 \mathrm{fb}^{-1}$ of data).

## 2 ATLAS detector, data selection and trigger

The ATLAS detector consists of an inner detector surrounded by a 2 T superconducting solenoid, electromagnetic and hadronic calorimeters, and a muon spectrometer with a toroidal magnetic field. Charged particle tracks in the pseudorapidity ${ }^{1}$ range $|\eta|<2.5$ are reconstructed with the inner detector, which consists of silicon pixel, silicon strip, and transition radiation detectors. The superconducting solenoid is surrounded by a hermetic calorimeter that covers $|\eta|<4.9$. For $|\eta|<2.5$, the electromagnetic calorimeter is finely segmented and plays an important role in electron identification. Outside the calorimeter, aircore toroids provide the magnetic field for the muon spectrometer. Three stations of precision drift tubes (with cathode strip chambers for the innermost station for $|\eta|>2.0$ ) provide an accurate measurement of the muon track curvature in the range $|\eta|<2.7$. Resistive-plate and thin-gap chambers provide muon triggering capability in the range $|\eta|<2.4$.

The data sample used in this analysis, recorded during 2011, corresponds to a total integrated luminosity of $4.9(5.0) \mathrm{fb}^{-1}$ in the dielectron (dimuon) channel. The trigger used in the electron channel

[^68]requires at least two electromagnetic clusters in the calorimeter, each with a transverse energy of at least 20 GeV . It was measured in data to be $99 \%$ efficient with respect to the event selection described below for dilepton masses above 100 GeV . For the muon channel, the trigger requires the presence of a single muon with a transverse momentum ( $p_{\mathrm{T}}$ ) threshold of 22 GeV ; the single-muon trigger efficiency was measured in data to be $85 \%$ in the barrel for most of the data-taking period, and $86 \%$ in the endcaps for the entire dataset. The muon trigger efficiency is lower than the electron trigger efficiency because of the lower geometrical acceptance of the muon trigger detectors.

## 3 Event selection

The triggered events are required to have a primary vertex with at least three associated charged particle tracks with $p_{\mathrm{T}}>0.4 \mathrm{GeV}$.

In the dielectron channel, two electron candidates are required with transverse energy $E_{\mathrm{T}}>25 \mathrm{GeV}$ and $|\eta|<2.47$; the transition region $1.37 \leq|\eta| \leq 1.52$ between the barrel and the endcap calorimeters is excluded. Electron candidates are formed from clusters of cells reconstructed in the electromagnetic calorimeter associated with a charged particle track in the inner detector. Criteria on the transverse shower shape, the longitudinal leakage into the hadronic calorimeter, and the association with an inner detector track are applied to the cluster to define a so-called Medium electron [24]. The electron energy is obtained from the calorimeter measurement and its direction from the associated track. The calorimeter energy resolution is dominated at large $E_{\mathrm{T}}$ by a constant term which is $1.2 \%$ in the barrel and $1.8 \%$ in the endcaps. A hit in the first active pixel layer is required to suppress background from photon conversions. To further suppress background from QCD multijet production, the higher $E_{\mathrm{T}}$ electron must be isolated, requiring that $\Sigma E_{\mathrm{T}}(\Delta R<0.2)<7 \mathrm{GeV}$, where $\Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}$ and $\Sigma E_{\mathrm{T}}(\Delta R<0.2)$ is the sum of the transverse energy deposition in the calorimeter around the electron direction. The core of the electron energy deposition is excluded and the sum is corrected for transverse shower leakage and pile-up from additional $p p$ collisions. Since the resolution on the dielectron mass is dominated by the calorimeter energy measurements, the two electron candidates are not required to have opposite charge, which to minimizes the losses due to charge mis-identification. For these selection criteria, the total signal acceptance for a $Z^{\prime} \rightarrow e^{+} e^{-}\left(G^{*} \rightarrow e^{+} e^{-}\right)$of mass 2 TeV is $71 \%$ ( $72 \%$ ), approximately independent of mass above 600 GeV . These numbers account for the acceptance of all selection criteria and efficiencies, and reflect the differences in lepton angular distributions due to spin.

In the dimuon channel, two muon candidates of opposite charge are required, each satisfying $p_{\mathrm{T}}>$ 25 GeV . Muon tracks are reconstructed independently in both the inner detector and muon spectrometer, and their momenta are determined from a combined fit to these two measurements. To optimize the momentum resolution, each muon candidate is required to pass quality cuts in both the inner detector and the muon spectrometer. Most muons used in the analysis have at least three hits in each of the inner, middle, and outer layers of the muon spectrometer. To increase the reconstruction efficiency, muons reconstructed in only two layers of the muon spectrometer are also included in the search if they are in regions where the toroidal field is strong and the detector well aligned. Muons with hits in both the barrel and the endcap regions are discarded because of residual misalignment between these two parts of the muon spectrometer. The effects of misalignments and intrinsic position resolution are included in the simulation by applying a smearing to $q / p_{\mathrm{T}}$, which reproduces the momentum resolution of the data. The $p_{\mathrm{T}}$ resolution at 1 TeV for muons reconstructed combining the measurements in the inner detector and muon spectrometer ranges from about $10 \%$ to $25 \%$.

To suppress background from cosmic rays, the $z$ position of the primary vertex is required to be within 200 mm of the centre of the detector, and the muon tracks are required to have a transverse impact parameter $\left|d_{0}\right|<0.2 \mathrm{~mm}$ and a distance along the beam-line to the primary vertex below 1 mm . To reduce background from jets, each muon is required to be isolated such that $\Sigma p_{\mathrm{T}}(\Delta R<0.3) / p_{\mathrm{T}}(\mu)<0.05$,
where only tracks with $p_{\mathrm{T}}>1 \mathrm{GeV}$, and not the muon track, enter the sum. The total signal acceptance is $43 \%(47 \%)$ for a $Z^{\prime} \rightarrow \mu^{+} \mu^{-}\left(G^{*} \rightarrow \mu^{+} \mu^{-}\right)$of mass 2 TeV , including $4 \%$ from events with one muon reconstructed in only two layers of the muon spectrometer. The lower acceptance compared to the electron channel is due to the stringent requirements on the muon selection criteria to improve the $p_{\mathrm{T}}$ resolution.

## 4 Signal and background simulation

For both channels, the dominant and irreducible background is due to the $Z / \gamma^{*}$ (Drell-Yan) process, characterized by the same final state as the signal. Small contributions from $t \bar{t}$ and diboson ( $W W, W Z$ and $Z Z$ ) production are also present in both channels. Semileptonic decays of $b$ and $c$ quarks in the dimuon sample and a mixture of photon conversions, semileptonic heavy quark decays, and hadrons misidentified as electrons in the $e^{+} e^{-}$sample are backgrounds that are referred to below as QCD background or QCD multijet. Jets accompanying $W$ bosons ( $W+$ jets) may similarly produce lepton candidates in addition to the one from $W \rightarrow \ell v$ decay.

The expected signal and backgrounds, with the exception of the QCD multijet background, are evaluated with simulated samples and rescaled using the most precise available cross-section predictions. The $Z^{\prime}, G^{*}$ signal and $Z / \gamma^{*}$ processes are generated with Pythia 6.425 [25] using MRST2007lomod [26] parton distribution functions (PDFs). Interference between the $Z / \gamma^{*}$ process and the $Z^{\prime}$ resonance is expected to be small and therefore neglected. The diboson processes are generated with HERWIG 6.510 [27] using MRST2007lomod PDFs. The $W+$ jets background is generated with ALPGEN [28] using CTEQ6L1 [29] PDFs and the $t \bar{t}$ background with MC@NLO 3.41 [30] using CTEQ66 [31] PDFs. JIMMY 4.31 [32] is used for both processes to describe multiple parton interactions and HERWIG to describe the remaining underlying event and parton showers. Final-state photon radiation is handled with PHOTOS [33]. The samples are processed through a full ATLAS detector simulation [34] based on GEANT4 [35].

The $Z / \gamma^{*}$ cross section is calculated at next-to-next-to-leading order (NNLO) using PHOZPR [36] with MSTW2008 PDFs [37]. The ratio of this cross section to the leading-order cross section is used to determine a mass-dependent QCD K-factor which is applied to the results of the leading-order simulations. The same QCD K-factor is applied to the $Z^{\prime}$ signal. It is 0.91 at 2 TeV and slowly increases towards lower masses. A different K-factor is applied to the $G^{*}$ signal. The calculated values vary between 1.6 and 1.8 , depending on the graviton mass and on $k / \bar{M}_{\mathrm{Pl}}$ [38]; in practice, 1.75 is used above 750 GeV . Electroweak corrections including virtual heavy gauge-boson loops are calculated using HORACE [39, 40], yielding an effective electroweak K-factor which is only applied to the Drell-Yan background.

The $t \bar{t}$ cross section is predicted at approximately NNLO, with $10 \%$ uncertainty [41, 42]. The diboson cross sections are calculated at next-to-leading order (NLO) using MCFM [43]; the $W$ inclusive cross section from ALPGEN, including all possible final states with and without jets, is renormalised to the NNLO calculation of FEWZ [44]; these cross sections are assigned a $5 \%$ uncertainty each, from scale, PDF and $\alpha_{s}$ variations. In the dimuon channel, the $W+$ jets Monte Carlo yield is assigned an overall $30 \%$ systematic uncertainty from the sum of the cross sections of the ALPGEN samples with at least one parton with $E_{\mathrm{T}}>20 \mathrm{GeV}$ accompanying the $W$ boson. In the electron channel, this uncertainty is replaced by a data-driven uncertainty, as explained below.

The QCD multijet background in the dielectron sample is estimated from data using a "reversed electron identification" technique. Data with both electron candidates failing a subset of identification criteria (chosen not to affect kinematic distributions) are used to determine the QCD background distribution versus $m_{e e}$. Contributions from other backgrounds are estimated from simulated samples and subtracted. An empirical function, $f(x)=p_{1} x^{p_{2}+p_{3} \log x}$, fitted in the $110-800 \mathrm{GeV}$ range, extrapolates the distribution to high $m_{e e}$. This QCD background shape and the sum of the $Z / \gamma^{*}$, diboson, $t \bar{t}$ and $W+$ jets backgrounds are fitted to the observed $m_{e e}$ distribution in a control region to determine the
normalization of the QCD contribution. This method provides the central QCD multijet estimate, and two other techniques are used to assign a systematic uncertainty. One is another shape-fitting procedure, this time on two-dimensional (leading and sub-leading electron) isolation distributions in bins of $m_{e e}$. A third independent data-driven QCD multijet estimate is based on fake rates computed from jet-enriched samples obtained from jet triggers or from the electromagnetic-cluster trigger used for the signal. These estimates are compatible with the central method. Since these alternative methods provide combined estimates of the QCD and $W+$ jets contributions, the central QCD multijet determination is summed with the Monte Carlo predicted $W+$ jets yield for the comparison. The largest difference with the alternative methods is assigned as the global systematic uncertainty to the QCD plus $W+$ jets yield in the dielectron channel.

The QCD background in the dimuon sample is evaluated from data using the reversed isolation method described in [45], based on the track isolation variable $\Sigma p_{\mathrm{T}}(\Delta R<0.3) / p_{\mathrm{T}}$.

The QCD and $W+$ jets backgrounds are small for the electron channel and very small for the muon channel. Backgrounds from cosmic rays are negligible.

## 5 Results

The observed invariant mass distributions are compared to the SM expectation, given by the Monte Carlo simulation for all components except QCD multijet, which is taken from the data. For this purpose, the Drell-Yan, $t \bar{t}$, diboson and $W+$ jets backgrounds from Monte Carlo simulation are scaled according to their respective cross sections and added to the data-driven QCD background. The simulated backgrounds are then rescaled so that the sum matches the observed number of data events in the normalization region, defined as the $70-110 \mathrm{GeV}$ mass interval. The scaling factor is within $1.6 \%$ of unity. The number of events in the normalization region is 1237292 in the dielectron channel, and 985004 in the dimuon channel; the Drell-Yan component amounts to more than $99 \%$ of the total in both cases. The advantage of this approach is that the uncertainty on the integrated luminosity, and any mass-independent uncertainties on efficiencies, cancel between the $Z^{\prime}\left(G^{*}\right)$ and the $Z$ boson in the limit computation presented below.

Table 1: The expected and observed numbers of events in the dielectron channel for various $m_{e e}$ bins. The expected numbers are shown separately for each of the background components discussed in the text. The errors quoted include both statistical and systematic uncertainties.

described by the prediction from SM processes.
The invariant mass distribution of the data is compared to templates of the background and of signals with pole masses in the search region, which extends from 0.13 to 3.0 TeV [14, 45]. A likelihood function is defined as the product of the Poisson probabilities over all mass bins in the search region. The Poisson probability in each bin is evaluated for the observed number of data events given the background and signal template expectation. The total signal acceptance as a function of mass is propagated into the expectation, and systematic uncertainties are incorporated in the likelihood via nuisance parameters [46].

The significance of a signal is summarized by a $p$-value, the probability of observing an excess at least as signal-like as the one observed in data, in the absence of signal. The outcome of the search is ranked against pseudo-experiments using a likelihood ratio, which is scanned as a function of $Z^{\prime}$ cross section and $m_{Z^{\prime}}$ over the full considered mass range. The data are consistent with the SM hypothesis, with global $p$-values of $13 \%$ and $82 \%$ for the dielectron and dimuon channels respectively.

In addition, the agreement between data and expectation is studied by computing the significance of the difference in each mass bin, with statistical and systematic errors taken into account [47]; the result is displayed in Figure 2. The largest positive local significance is $\sim 2.5 \sigma$ in the electron channel and less than $2 \sigma$ in the muon channel, and the largest negative significance is about $-3 \sigma$ in both channels.

Given the absence of any significant signal, an upper limit on the number of signal events is determined at the $95 \%$ confidence level (C.L.) using a Bayesian approach [46] with a flat, positive prior on the signal cross section.

## 6 Systematic uncertainties

Systematic uncertainties include the normalization to the $Z$-peak, PDF, QCD and electroweak corrections, as well as the trigger, reconstruction and identification efficiencies. For each source of uncertainty, the correlations across bins, as well as the correlations between signal and background, are taken into account.

Since the total background is normalized to the data in the region of the $Z \rightarrow \ell^{+} \ell^{-}$mass peak, the residual systematic uncertainties (with the exception of the $Z$ cross section uncertainty) are small at the $Z$ pole and grow at higher mass. The dominant uncertainties are theoretical. The overall uncertainty due to $\mathrm{PDF}, \alpha_{S}$, and scale variations is estimated to be $20 \%$ at 2 TeV , where the PDF contribution is dominant. The $\alpha_{S}$ and PDF uncertainties are evaluated using the MSTW2008NNLO eigenvector PDF sets and the PDF sets corresponding to variations of $\alpha_{S}$, at the $90 \%$ C.L. The spread of the variations covers the

Figure 1: The dielectron (top) and dimuon (bottom) invariant mass ( $m_{\ell \ell}$ ) distribution after final selection, compared to the stacked sum of all expected backgrounds, with three example $Z_{\mathrm{SSM}}^{\prime}$ signals overlaid. The bin width is constant in $\log m_{\ell \ell}$.

Figure 2: The dielectron (left) and dimuon (right) invariant mass ( $m_{\ell \ell}$ ) distributions after final selection, compared to the expected background. The bin width is the same as in Figure 1. The bottom part of each histogram shows the significance of the difference between data and expectation in each bin.
difference between the central values obtained with the CTEQ and MSTW PDF sets. The scale uncertainties are estimated by varying the renormalization $\left(\mu_{R}\right)$ and factorization $\left(\mu_{F}\right)$ scales independently up and down by a factor of two, but with the constraint $0.5 \leq \mu_{F} / \mu_{R} \leq 2$. The resulting maximum variations are taken as the uncertainties. Additionally, a systematic uncertainty of $4.5 \%$ is attributed to electroweak corrections [45].

The uncertainty on the $Z / \gamma^{*}$ cross section is $5 \%$, which is applied as a systematic uncertainty on the signal yield. It replaces the uncertainty on the integrated luminosity due to the normalization to the data under the $Z \rightarrow \ell^{+} \ell^{-}$mass peak.

The experimental systematic effects due to resolution and inefficiencies at high mass were also studied. The uncertainty on the energy resolution is measured to be negligible in the electron channel. In the muon channel, the uncertainty on the momentum resolution is due to residual misalignments and intrinsic position uncertainties in the muon spectrometer that propagate to a change in the observed width of the $Z^{\prime}\left(G^{*}\right)$ line-shape. The simulation was adjusted to reproduce the data at high muon momentum. The residual uncertainty translates into an event yield uncertainty of less than $3 \%$. The combined uncertainty on the muon trigger and reconstruction efficiency is estimated to be $6 \%$ at 2 TeV . This uncertainty is dominated by a conservative estimate of the impact of large energy loss from muon bremsstrablung in the calorimeter on the muon reconstruction performance in the muon spectrometer. In the electron channel, a systematic uncertainty of $2 \%$ at 2 TeV is estimated for a possible identification inefficiency caused by the isolation requirement.

The dominant systematic uncertainties are summarized in Table 3. Uncertainties of $3 \%$ and less are neglected in the limit setting procedure described below, and no theory uncertainties are applied to the $Z^{\prime}$ or $G^{*}$ signal.

## 7 Interpretation

The limit on the number of produced $Z^{\prime}\left(G^{*}\right)$ events is converted into a limit on cross section times branching fraction $\sigma B$ by scaling with the observed number of $Z$ boson events and the theoretical value

Table 3: Summary of systematic uncertainties on the expected numbers of events at $m_{\ell^{+} \ell^{-}}=2 \mathrm{TeV}$. NA indicates that the uncertainty is not applicable, and "-" denotes a negligible entry.

| Source | Dielectrons |  | Dimuons |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Signal | Background | Signal | Background |
| Normalization | $5 \%$ | NA | $5 \%$ | NA |
| PDF/ $\alpha_{s} /$ scale | NA | $20 \%$ | NA | $20 \%$ |
| Electroweak corrections | NA | $4.5 \%$ | NA | $4.5 \%$ |
| Efficiency | - | - | $6 \%$ | $6 \%$ |
| $W+$ jets and QCD background | NA | $3.5 \%$ | NA | - |
| Total | $5 \%$ | $21 \%$ | $8 \%$ | $21 \%$ |

Figure 3: The expected and observed 95\% C.L. upper limits on $\sigma B$ as a function of mass for $Z^{\prime}$ (left) and $G^{*}$ (right) models for the electron channel. The thickness of the $Z_{\mathrm{SSM}}^{\prime}$ (left) and the $G^{*}$ for $k / \bar{M}_{\mathrm{Pl}}=0.1$ (right) theory curves illustrate the theoretical uncertainties.
of $\sigma B(Z \rightarrow l l)$. The expected exclusion limits are determined using pseudo-experiments containing only SM processes, by evaluating the $95 \%$ C.L. upper limits for each pseudo-experiment for each fixed value of $m_{Z^{\prime}}\left(m_{G^{*}}\right)$. The median of the distribution of limits represents the expected limit. The ensemble of limits is used to find the $68 \%$ and $95 \%$ envelopes of the expected limits as a function of $m_{Z^{\prime}}\left(m_{G^{*}}\right)$.

Figure 3 shows the $95 \%$ C.L. observed and expected exclusion limits on $\sigma B\left(Z^{\prime} \rightarrow e^{+} e^{-}\right)$and on $\sigma B\left(G^{*} \rightarrow e^{+} e^{-}\right)$. It also shows the theoretical cross section times branching fraction for the $Z_{\mathrm{SSM}}^{\prime}$ and for $\mathrm{E}_{6}$-motivated $Z^{\prime}$ models with the lowest and highest $\sigma B$. The same information is shown in Figure 4 for the muon channel. Figure 5 shows the combined dielectron and dimuon $95 \%$ C.L. observed and expected exclusion limits on $\sigma B\left(Z^{\prime} \rightarrow l l\right)$ and on $\sigma B\left(G^{*} \rightarrow l l\right)$.

Figure 6 shows the ratio between the observed limit and the expected cross section times branching fraction as a function of the $Z^{\prime}$ mass for the SSM model, for previous results at the Tevatron and in ATLAS, together with the results presented here. Mass limits obtained for the $Z_{\mathrm{SSM}}^{\prime}$ and $G^{*}$ (with $k / \bar{M}_{\mathrm{Pl}}=0.1$ ) are displayed in Table 4. The combined mass limits on the $\mathrm{E}_{6}$-motivated models and the $G^{*}$ with various couplings are given in Table 5.

Figures 7 and 8 show event displays of the dielectron and dimuon candidates reconstructed with the highest invariant mass.

Figure 4: The expected and observed $95 \%$ C.L. upper limits on $\sigma B$ as a function of mass for $Z^{\prime}$ (left) and $G^{*}$ (right) models for the muon channel. The thickness of the $Z_{\mathrm{SSM}}^{\prime}$ (left) and the $G^{*}$ for $k / \bar{M}_{\mathrm{P} 1}=0.1$ (right) theory curves illustrate the theoretical uncertainties.

Table 4: The observed (expected) $95 \%$ C.L. mass lower limits in TeV on $Z_{\text {SSM }}^{\prime}$ resonance and $G^{*}$ graviton (with $k / \bar{M}_{\mathrm{P}}=0.1$ ), for the dielectron and dimuon channels separately and for their combination.

| Model | Mass limit [TeV] |  |  |
| :--- | :---: | :---: | :---: |
|  | $e^{+} e^{-}$ | $\mu^{+} \mu^{-}$ | $\ell^{+} \ell^{-}$ |
| $Z_{\text {SSM }}^{\prime}$ | $2.07(2.14)$ | $1.99(2.01)$ | $2.21(2.26)$ |
| $G^{*}$ | $2.03(2.05)$ | $1.90(1.92)$ | $2.16(2.17)$ |

Table 5: The observed $95 \%$ C.L. lower limits on the masses of $\mathrm{E}_{6}$-motivated $Z^{\prime}$ bosons and RS gravitons $G^{*}$ for various values of the coupling $k / \bar{M}_{\mathrm{Pl}}$. Both lepton channels are combined.

|  | $\mathrm{E}_{6} Z^{\prime}$ models |  |  |  |  |  | RS graviton |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Model/Coupling | $Z_{\psi}^{\prime}$ | $Z_{N}^{\prime}$ | $Z_{\eta}^{\prime}$ | $Z_{I}^{\prime}$ | $Z_{S}^{\prime}$ | $Z_{\chi}^{\prime}$ | 0.01 | 0.03 | 0.05 |  |
| Mass limit [TeV] | 1.76 | 1.78 | 1.84 | 1.84 | 1.90 | 1.96 | 0.91 | 1.45 | 1.71 |  |

## 8 Conclusion

The ATLAS detector has been used to search for narrow, high-mass resonances in the dilepton invariant mass spectrum. Proton-proton collision data with integrated luminosities of $4.9(5.0) \mathrm{fb}^{-1}$ in the dielectron (dimuon) channel have been used. The observed invariant mass spectra are consistent with the SM expectations. Limits are set on the cross section times branching fraction $\sigma B$. The resulting lower limits on the mass of a new resonance are 2.21 TeV for a Sequential Standard Model $Z^{\prime}, 1.76-1.96 \mathrm{TeV}$ for various $\mathrm{E}_{6}$-motivated $Z^{\prime}$ bosons and $0.91 \mathrm{TeV}-2.16 \mathrm{TeV}$ for a Randall-Sundrum graviton with couplings $\left(k / \bar{M}_{\mathrm{PI}}\right)$ in the range $0.01-0.1$.

Figure 5: The expected and observed $95 \%$ C.L. upper limits on $\sigma B$ as a function of mass for $Z^{\prime}$ (top) and $G^{*}$ (bottom) models. Both results show the combination of the electron and muon channels. The thickness of the $Z_{\mathrm{SSM}}^{\prime}$ (top) and the $G^{*}$ for $k / \bar{M}_{\mathrm{Pl}}=0.1$ (bottom) theory curves illustrate the theoretical uncertainties.

Figure 6: The ratio between the observed limit and the predicted cross section times branching ratio as a function of the $Z^{\prime}$ mass for the SSM model. The results are shown for the most recent limits from the Tevatron [13, 12], the latest ATLAS published data [14] and the analysis presented here. No uncertainties on the theoretical prediction are applied.

ATLAS NOTE
ATLAS-CONF-2012-092

July 6, 2012

# Observation of an excess of events in the search for the Standard Model Higgs boson in the $H \rightarrow Z Z Z^{(*)} \rightarrow 4 \ell$ channel with the ATLAS detector 

The ATLAS Collaboration

#### Abstract

This note presents a search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{\prime}+\ell^{\prime}$, where $\ell, \ell^{\prime}=e$ or $\mu$, using $4.8 \mathrm{fb}^{-1}$ and $5.8 \mathrm{fb}^{-1}$ of proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ and 8 TeV , respectively, recorded with the ATLAS detector. The four-lepton invariant mass distribution is compared with Standard Model background expectations to derive upper limits on the cross section of a Standard Model Higgs boson with a mass between 110 GeV and 600 GeV . The mass ranges $131-162 \mathrm{GeV}$ and $170-$ 460 GeV are excluded at the $95 \%$ confidence level, while the expected exclusion ranges at the $95 \%$ confidence level are $124-164 \mathrm{GeV}$ and $176-500 \mathrm{GeV}$. An excess of events is observed around $m_{H}=125 \mathrm{GeV}$, whose local $p_{0}$ value is $0.029 \%$ ( 3.4 standard deviations) in the combined analysis of the two datasets.

## 1 Introduction

The Higgs mechanism in the context of the Standard Model (SM) is the source of electroweak symmetry breaking and results in the appearance of the Higgs boson [1-3], which remains the only unobserved particle of the Standard Model. Direct searches performed at the CERN Large Electron-Positron Collider (LEP) excluded at $95 \%$ confidence level (CL) the production of a SM Higgs boson with mass, $m_{H}$, less than 114.4 GeV [4]. The searches at the Fermilab Tevatron $p \bar{p}$ collider have excluded at $95 \%$ CL the region $147 \mathrm{GeV}<m_{H}<179 \mathrm{GeV}$ [5]. At the LHC, the ATLAS experiment using $4.9 \mathrm{fb}^{-1}$ of data at $\sqrt{s}=7 \mathrm{TeV}$ collected in 2011 [6] has excluded [7] the $m_{H}$ regions $112.9-115.5 \mathrm{GeV}, 131-238 \mathrm{GeV}$ and $251-466 \mathrm{GeV}$ at the $95 \% \mathrm{CL}$. The CMS results [8] based to up to $4.8 \mathrm{fb}^{-1}$ of data have excluded at the $95 \% \mathrm{CL}$ the $m_{H}$ range $127-600 \mathrm{GeV}$ [9].

The search for the SM Higgs boson through the decay $H \rightarrow Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{\prime}+\ell^{\prime}-$, where $\ell, \ell^{\prime}=e$ or $\mu$, provides good sensitivity over a wide mass range. The largest background to this search comes from continuum $\left(Z^{* *} / \gamma^{*}\right)\left(Z^{*} / \gamma^{*}\right)$ production, referred to as $Z Z^{(*)}$ hereafter. For low masses, there are also important background contributions from $Z+$ jets and $t \bar{t}$ production, where the additional charged lepton candidates arise either from decays of hadrons with $b$ - or $c$-quark content or from mis-identification of jets. Previous results from ATLAS in this channel [6] excluded the mass regions $134-156 \mathrm{GeV}$, $182-233 \mathrm{GeV}, 256-265 \mathrm{GeV}$ and $268-415 \mathrm{GeV}$ at $95 \% \mathrm{CL}$ with $4.8 \mathrm{fb}^{-1}$ of $\sqrt{s}=7 \mathrm{TeV}$ data. The corresponding search from CMS [8] excluded at $95 \%$ CL the mass regions $134-158 \mathrm{GeV}, 180-305 \mathrm{GeV}$ and $340-465 \mathrm{GeV}$.

This note updates the results presented in Ref. [6], with a new analysis of the $\sqrt{s}=7 \mathrm{TeV}$ data corresponding to an integrated luminosity of $4.8 \mathrm{fb}^{-1}$ collected in 2011, combined with the first analysis of $\sqrt{s}=8 \mathrm{TeV}$ data corresponding to an integrated luminosity of $5.8 \mathrm{fb}^{-1}$ collected between April and June 2012 [10, 11]. The analysis selection has been optimised with respect to the one described in Ref. [6] to enhance the sensitivity to a low mass Higgs boson. The $\sqrt{s}=8 \mathrm{TeV}$ data analysis benefits from substantial improvements in the electron reconstruction and identification compared to the one used for the $\sqrt{s}=7 \mathrm{TeV}$ data, which have not yet been reprocessed to take advantage of these improvements.

In the following, the ATLAS detector is briefly described in Section 2, and the signal and background simulation is presented in Section 3. The analysis of the $\sqrt{s}=8 \mathrm{TeV}$ data collected between March and June 2012 is discussed in Section 4 and that of the $\sqrt{s}=7 \mathrm{TeV}$ data collected in 2011 is described in Section 5. After a description of the systematic uncertainties in Section 6, Section 7 presents the result of the combined analysis of the two datasets.

## 2 The ATLAS Detector

The ATLAS detector [12] is a multi-purpose particle physics detector with approximately forwardbackward symmetric cylindrical geometry ${ }^{1}$. The inner tracking detector (ID) [13] covers $|\eta|<2.5$ and consists of a silicon pixel detector, a silicon micro-strip detector, and a transition radiation tracker. The ID is surrounded by a thin superconducting solenoid providing a 2 T axial magnetic field. A highgranularity lead/liquid-argon (LAr) sampling calorimeter [14] measures the energy and the position of electromagnetic showers with $|\eta|<3.2$. LAr sampling calorimeters are also used to measure hadronic showers in the end-cap ( $1.5<|\eta|<3.2$ ) and forward ( $3.1<|\eta|<4.9$ ) regions, while an iron/scintillator tile calorimeter [15] measures hadronic showers in the central region $(|\eta|<1.7)$. The muon spectrometer (MS) [16] surrounds the calorimeters and consists of three large superconducting air-core toroid magnets,

[^69]each with eight coils, a system of precision tracking chambers $(|\eta|<2.7)$, and fast tracking chambers for triggering. A three-level trigger system [17] selects events to be recorded for offline analysis.

## 3 Signal and Background Simulation

The $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ signal is modelled using the Powheg Monte Carlo (MC) event generator $[18,19]$, which calculates separately the gluon fusion and vector-boson fusion production mechanisms with matrix elements up to next-to-leading order (NLO). The Higgs boson transverse momentum ( $p_{\mathrm{T}}$ ) spectrum in the gluon fusion process follows the calculation of Ref. [20], which includes QCD corrections up to NLO and QCD soft-gluon re-summations up to next-to-next-to-leading logarithm (NNLL). Powheg is interfaced to Pythia [21,22] for showering and hadronization, which in turn is interfaced to Рнотоs [23, 24] for quantum electrodynamics (QED) radiative corrections in the final state. Pythia is used to simulate the production of a Higgs boson in association with a $W$ or a $Z$ boson.

The Higgs boson production cross sections and decay branching ratios, as well as their uncertainties, are taken from Refs. [25,26]. The cross sections for the gluon-fusion process have been calculated to next-to-leading order (NLO) [27-29], and next-to-next-to-leading order (NNLO) [30-32] in QCD. In addition, QCD soft-gluon re-summations calculated in the next-to-next-to-leading log (NNLL) approximation are applied for the gluon-fusion process [33]. NLO electroweak (EW) radiative corrections are also applied $[34,35]$. These results are compiled in Refs. [36-38] assuming factorisation between QCD and EW corrections. The cross sections for vector-boson fusion processes are calculated with full NLO QCD and EW corrections [39-41], and approximate NNLO QCD corrections are available [42]. The cross sections for the associated $W H / Z H$ production processes are calculated at NLO [43] and at NNLO [44] in QCD, and NLO EW radiative corrections [45] are applied.

The Higgs boson decay branching ratios [46] to the different four-lepton final states is provided by Prophecy4F [47, 48], which includes the complete NLO QCD+EW corrections, interference effects between identical final-state fermions, and leading two-loop heavy Higgs boson corrections to the fourfermion width. Table 1 gives the production cross sections and branching ratios for $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$, which are used to normalise the signal MC, for several Higgs boson masses.

The QCD scale uncertainties for $m_{\mathrm{H}}=125 \mathrm{GeV}$ [25] amount to ${ }_{-8}^{+7} \%$ for the gluon-fusion process and $\pm 1 \%$ for the vector-boson fusion and associated $W H / Z H$ production processes. The uncertainty of the production cross section due to uncertainties of the parton distribution function (PDF) and $\alpha_{s}$ is $\pm 8 \%$ for gluon-initiated processes and $\pm 4 \%$ for quark-initiated processes, estimated by following the prescription in Ref. [49] and by using the PDF sets of CTEQ [50], MSTW [51] and NNPDF [52]. The PDF uncertainties are assumed to be $100 \%$ correlated among processes with identical initial states, regardless of these being signal or background [49-53].

The cross section calculations do not take into account the width of the Higgs boson, which is implemented through a relativistic Breit-Wigner line shape applied at the event-generator level. In the absence of a full calculation, the possible size of such effects is included as an extra signal normalisation systematic uncertainty for $m_{H} \geq 300 \mathrm{GeV}$, on top of the one presented in Table 1, following a parametrisation as a function of $m_{H}: 150 \% \times m_{H}^{3}[\mathrm{TeV}][26]$.

The $Z Z^{(*)}$ continuum background is modelled using Powheg [54] for quark-antiquark annihilation and gg2ZZ [55] for gluon fusion, normalised to the mcFm prediction [56]. The QCD scale uncertainty has a $\pm 5 \%$ effect on the expected $Z Z^{(*)}$ background, and the effect due to the PDF and $\alpha_{s}$ uncertainties is $\pm 4 \%( \pm 8 \%)$ for quark-initiated (gluon-initiated) processes. In addition, the shape uncertainty of the four-lepton invariant mass spectrum has been assigned as discussed in Ref. [26]. For the simulation of $\tau$ lepton decays Tauola [57,58] is used. The $Z+$ jets production is modelled using Alpgen [59] and is divided into two sources: $Z+$ light jets, which includes $Z c \bar{c}$ in the massless $c$-quark approximation and $Z b \bar{b}$ from parton showers, and $Z b \bar{b}$ using matrix element calculations that take into account the $b$-quark

Table 1: Higgs boson production cross sections for gluon fusion, vector-boson fusion and associated production with a $W$ or $Z$ boson in $p p$ collisions at $\sqrt{s}$ of 7 TeV and 8 TeV [25]. The quoted uncertainties correspond to the total theoretical systematic uncertainties. The production cross section for the associated production with a $W$ or $Z$ boson is negligibly small for $m_{H}>300 \mathrm{GeV}$. The decay branching ratio for $H \rightarrow 4 \ell$, with $\ell=e$ or $\mu$, is reported in the last column [25].

mass. The MLM [60] matching scheme is used to remove any double counting of identical jets produced via the matrix element calculation and the parton shower, but this scheme is not implemented for $b$-jets. Therefore, $b \bar{b}$ pairs with separation $\Delta R=\sqrt{(\Delta \phi)^{2}+(\Delta \eta)^{2}}>0.4$ between the $b$-quarks are taken from the matrix-element calculation, whereas for $\Delta R<0.4$ the parton-shower $b \bar{b}$ pairs are used. In this search the $Z+$ jets background is normalised using control samples from data. For comparison between data and simulation, the QCD NNLO FEWz [61,62] and MCFM cross section calculations are used for inclusive $Z$ boson and $Z b \bar{b}$ production, respectively. The $t \bar{t}$ background is modelled using MC@NLO [63] and is normalised to the approximate NNLO cross section calculated using hatноr [64]. The effect of the QCD scale uncertainty of the cross section is ${ }_{-9}^{+4} \%$, while the effect of PDF and $\alpha_{s}$ uncertainties is $\pm 7 \%$. Both Alpgen and MC@NLO are interfaced to Herwig [65] for parton shower hadronization and to Jimmy [66] for the underlying event simulation.

Generated events are fully simulated using the ATLAS detector simulation [67] within the Geant4 framework [68]. Additional pp interactions in the same and nearby bunch crossings (pile-up) are included in the simulation. The MC samples are re-weighted to reproduce the observed distribution of the mean number of interactions per bunch crossing in the data.

## 4 Analysis of $\sqrt{s}=8 \mathrm{TeV}$ data

The data are subjected to quality requirements: events recorded during periods when the relevant detector components were not operating normally are rejected. The resulting integrated luminosity is $5.8 \mathrm{fb}^{-1}$.

### 4.1 Lepton Reconstruction/Identification and Event Selection

The data considered in this analysis are selected using single-lepton or di-lepton triggers. For the singlemuon trigger the transverse momentum $p_{\mathrm{T}}$ threshold is 24 GeV , while for the single-electron trigger the transverse energy, $E_{\mathrm{T}}$, threshold is 24 GeV . For the di-muon triggers the thresholds are $p_{\mathrm{T}}=13 \mathrm{GeV}$
for each muon or $p_{\mathrm{T} 1}=18 \mathrm{GeV}, p_{\mathrm{T} 2}=8 \mathrm{GeV}$ in the case of the asymmetric di-muon trigger, while for the di-electron triggers the thresholds are $E_{\mathrm{T}}=12 \mathrm{GeV}$ for each electron.

Electron candidates consist of clusters of energy deposited in the electromagnetic calorimeter that are associated to ID tracks. For the 2012 LHC data taking, the electron reconstruction algorithm has been improved with respect to 2011 , improving the performance at low $p_{\mathrm{T}}$. The ATLAS track pattern recognition and fit procedure were updated to account for energy losses due to bremsstrahlung, and the track-to-cluster matching algorithm was improved to be less sensitive to bremsstrahlung losses. Furthermore, all tracks associated to electromagnetic clusters are re-fitted using a Gaussian-Sum Filter [69], which allows for bremsstrahlung energy losses.

Electron candidates must have a well-reconstructed ID track pointing to the corresponding cluster, and the cluster should satisfy a set of identification criteria [70] that requires the longitudinal and transverse shower profiles to be consistent with those expected for electromagnetic showers. These identification criteria were optimised to maintain good performance in high pile-up conditions, and to take advantage of the new electron reconstruction. The electron transverse momentum is computed from the cluster energy and the track direction at the interaction point.

Muon candidates are formed by matching reconstructed ID tracks with either complete or partial tracks reconstructed in the MS [71]. If a complete track is present, the two independent momentum measurements are combined; otherwise the momentum is measured using the ID or the MS information alone. The muon reconstruction/identification coverage is extended by using tracks reconstructed in the forward region $(2.5<|\eta|<2.7)$ of the MS, which is outside the ID coverage. In the centre of the barrel region $(|\eta|<0.1)$, which lacks MS geometrical coverage, ID tracks with $p_{\mathrm{T}}>15 \mathrm{GeV}$ are identified as muons using the profile of the associated energy deposits in the calorimeter.

This analysis searches for Higgs boson candidates by selecting two same-flavour, opposite-sign lepton pairs in an event. The impact parameter of the leptons along the beam axis is required to be within 10 mm of the reconstructed primary vertex. To reject cosmic rays, muon tracks are required to have a transverse impact parameter, defined as the impact parameter in the bending plane with respect to the primary vertex, of less than 1 mm . The primary vertex is defined as the reconstructed vertex with the highest $\sum p_{\mathrm{T}}^{2}$ of associated tracks among the reconstructed vertices with at least three associated tracks.

Each electron (muon) must satisfy $p_{\mathrm{T}}>7 \mathrm{GeV}\left(p_{\mathrm{T}}>6 \mathrm{GeV}\right)$ and be measured in the pseudo-rapidity range $|\eta|<2.47(|\eta|<2.7)$. The most energetic lepton in the quadruplet must satisfy $p_{\mathrm{T}}>20 \mathrm{GeV}$, and the second (third) lepton in $p_{\mathrm{T}}$ order must satisfy $p_{\mathrm{T}}>15 \mathrm{GeV}\left(p_{\mathrm{T}}>10 \mathrm{GeV}\right)$. The leptons are required to be separated from each other by $\Delta R>0.1$ if they are of the same flavour and $\Delta R>0.2$ otherwise. The same-flavour and opposite-sign lepton pair closest to the $Z$ boson mass $\left(m_{Z}\right)$ is the leading di-lepton, its invariant mass, denoted by $m_{12}$, is required to be between 50 and 106 GeV . The remaining sameflavour, opposite-sign lepton pair is the sub-leading di-lepton and its invariant mass, $m_{34}$, is required to be in the range $m_{\min }<m_{34}<115 \mathrm{GeV}$, where the value of $m_{\min }$ depends on the reconstructed fourlepton invariant mass, $m_{4 \ell}$, and is shown in Table 2. All possible same-flavour opposite-charge di-lepton combinations in the quadruplet must satisfy $m_{\ell \ell}>5 \mathrm{GeV}$. Four different analysis sub-channels ( $4 e$, $2 e 2 \mu, 2 \mu 2 e, 4 \mu)$ ordered by the flavour of the leading di-lepton are defined. Data quality requirements result in slightly different integrated luminosities, $5.8 \mathrm{fb}^{-1}, 5.8 \mathrm{fb}^{-1}$ and $5.9 \mathrm{fb}^{-1}$ for the $4 \mu, 2 e 2 \mu / 2 \mu 2 e$ and $4 e$ sub-channels, respectively.

Table 2: The lower thresholds applied to $m_{34}$ for reference values of $m_{4 \ell}$. For $m_{4 \ell}$ values between these reference values the selection requirement is obtained via linear interpolation.

| $m_{4 \ell}[\mathrm{GeV}]$ | $\leq 120$ | 130 | 150 | 160 | 165 | 180 | $\geq 190$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $m_{\text {min }}$ threshold $[\mathrm{GeV}]$ | 17.5 | 22.5 | 30 | 30 | 35 | 40 | 50 |

The $Z+$ jets and $t \bar{t}$ background contributions are further reduced by applying impact parameter as well as track- and calorimeter-based isolation requirements on the leptons. The normalised track isolation discriminant is defined as the sum of the transverse momenta of tracks, $\Sigma p_{\mathrm{T}}$, inside a cone of $\Delta R<0.2$ around the lepton, excluding the lepton track, divided by the lepton $p_{\mathrm{T}}$. The tracks considered in the sum are of good quality; i.e., they have at least four hits in the pixel and silicon strip detectors ("silicon hits") and $p_{\mathrm{T}}>1 \mathrm{GeV}$ for muons, and at least nine silicon hits, one hit in the innermost pixel layer (the $b$-layer) and $p_{\mathrm{T}}>0.4 \mathrm{GeV}$ for electrons. Each lepton is required to have a normalised track isolation smaller than 0.15 .

The normalised calorimetric isolation for electrons is computed as the sum of the positive-energy topological clusters with a reconstructed barycenter falling in a cone of $\Delta R<0.2$ around the candidate electron cluster divided by the electron $p_{\mathrm{T}}$. The cut value is 0.20 . The cells within $0.125 \times 0.175$ in $\eta \times \phi$ around the electron barycenter are excluded. The algorithm for topological clusters suppresses noise by keeping only those cells with a significant energy deposit and their neighbouring cells. The ambient energy deposition in the event from pileup as well as from the underlying event is corrected for by calculating the transverse energy density from low $-p_{\mathrm{T}}$ jets, averaged over azimuth in two $\eta$ regions, and subtracting it from the isolation cone transverse energy. In the case of muons, the normalised calorimetric isolation discriminant is defined as the sum of the calorimeter cells, $\Sigma E_{T}$, inside a cone of $\Delta R<0.2$ around the muon direction, divided by the muon $p_{\mathrm{T}}$. Muons are required to have a normalised calorimetric isolation less than 0.30 ( 0.15 in case of muons without an ID track). For both the track- and calorimeter-based isolation any contributions arising from other leptons of the quadruplet are subtracted. The impact parameter significance, defined as the impact parameter divided by its uncertainty, $d_{0} / \sigma_{d_{0}}$, for all muons (electrons) is required to be lower than 3.5 (6.5). The electron impact parameter is affected by bremsstrahlung and it thus has a broader distribution.

The combined signal reconstruction and selection efficiency for $m_{H}=130 \mathrm{GeV}\left(m_{H}=360 \mathrm{GeV}\right)$ is $41 \%$ ( $67 \%$ ) for the $4 \mu$ channel, $27 \%(59 \%)$ for the $2 e 2 \mu / 2 \mu 2 e$ channel and $23 \% ~(51 \%)$ for the $4 e$ channel. The final discriminating variable for this search is $m_{4 \ell}$. The invariant mass resolution is further improved by applying a $Z$-mass constraint to the leading di-lepton for $m_{4 \ell}<190 \mathrm{GeV}$ and to both di-leptons for higher masses. The $Z$ line-shape and the experimental uncertainty in the di-lepton mass are accounted for in the $Z$-mass constraint. Figure 1 presents the $m_{4 \ell}$ distributions before and after the $Z$ mass constraint, for a simulated signal sample with $m_{H}=130 \mathrm{GeV}$, at $\sqrt{s}=8 \mathrm{TeV}$. The width of the reconstructed Higgs boson mass distribution is dominated by the experimental resolution for $m_{H}<350 \mathrm{GeV}$, while for higher $m_{H}$ the reconstructed width is dominated by the natural width of the Higgs boson. The predicted natural width of the Higgs boson is approximately 29 GeV at $m_{H}=400 \mathrm{GeV}$.

### 4.2 Background Estimation

The expected background yield and its composition is estimated using MC simulation normalised to the theoretical cross section for $Z Z^{(*)}$ production and by data-driven methods for the $\ell \ell+$ jets and $t \bar{t}$ processes. The background composition depends on the flavour of the sub-leading di-lepton and different approaches are taken for the $\ell \ell+\mu \mu$ and the $\ell \ell+e e$ final states.

### 4.2.1 $\quad \ell \ell+\mu \mu$ background

The number of $t \bar{t}$ and $Z+$ jets (dominated by $Z b \bar{b}$ ) background events in the signal region is estimated using a control region with an enhanced $b \bar{b}$ contribution. The control region is obtained by modifying the event selection as follows: no isolation requirement is applied to leptons in the sub-leading pair, and at least one of the sub-leading leptons is required to fail the impact parameter significance requirement. These modifications remove $Z Z^{(*)}$ contributions, and allow both the $t \bar{t}$ and $Z+$ jets backgrounds to be estimated simultaneously.

Figure 1: Invariant mass distributions for simulated (a) $H \rightarrow Z Z^{(*)} \rightarrow 4 \mu$, (b) $H \rightarrow Z Z^{(*)} \rightarrow 2 e 2 \mu$ and (c) $H \rightarrow Z Z^{(*)} \rightarrow 4 e$ events for $m_{H}=130 \mathrm{GeV}$, at $\sqrt{s}=8 \mathrm{TeV}$. The fitted range for the Gaussian is chosen to be: $-2 \sigma$ to $2 \sigma(-1.5 \sigma$ to $2.5 \sigma)$ for the $4 \mu(2 e 2 \mu / 4 e)$ channel. The slightly reduced mean values arise from radiative losses which are more explicit in channels involving electrons [70]. In (d), (e) and (f) the corresponding results after applying the $Z$ mass constraint are shown.

As shown in Fig. 2, the $m_{12}$ distribution is fitted using a second order Chebychev polynomial for the $t \bar{t}$ component and a Breit-Wigner line-shape convolved with a Crystal-Ball resolution function for the $Z+$ jets component. The shapes used in the fit are obtained from MC. The number of events in the control region is then extrapolated to the signal region using a transfer factor obtained from MC. The MC description of the selection efficiency has been verified with data using a control region obtained by requiring a $Z$ and exactly one extra muon. This $Z$ is selected using the leading di-lepton requirements of this analysis for the two highest $p_{\mathrm{T}}$ same-flavor opposite sign leptons. The systematic errors associated to the extrapolation from the control region to the signal region are comparable with the statistical errors of the fit.

The $t \bar{t}$ background is cross-checked using a control region defined by selecting events with an $e^{ \pm} \mu^{\mp}$ di-lepton pair with an invariant mass between 50 and 106 GeV , accompanied by an opposite sign dimuon. Events with a $Z$ candidate decaying to a pair of electrons or muons, in the aforementioned mass range, are excluded. Isolation and impact parameter requirements are applied only to the leptons of the $e \mu$ pair. In data, $16 e^{ \pm} \mu^{\mp}+\mu^{+} \mu^{-}$events are observed, to be compared with $18.9 \pm 1.1$ expected from MC.

The expected $\ell \ell+\mu \mu$ background yields in the signal region are summarised in Table 4.

Figure 2: Distribution of $m_{12}$, for $\sqrt{s}=8 \mathrm{TeV}$, in the control region where the isolation requirements are not applied to the two sub-leading muons, and at least one of these muons fails the impact parameter significance requirement. The fit used to obtain the yields for $t \bar{t}$ and $Z+$ jets is presented, the MC expectations are also shown for comparison.

### 4.2.2 $\ell \ell+e e$ background

A sample of reconstruction-level objects identified as electron candidates will contain true isolated electrons, electrons from heavy flavour semi-leptonic decays (Q), electrons from photon conversion $(\gamma)$ or light jets mis-reconstructed as electrons and denoted as fake electrons (f).

An $\ell \ell+e e$ background control region is formed by relaxing the electron selection criteria for the electrons of the sub-leading pair. The different sources of electron background are then separated into reconstruction categories which are electron-like (E), conversion-like (C) and fake-like (F), using appropriate discriminating variables [72]. The variables used are: the number of $b$-layer hits ( $n$ hits blay , the fraction of high threshold hits in the Transition Radiation Tracker ( $\mathrm{TRT}_{\text {Ratio }}$ ), the energy in the first layer of the electromagnetic calorimeter $\left(f_{1}\right)$ and the lateral containment of the cluster along $\phi$ in the second layer of the electromagnetic calorimeter $\left(R_{\phi}\right)$. The variable $n_{\text {hits }}^{\text {blayer }}$ is used to identify converted photons, and the latter three variables are used to discriminate electrons from hadrons. The numbers of observed events in each category of the control region are presented in Table 3. The expected numbers of events from MC are also given for comparison. Since only events from this control region can enter the signal region, this method directly accounts for most of the fluctuations in data. The efficiency needed to extrapolate the background yield of each category from the control region to the signal region is obtained from MC. This method estimates the sum of $Z+$ jets and $t \bar{t}$ background contributions. As a cross-check the same method is also applied to a similar control region containing same-sign sub-leading di-electrons.

The $\ell \ell+e e$ background is also estimated using a control region with same-sign sub-leading dielectrons, where the three highest $p_{\mathrm{T}}$ leptons satisfy all the analysis criteria and the remaining electron is required to only fulfill the good track criteria (silicon hits $>=7$ and pixel hits $>=1$ ) and the lateral containment of the cluster energy along $\eta\left(R_{\eta}\right)$. This method will be referred to as $3 \ell+\ell$ hereafter. In this case a simultaneous fit of templates, obtained from the $n_{\text {hits }}^{\text {blayer }}$ and the $\mathrm{TRT}_{\text {Ratio }}$ distributions, is used to estimate the yields for the different truth components: $\mathrm{f}, \gamma$ and Q . The templates used are obtained from MC. The fits for the $2 \mu 2 e$ and $4 e$ sub-channels are presented in Fig. 3. Additional checks are performed

Table 3: The observed yields of the various categories in the $\ell \ell+e e$ control region for $\sqrt{s}=8 \mathrm{TeV}$. Events are classified according to whether the electron candidates of the sub-leading di-electrons are: electron-like (E), conversion-like (C) and fake-like (F). For comparison the MC expectations are also shown. The di-lepton categorisation in reconstruction categories is ordered in $p_{\mathrm{T}}$.

|  | $4 e$ |  | $2 \mu 2 e$ |  |
| :--- | :---: | ---: | :---: | ---: |
|  | Data | MC | Data | MC |
| EE | 32 | $22.7 \pm 4.8$ | 31 | $24.9 \pm 5.0$ |
| EC | 6 | $6.0 \pm 2.5$ | 2 | $1.9 \pm 1.4$ |
| EF | 18 | $19.0 \pm 4.4$ | 26 | $15.3 \pm 3.9$ |
| CE | 4 | $8.8 \pm 3.0$ | 6 | $5.1 \pm 2.3$ |
| CC | 1 | $5.3 \pm 2.3$ | 6 | $4.2 \pm 2.0$ |
| CF | 12 | $8.8 \pm 3.0$ | 15 | $15.3 \pm 3.9$ |
| FE | 16 | $5.7 \pm 2.4$ | 12 | $8.4 \pm 2.9$ |
| FC | 6 | $6.5 \pm 2.6$ | 7 | $4.3 \pm 2.1$ |
| FF | 12 | $17.4 \pm 4.2$ | 16 | $33.6 \pm 5.8$ |
| Total | 107 | $100 \pm 10$ | 121 | $113 \pm 11$ |

by replacing the $\operatorname{TRT}_{\text {Ratio }}$ with $f_{1}$ or the distance in $\eta$ between the extrapolated impact point of the track on the calorimeter and the cluster barycenter using the strips $\left(\Delta \eta_{1}\right)$. The difference in the results is taken into account as a systematic error.

Finally, the $\ell \ell+e e$ background is also estimated by performing the full analysis but selecting samesign pairs for the sub-leading di-electrons. In this case, there remain 4 (3) events below $m_{4 \ell}=160 \mathrm{GeV}$ in the $4 e(2 \mu 2 e)$ sub-channel.

The expected $\ell \ell+e e$ background yields in the signal region are summarised in Table 4.

### 4.2.3 Summary of background estimates

The results of all the background estimation methods are summarised in Table 4. The $m_{12}$ and $m_{34}$ distributions, for events selected by the analysis when relaxing the isolation and impact parameter requirements for the sub-leading di-lepton, are presented in Fig. 4. The events are divided according to the flavour of the sub-leading lepton pair into $\ell \ell+\mu \mu$ and $\ell \ell+e e$ samples. In Figs. 4(a) and 4(c) the $m_{12}$ and $m_{34}$ distributions are presented for $\ell \ell+\mu \mu$ events, while in Figs. 4(b) and 4(d) the corresponding distributions are presented for $\ell \ell+e e$ events. The shape and normalisation of the backgrounds discussed earlier are in good agreement with data. This is observed both for large values of $m_{34}$, where the $Z Z^{(*)}$ background dominates, and for low $m_{34}$ values.

Figure 3: The results of a simultaneous fit to (a) $n_{\text {hits }}^{\text {blayer }}$ and (b) $\mathrm{TRT}_{\text {Ratio }}$ for the background components in the $2 \mu 2 e$ channel. In (c) and (d) the corresponding results for the $4 e$ channel are given. The sources of background electrons are denoted as: light jets faking an electron ( f ), photon conversions ( $\gamma$ ) and electrons from heavy quark semi-leptonic decays ( Q ).

Table 4: Summary of the background estimates for the $\sqrt{s}=8 \mathrm{TeV}$ data. The " $\dagger$ " symbol indicates the estimated number of events used for the background normalisation, the others being cross-checks. The first uncertainty is statistical, while the second is systematic.

| Method | Estimated <br> number of events |  |

| $3 \ell+\ell$ (same-sign) | $3.1 \pm 0.5 \pm 0.6$ |  |
|  | $3.0 \pm 0.4 \pm 0.4$ |  |

Figure 4: Invariant mass distributions of the lepton pairs in the control sample defined by a $Z$ boson candidate and an additional same-flavour lepton pair, for the $\sqrt{s}=8 \mathrm{TeV}$ dataset. The sample is divided according to the flavour of the additional lepton pair. In (a) the $m_{12}$ and in (c) the $m_{34}$ distributions are presented for $\ell \ell\left(\mu^{+} \mu^{-} / e^{+} e^{-}\right)+\mu^{+} \mu^{-}$events. In (b) the $m_{12}$ and in (d) the $m_{34}$ distributions are presented for $\ell \ell\left(\mu^{+} \mu^{-} / e^{+} e^{-}\right)+e^{+} e^{-}$events. The kinematic selection of the analysis is applied. Isolation and impact parameter significance requirements are applied to the first lepton pair only. The MC is normalized to the data driven background estimations given in Table 4.

## 5 Analysis of $\sqrt{s}=7 \mathrm{TeV}$ data

In this section the analysis of the $2011 \sqrt{s}=7 \mathrm{TeV}$ data, using the same kinematic selection as the $\sqrt{s}=8 \mathrm{TeV}$ analysis, is presented.

The data collected during 2011 are subjected to quality requirements similar to those used for the 2012 data. The resulting integrated luminosity being $4.8 \mathrm{fb}^{-1}, 4.8 \mathrm{fb}^{-1}$ and $4.9 \mathrm{fb}^{-1}$ for the $4 \mu, 2 e 2 \mu / 2 \mu 2 e$ and $4 e$ final states, respectively.

### 5.1 Lepton Reconstruction/Identification and Event Selection

The data considered in this analysis are selected using single-lepton or di-lepton triggers. For the singlemuon trigger the $p_{\mathrm{T}}$ threshold is 18 GeV , while for the single-electron trigger the $E_{\mathrm{T}}$ threshold is $20-22 \mathrm{GeV}$ depending on the LHC data-taking period. For the di-muon and di-electron triggers the thresholds are $p_{\mathrm{T}}=10 \mathrm{GeV}$ for each muon, and $E_{\mathrm{T}}=12 \mathrm{GeV}$ for both electrons.

For the $\sqrt{s}=7 \mathrm{TeV}$ dataset, the electron reconstruction proceeds as described in Ref. [70], with the exception that electron candidates are refitted using a Gaussian-sum filter [73], which recovers electron candidates that suffered large energy losses due to bremsstrahlung emissions. Electron reconstruction and identification is similar to that used in Ref. [6].

The event selection is identical between $\sqrt{s}=7 \mathrm{TeV}$ and 8 TeV data analyses with the following exceptions:

- For the electron track isolation, tracks are required to have at least seven silicon hits, one $b$-layer hit and $p_{\mathrm{T}}>1 \mathrm{GeV}$.
- The calorimeter isolation of electrons in 2011 is cell-based rather than topological cluster based and the actual cut is 0.3 instead of 0.2 .

The combined signal reconstruction and selection efficiency for $m_{H}=130 \mathrm{GeV}\left(m_{H}=360 \mathrm{GeV}\right)$ is $43 \%$ ( $70 \%$ ) for the $4 \mu$ channel, $23 \%(56 \%)$ for the $2 e 2 \mu / 2 \mu 2 e$ channel and $17 \% ~(45 \%)$ for the $4 e$ channel.

### 5.2 Background Estimation

The background estimation strategy in the $\sqrt{s}=7 \mathrm{TeV}$ data sample is identical to the $\sqrt{s}=8 \mathrm{TeV}$ one, described in Section 4.2.

The estimation of the $t \bar{t}$ and $Z+$ jets (dominated by $Z b \bar{b}$ ) background events in the signal region using the fit in $m_{12}$, described in Section 4.2.1, is shown in Fig. 5. For the $e^{ \pm} \mu^{\mp}+\mu^{+} \mu^{-}$control region 8 events are observed in data with $11.0 \pm 0.6$ expected from MC. For the $\ell \ell+e e$ control region (defined in Section 4.2.2), the number of events observed in the dataset from $\sqrt{s}=7 \mathrm{TeV}$ in each category of the control region are summarised in Table 5. The final expectations in the signal region are summarised in Table 6.

The $\ell \ell+e e$ background estimate from performing the full analysis but selecting same-sign pairs for the sub-leading di-electrons gives 4 (1) events below $m_{4 \ell}=160 \mathrm{GeV}$ in the $4 e(2 \mu 2 e)$ sub-channel.

Figure 6 displays the invariant masses of lepton pairs in events with a $Z$ boson candidate and an additional same-flavour lepton pair, selected by applying the kinematic requirements of the analysis, and by applying isolation requirements to the first lepton pair only. The events are divided according to the flavour of the additional lepton pair into $\ell \ell+\mu \mu$ and $\ell \ell+e e$ samples. In Figs. 6(a) and 6(c) the $m_{12}$ and $m_{34}$ distributions are presented for $\ell \ell+\mu \mu$ events, while in Figs. 6(b) and 6(d) the corresponding distributions are presented for $\ell \ell+e e$ events. The shape and normalisation of the backgrounds discussed earlier are in good agreement with data; this is observed both for large values of $m_{34}$, where the $Z Z^{(*)}$ background dominates, and for low $m_{34}$ values.

Figure 5: Distribution of $m_{12}$, for $\sqrt{s}=7 \mathrm{TeV}$, in the control region where the isolation requirements are not applied to the two sub-leading muons, and at least one of these muons fails the impact parameter significance requirement. The fit used to obtain the yields for $t \bar{t}$ and $Z+$ jets is presented, the MC expectations are also shown for comparison.

Table 5: The observed yields of the various categories in the $\ell \ell+e e$ control region for $\sqrt{s}=7 \mathrm{TeV}$. Events are classified according to whether the electron candidates of the sub-leading di-electrons are: electron-like (E), conversion-like (C) and fake-like (F). For comparison the MC expectations are also shown. The di-lepton categorization in reconstruction categories is ordered in $p_{\mathrm{T}}$.

Figure 6: Invariant mass distributions of the lepton pairs in the control sample defined by a $Z$ boson candidate and an additional same-flavour lepton pair for the $\sqrt{s}=7 \mathrm{TeV}$ data sample. The sample is divided according to the flavour of the additional lepton pair. In (a) the $m_{12}$ and in (c) the $m_{34}$ distributions are presented for $\ell \ell\left(\mu^{+} \mu^{-} / e^{+} e^{-}\right)+\mu^{+} \mu^{-}$events. In (b) the $m_{12}$ and in (d) the $m_{34}$ distributions are presented for $\ell \ell\left(\mu^{+} \mu^{-} / e^{+} e^{-}\right)+e^{+} e^{-}$events. The kinematic selections of the analysis are applied. Isolation requirements are applied to the first lepton pair only. The MC is normalized to the data driven background estimations given in Table 6.

## 6 Systematic Uncertainties

The uncertainty of the lepton reconstruction and identification efficiencies, and of the momentum resolution and scale, are determined using samples of $W, Z$ and $J / \psi$ decays [70]. The uncertainty of the muon identification and reconstruction efficiency results in a relative acceptance uncertainty of the signal and the $Z Z^{(*)}$ background which is uniform over the mass range of interest, and amounts to $\pm 0.16 \% ~( \pm 0.12 \%)$ for the $4 \mu(2 e 2 \mu)$ channel. The uncertainty of the electron identification efficiency results in a relative acceptance uncertainty of $\pm 3.0 \%( \pm 1.7 \%)$ for the $4 e(2 e 2 \mu)$ channel at $m_{4 \ell}=600 \mathrm{GeV}$ and reaches $\pm 8.0 \%( \pm 4.6 \%)$ at $m_{4 \ell}=110 \mathrm{GeV}$. The effects of muon momentum resolution and scale uncertainty are found to be negligible. The effect of the uncertainty of the energy resolution for electrons is negligible, while the uncertainty of the electron energy scale results in an uncertainty of less than $\pm 0.7 \%$ ( $\pm 0.4 \%$ ) on the mass scale of the $m_{4 \ell}$ distribution for the $4 e(2 e 2 \mu)$ channel.

The selection efficiency of the isolation and impact parameter requirements is studied using data for both isolated and non-isolated leptons. Isolated leptons are obtained from $Z \rightarrow \ell \ell$ decays, while additional leptons reconstructed in events with $Z \rightarrow \ell \ell$ decays constitute the sample of non-isolated leptons. Additional checks are performed with non-isolated leptons from semi-leptonic $b$ - and $c$-quark decays in a heavy-flavour enriched di-jet sample. Good agreement is observed between data and simulation and the systematic uncertainty is, in general, estimated to be small with respect to the other systematic uncertainties.

An additional uncertainty on the signal selection efficiency is added in the 2011 analysis only, which is not needed in the 2012 analysis due to an improved modelling of the signal kinematics. This additional uncertainty is evaluated by varying the Higgs boson $p_{\mathrm{T}}$ spectrum in the gluon fusion process according to the PDF and QCD scale uncertainties.

The background uncertainties of the data driven methods have already been presented in Sections 4 and 5. The overall uncertainty of the integrated luminosity for the complete 2011 dataset is $\pm 1.8 \%$ and is described in Refs. [10, 11]. For the 2012 dataset the corresponding preliminary uncertainty is $\pm 3.6 \%$ based on the calibration described in Ref. [11].

The theory-related systematic uncertainty, for both signal and $Z Z^{(*)}$ background, has been discussed in Section 3. The uncertainties related to the data-driven methods are summarised in Tables 4 and 6.

## 7 Results

In Table 7, the numbers of events observed in each final state are summarised and compared to the expected backgrounds, separately for $m_{4 \ell}<160 \mathrm{GeV}$ and $m_{4 \ell} \geq 160 \mathrm{GeV}$, and to the expected signal for various $m_{H}$ hypotheses. Table 8 presents the observed and expected events, in a window of $\pm 5 \mathrm{GeV}$ around various hypothesized Higgs boson masses, for the $5.8 \mathrm{fb}^{-1}$ at $\sqrt{s}=8 \mathrm{TeV}$ and the $4.8 \mathrm{fb}^{-1}$ at $\sqrt{s}=7 \mathrm{TeV}$ datasets as well as for their combination.

The expected $m_{4 \ell}$ distributions for the total background and several signal hypotheses are compared to the data in Fig. 7. Figure 8 presents the same distributions only for the low mass range $80-250 \mathrm{GeV}$. In Figures 9 and 10 the $m_{4 \ell}$ mass distributions for each sub-channel $(4 \mu, 2 \mu 2 e, 2 e 2 \mu, 4 e)$ are shown for the data at $\sqrt{s}=8 \mathrm{TeV}$ and $\sqrt{s}=7 \mathrm{TeV}$, respectively. High- $p_{\mathrm{T}}$ photon emissions from final-state radiation (FSR), although occurring at a low rate, are not taken into account explicitely in the lepton reconstruction, and affect the reconstructed invariant mass in rare cases. In MC, QED corrections are fully considered and accounted for in the templates used for the mass distributions. All candidates selected have been checked and no appreciable FSR activity has been found for the candidates below 160 GeV .

Upper limits are set on the Higgs boson production cross section at $95 \% \mathrm{CL}$, using the $C L_{s}$ modified frequentist formalism [74] with the profile likelihood ratio test statistic [75]. The test statistic is evaluated using a maximum-likelihood fit of signal and background models to the observed $m_{4 \ell}$ distribution.

Table 7: The observed numbers of events and the final estimate for the expected backgrounds, separated into "Low mass" ( $m_{4 \ell}<160 \mathrm{GeV}$ ) and "High mass" ( $m_{4 \ell} \geq 160 \mathrm{GeV}$ ) regions. The expected numbers of signal events is also shown for various Higgs boson mass hypotheses. For signal and background estimates, the corresponding total uncertainty is given.

Figure 7: The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates compared to the background expectation in the range $80-600 \mathrm{GeV}$ for the (a) $\sqrt{s}=8 \mathrm{TeV} 8$ and (b) $\sqrt{s}=7 \mathrm{TeV}$ datasets. The error bars represent the $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown. The resolution of the reconstructed Higgs boson mass is dominated by detector resolution at low $m_{H}$ values and by the Higgs boson width at high $m_{H}$.

Figures 11, 12 and 13 show the observed and expected $95 \%$ CL cross section upper limits, as a function of $m_{H}$, for the $\sqrt{s}=8 \mathrm{TeV}$ data, the $\sqrt{s}=7 \mathrm{TeV}$ data and for the combination of the two datasets. Combining the two datasets, the SM Higgs boson is excluded at $95 \% \mathrm{CL}$ in the mass ranges $131-162 \mathrm{GeV}$ and $170-460 \mathrm{GeV}$. The expected exclusion ranges are $124-164 \mathrm{GeV}$ and $176-500 \mathrm{GeV}$.

Figure 8: The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates compared to the background expectation in the $80-250 \mathrm{GeV}$ mass range for the (a) $\sqrt{s}=8 \mathrm{TeV}$ and (b) $\sqrt{s}=7 \mathrm{TeV}$ datasets. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown.

The significance of an excess is given by the probability, $p_{0}$, that a background-only experiment is more signal-like in terms of the test statistic than the observed data. In Figure 14 the local $p_{0}$, obtained using the asymptotic approximation of Ref. [75], is presented as a function of the $m_{H}$ hypothesis for the combination of $\sqrt{s}=8$ and 7 TeV data samples. For comparison the results for the two data samples are given separately in Fig. 15.

The most significant upward deviations from the background-only hypothesis in the $\sqrt{s}=7 \mathrm{TeV}$ data are observed for $m_{H}=242 \mathrm{GeV}$ with a local $p_{0}$ of $0.5 \%$ ( 2.6 standard deviations), and for $m_{H}=125 \mathrm{GeV}$ with a local $p_{0}$ of $1.1 \%$ ( 2.3 standard deviations). In the $\sqrt{s}=8 \mathrm{TeV}$ data, they are at $m_{H}=125.5 \mathrm{GeV}$ with a local $p_{0}$ of $0.4 \%$ ( 2.7 standard deviations), and for $m_{H}=266 \mathrm{GeV}$ with a local $p_{0}$ of $3.5 \%$ ( 1.8 standard deviations). In the combined analysis of the two datasets, the lowest local $p_{0}$ value is $0.029 \%$ ( 3.4 standard deviations), at $m_{H}=125 \mathrm{GeV}$. The probability that such an excess occurs anywhere in the full mass range considered in this search (i.e., the look-elsewhere effect on the above $p_{0}$ value), is evaluated using the method of Ref. [76], using the mass range between 110 GeV and 141 GeV (i.e., the mass range not previously excluded at the $95 \%$ C.L. by the LHC experiments [77]). The global $p_{0}$ of the excess located at $m_{H}=125 \mathrm{GeV}$ is $0.65 \%$, or 2.5 standard deviations. In the high mass region ( $m_{H}>160 \mathrm{GeV}$ ), the lowest $p_{0}$ is at $1.9 \%$ ( 2.1 standard deviations), at $m_{H}=266 \mathrm{GeV}$.

To determine the potential effect on the $p_{0}$ due to the $S M Z Z^{(*)}$ production normalisation, a test is performed where the $Z Z^{(*)}$ normalisation is obtained directly from the data. No significant modification of the observed and expected $p_{0}$ in the low $m_{H}$ region is observed.

In Fig. 16(a) the signal strength parameter $\mu=\sigma / \sigma_{S M}$ is presented as a function of $m_{H}$ for the combination of the two data samples. The corresponding result in the case where a SM Higgs signal of $m_{H}=125 \mathrm{GeV}$ is injected is shown in Fig. 16(b). The bands illustrate the $\mu$ interval corresponding to $-2 \ln \lambda(\mu)<1$, where $\lambda$ is the profile likelihood ratio test statistic, and represent an approximate $\pm 1 \sigma$ variation. The fitted signal strength divided by the expected SM rate is denoted with $\hat{\mu}$. The expected $\hat{\mu}$ has an asymmetric shape and because the expected SM rate rises rapidly with $m_{H}$ in the low mass region, the expected $\hat{\mu}$ is increased below the injected signal mass and slightly exceeds one for a small mass

Figure 9: The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates for the $\sqrt{s}=8 \mathrm{TeV}$ analysis, for the various sub-channels (a) $4 \mu$, (b) $2 \mu 2 e$, (c) $2 e 2 \mu$, (d) $4 e$, compared to the background expectation for the $80-250 \mathrm{GeV}$ mass range. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown.
range.
Figure 17 presents the best $\mu$ and $m_{H}$ fit and the profile likelihood ratio contours that, in the asymptotic limit, would correspond to $68 \%$ and $95 \%$ confidence levels.

## 8 Summary

A search for the SM Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ based on $4.8 \mathrm{fb}^{-1}$ of data recorded with the ATLAS detector at $\sqrt{s}=7 \mathrm{TeV}$ during 2011 and $5.8 \mathrm{fb}^{-1}$ recorded at $\sqrt{s}=8 \mathrm{TeV}$ during 2012 has been presented. The SM Higgs boson is excluded at $95 \%$ CL in the mass ranges $131-$ 162 GeV and $170-460 \mathrm{GeV}$. An excess of events is observed around $m_{H}=125 \mathrm{GeV}$, whose $p_{0}$ value is

Figure 10: The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates for the $\sqrt{s}=7 \mathrm{TeV}$ analysis for the various sub-channels (a) $4 \mu$, (b) $2 \mu 2 e$, (c) $2 e 2 \mu$, (d) $4 e$, compared to the background expectation for the $80-250 \mathrm{GeV}$ mass range. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown.
$0.029 \%$ ( 3.4 standard deviations) in the combined analysis of the two datasets.

Figure 11: The expected (dashed) and observed (full line) 95\% CL upper limits on the Standard Model Higgs boson production cross section as a function of $m_{H}$, divided by the expected SM Higgs boson cross section, for the $\sqrt{s}=8 \mathrm{TeV}$ data sample. The dark (green) and light (yellow) bands indicate the expected limits with $\pm 1 \sigma$ and $\pm 2 \sigma$ fluctuations, respectively; (a) shows the low mass range, and (b) the full range under consideration.

Figure 12: The expected (dashed) and observed (full line) 95\% CL upper limits on the SM Higgs boson production cross section as a function of $m_{H}$, divided by the expected SM Higgs boson cross section for the $\sqrt{s}=7 \mathrm{TeV}$ data sample. The dark (green) and light (yellow) bands indicate the expected limits with $\pm 1 \sigma$ and $\pm 2 \sigma$ fluctuations, respectively; (a) shows the low mass range, and (b) the full range under consideration.

Figure 13: The expected (dashed) and observed (full line) $95 \%$ CL upper limits on the Standard Model Higgs boson production cross section as a function of $m_{H}$, divided by the expected SM Higgs boson cross section, for the combination of the $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data samples. The dark (green) and light (yellow) bands indicate the expected limits with $\pm 1 \sigma$ and $\pm 2 \sigma$ fluctuations, respectively; (a) shows the low mass range, and (b) the full range under consideration.

Figure 14: The observed local $p_{0}$ for the combination of the 2011 and 2012 datasets (solid line). The dashed curve shows the expected median local $p_{0}$ for the signal hypothesis when tested at the corresponding $m_{H}$. The horizontal dashed lines indicate the $p_{0}$ values corresponding to local significances of $1 \sigma, 2 \sigma, 3 \sigma$ and $4 \sigma$.

Figure 15: The observed local $p_{0}$ for the combination of the 2011 and 2012 datasets (solid black line); the $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data results are shown in solid lines (blue and red, respectively). The dashed curves show the expected median local $p_{0}$ for the signal hypothesis when tested at the corresponding $m_{H}$. The horizontal dashed lines indicate the $p_{0}$ values corresponding to local significances of $1 \sigma, 2 \sigma, 3 \sigma$ and $4 \sigma$.

Figure 16: The signal strength parameter $\mu=\sigma / \sigma_{S M}$ obtained from a fit to the data is presented (a) for the combined fit to the 2011 and 2012 data samples and (b) for the expected value of $\mu$ as a function of $m_{H}$ when a SM Higgs signal with $m_{H}=125 \mathrm{GeV}$ is injected.

Figure 17: Best fit values for $\mu$ and $m_{H}$, and likelihood ratio contours that, in the asymptotic limit, correspond to $68 \%$ and $95 \%$ level contours in the ( $\mu, m_{H}$ ) plane.

## A Auxiliary material

Figure 18: Invariant mass of the four leptons, combining all final states, demonstrating the singleresonant peak $p p \rightarrow Z \rightarrow 4 \ell$. To improve the acceptance the following modifications were performed to the nominal analysis: the requirement on $m_{12}$ is relaxed to $30 \mathrm{GeV}<m_{12}<106 \mathrm{GeV}$, the requirement on $m_{34}$ is relaxed to $5 \mathrm{GeV}<m_{34}<115 \mathrm{GeV}$, and the $p_{\mathrm{T}}$ requirement on the softest muon was relaxed to $p_{\mathrm{T}}>4 \mathrm{GeV}$. For $4 \mu$ events, the requirement on the third muon is $p_{\mathrm{T}}>8 \mathrm{GeV}$. The data are shown for (a) $\sqrt{s}=8 \mathrm{TeV}$, (b) $\sqrt{s}=7 \mathrm{TeV}$ and (c) combined.

Figure 19: Ratio of the isolation and impact parameter efficiencies between data and simulation, estimated with the Tag \& Probe method, using (a) $Z \rightarrow \mu \mu$ and (b) $Z \rightarrow e e$ events.

Figure 20: Invariant mass distributions of the lepton pairs in the control sample defined by a $Z$ boson candidate and an additional same-flavour lepton pair, for the $\sqrt{s}=8 \mathrm{TeV}$ and $\sqrt{s}=7 \mathrm{TeV}$ datasets combined. The sample is divided according to the flavour of the additional lepton pair. In (a) the $m_{12}$ and in (c) the $m_{34}$ distributions are presented for $\ell \ell+\mu \mu$ events. In (b) the $m_{12}$ and in (d) the $m_{34}$ distributions are presented for $\ell \ell+e e$ events. The kinematic selection of the analysis is applied. Isolation and impact parameter significance requirements are applied to the first lepton pair only. The MC is normalized to the data driven background estimations.

Figure 21: The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates compared to the background expectation for the $80-250 \mathrm{GeV}$ mass range for the (a) $\sqrt{s}=8 \mathrm{TeV}$, (b) $\sqrt{s}=$ 7 TeV and (c) combined datasets. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown.

Figure 22: The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates for the combination of both analyses, compared to the background expectation. The $\sqrt{s}=8$ and $\sqrt{s}=7 \mathrm{TeV}$ datasets are shown separately in (a) and (b), respectively, and combined in (c). The combined result in the range $80-600 \mathrm{GeV}$ is also shown (d). Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown.

Figure 23: The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates for the combination of both analyses for the various sub-channels, (a) $4 \mu$, (b) $2 \mu 2 e$, (c) $2 e 2 \mu$, (d) $4 e$, compared to the background expectation for the $80-250 \mathrm{GeV}$ mass range. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for several $m_{H}$ hypotheses is also shown.

Figure 24: Observed local $p_{0}$, the probability that the background fluctuates to the observed number of events or higher, for each analysis sub-channel, and for their combination. Dashed curves show the expected median local $p_{0}$ for the signal hypothesis when tested at $m_{H}$; (a) $2012(\sqrt{s}=8 \mathrm{TeV})$ data, (b) $2011(\sqrt{s}=7 \mathrm{TeV})$ data.

Figure 25: Observed local $p_{0}$, the probability that the background fluctuates to the observed number of events or higher, separating the two analyses with sub-leading muons ( $\ell \ell \mu \mu)$ from the two analyses with sub-leading electrons (८८ee); the black line shows the combined result. Dashed curves show the expected median local $p_{0}$ for the signal hypothesis when tested at $m_{H}$; (a) low mass region, (b) full mass range.

Figure 26: Observed local $p_{0}$, the probability that the background fluctuates to the observed number of events or higher, before and after the application of a $Z$ mass constraint. Dashed curves show the expected median local $p_{0}$ for the signal hypothesis when tested at $m_{H}$; (a) low mass region, (b) full mass range.

Figure 27: The observed local $p_{0}$, the probability that the background fluctuates to the observed number of events or higher, is shown as solid lines. The dashed curve shows the expected median local $p_{0}$ for the signal hypothesis when tested at $m_{H}$. (a) compares the local $p_{0}$ for the $\sqrt{s}=8 \mathrm{TeV}$ and the $\sqrt{s}=7 \mathrm{TeV}$ data samples; (b) shows the effect of allowing the irreducible background normalisation to float freely in the fit, for the $\sqrt{s}=8 \mathrm{TeV}$ data sample. The horizontal dashed lines indicate the $p_{0}$ values corresponding to local significances of $1 \sigma, 2 \sigma, 3 \sigma$ and $4 \sigma$.

Figure 28: Shape comparison of the $m_{4 \ell}$ distribution used for the $Z+j$ jets and $t \bar{t}$ contributions, in a control region where the sub-leading di-lepton fails either the isolation or the impact parameter significance requirements of the analysis, for both the $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data samples.

## ATLAS NOTE

ATLAS-CONF-2012-093
July 5, 2012

# Observation of an Excess of Events in the Search for the Standard Model Higgs boson with the ATLAS detector at the LHC 

The ATLAS Collaboration

#### Abstract

A preliminary combined search for the Standard Model Higgs boson with the ATLAS detector at the LHC is presented. The $p p$ collisions datasets used correspond to integrated luminosities of $4.6 \mathrm{fb}^{-1}$ to $4.9 \mathrm{fb}^{-1}$ at $\sqrt{s}=7 \mathrm{TeV}$ in 2011 and $5.8 \mathrm{fb}^{-1}$ to $5.9 \mathrm{fb}^{-1}$ at $\sqrt{s}=$ 8 TeV in 2012. Searches for $H \rightarrow \gamma \gamma, H \rightarrow Z Z^{(*)}, H \rightarrow W W^{(*)}, H \rightarrow b \bar{b}$, and $H \rightarrow \tau^{+} \tau^{-}$ have been performed on the 2011 data, while only the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$ searches are improved compared to previous analyses and use both the 2011 and 2012 data. The Standard Model Higgs boson is excluded at the $95 \%$ confidence level for masses in the range 110 GeV to 122.6 GeV and 129.7 GeV to 558 GeV . An excess of events is observed for a Higgs boson mass hypothesis near 126.5 GeV . The local significance of this excess is $5.0 \sigma$, where the expected significance in the presence of a Standard Model Higgs boson for that mass hypothesis is $4.6 \sigma$.

## 1 Introduction

Based on $p p$ collision data taken in 2011 at $\sqrt{s}=7 \mathrm{TeV}$, the ATLAS Collaboration reported an indication of an excess for Standard Model (SM) Higgs boson with a mass near $\sim 126.5 \mathrm{GeV}$ with a local significance of 2.9 standard deviations $(\sigma)[1]$. The global probability for the background to produce an excess at least as significant anywhere in the entire explored Higgs boson mass range of $110-600 \mathrm{GeV}$ was estimated to be $\sim 15 \%$. The mass ranges from 110.0 GeV to $117.5 \mathrm{GeV}, 118.5 \mathrm{GeV}$ to 122.5 GeV , and 129 GeV to 539 GeV were excluded at $95 \%$ confidence level (CL). The CMS collaboration performed a similar analysis of data collected in 2011, and found an excess corresponding to a local significance of $2.8 \sigma$ for $m_{H} \sim 125 \mathrm{GeV}$ [2]. The CDF and D 0 collaborations at the Tevatron have also reported an excess in the low mass region, in their combined searches for the SM Higgs boson in $p \bar{p}$ collisions [3]. The combined LEP limit [4] excludes a SM Higgs boson with a mass below 114.4 GeV at $95 \%$ CL.

These results have made the remaining mass region around 125 GeV the primary focus of the Higgs searches. This note describes the preliminary results from an improved analysis of the 2011 data and the additional 2012 data collected at $\sqrt{s}=8 \mathrm{TeV}$.

In the Standard Model [5-7], electroweak symmetry breaking is achieved via the Higgs mechanism, which results in a new particle referred to as the Higgs boson [8--13]. The Higgs boson mass, $m_{H}$, is a free parameter of the SM. However, for a given $m_{H}$ hypothesis, the production cross sections and branching ratios can be predicted. Searches for the Higgs boson in ATLAS are currently performed for twelve Higgs boson decay modes, taking into account subsequent decays of vector bosons and tau leptons. These channels are further subdivided according to lepton flavor, the presence of additional jet activity, kinematic regions, and other experimental factors in order to enhance the sensitivity. An overview of the channels is given in Table 1.

By July 2012, the LHC delivered to ATLAS $6.6 \mathrm{fb}^{-1}$ of $p p$ collisions at a center-of-mass energy of 8 TeV of which $6.2 \mathrm{fb}^{-1}$ were collected. In general, the increase in center-of-mass energy, with respect to the 7 TeV data taken in 2011, increases the signal production cross sections more than those of the backgrounds in all channels. The resulting increase in sensitivity of the analyses due to the increase in energy is equivalent to an increase in integrated luminosity of approximately 15-20\%. During 2012, the instantaneous luminosity reached record levels of approximately $7 \cdot 10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$, almost double the peak luminosity of 2011 with the same 50 ns bunch spacing. The increased luminosity thus came at the expense of an unprecedented number of $p p$ collisions per bunch crossing (pile-up), where the peak number of collisions corresponded to about 30 on average.

Due to the challenging running conditions of 2012, only the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$ channels, the two analyses most robust against pile-up, have been updated so far. The analysis of the 2011 data in these two channels has also been updated to benefit from improvements that have been made since the published result, which enhance the sensitivity to the SM Higgs boson. For $m_{H}=126.5 \mathrm{GeV}$ the expected significance in the presence of a SM from these two channels combined improves by $\sim 25 \%$ with respect to the results presented in Ref. [1]. All the other channels are unchanged with respect to Ref. [1].

## 2 Additions and Updates to 2011 Combination

## $2.1 H \rightarrow \gamma \gamma$

The $H \rightarrow \gamma \gamma$ search is carried out for $m_{H}$ hypotheses between 110 GeV and 150 GeV . The datasets used correspond to an integrated luminosity of $4.9 \mathrm{fb}^{-1}$ of $p p$ collisions collected at $\sqrt{s}=7 \mathrm{TeV}$ in 2011 and $5.9 \mathrm{fb}^{-1}$ of $p p$ collisions taken at $\sqrt{s}=8 \mathrm{TeV}$ in 2012 [14]. For this improved 2011 data analysis, the photon identification has been updated to use a neural network algorithm combining variables related

Table 1: Summary of the individual channels entering the combination. The transition points between separately optimized $m_{H}$ regions are indicated when applicable. The symbols $\otimes$ and $\oplus$ represent direct products or sums over sets of selection requirements.

to the shape of the shower in the electromagnetic calorimeter. For the 2012 data analysis, a cut-based identification algorithm is used. The analysis in this channel separates events into ten independent categories of varying sensitivity. Similarly to the analysis of Ref. [22], the categorization is based on the pseudorapidity of each photon, whether it was reconstructed as a converted or unconverted photon, and the momentum component of the diphoton system transverse to the diphoton thrust axis $\left(p_{\mathrm{T}_{t}}\right)$.

An additional two-jets category, specifically aimed at selecting events produced in the vector boson fusion (VBF) process, has been added to the analysis for both 2011 and 2012. In this category, events are required to have at least two hadronic jets with pseudorapidities $\left|\eta_{\text {jet }}\right|<4.5$ and transverse momenta in excess of 25 GeV . For the 2012 data sample, the minimum $p_{\mathrm{T}}^{\text {jet }}$ requirement is raised to 30 GeV for forward jets ( $2.5<\left|\eta_{\text {jet }}\right|<4.5$ ). The two jets are further required to have a large difference in pseudorapidity $\left(\left|\Delta \eta_{j j}\right|>2.8\right)$ and a large reconstructed invariant mass $\left(m_{j j}>400 \mathrm{GeV}\right)$. Jets in the acceptance of the inner tracking system are required to have more than $75 \%$ of their associated track momentum matched to the primary vertex. The azimuthal angle difference between the dijet and the diphoton systems is required to be larger than 2.6.

For all categories the diphoton invariant mass distribution is fitted to estimate the background and used as a discriminating variable to distinguish signal and background. The mass resolution is approximately 1.7 GeV for $m_{H} \sim 126.5 \mathrm{GeV}$, varying slightly by category. A detailed description of the $H \rightarrow \gamma \gamma$ analysis updates is reported in Ref. [14].

## 2.2 $H \rightarrow Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$

The $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$search is performed for $m_{H}$ hypotheses in the mass range between 110 GeV to 600 GeV . The datasets correspond to an integrated luminosities of $4.8 \mathrm{fb}^{-1}$ and $5.8 \mathrm{fb}^{-1}$ of $p p$ for 2011 and 2012, respectively [15]. The main irreducible $Z Z^{(*)}$ background is estimated using a Monte Carlo simulation. The reducible $Z+$ jets background, which has an impact mostly for low four-lepton invariant masses, is estimated from control regions in the data obtained by loosening the isolation and
impact parameter requirements placed on the sub-leading pair of leptons. The top-quark ( $t \bar{t}$ ) background normalization is simultaneously derived in this control region, and is validated in a separate top-enriched control region in which Z candidates are excluded. The events are categorized according to the lepton flavor combinations. The electron identification criteria have been reoptimized and the muon selection has been complemented with muons reconstructed exclusively in the muon system and muons reconstructed from tracks in the inner detector associated with energy deposits in the calorimeter compatible with minimum ionizing particles. The invariant mass of the lepton pair which is closest in mass to the Z-boson mass is required to be between $50 \mathrm{GeV}-106 \mathrm{GeV}$. The invariant mass of the other lepton pair is required to be smaller than 115 GeV and larger than a threshold ranging from 17.5 GeV to 50 GeV , depending on the reconstructed invariant four-leptons mass. A $J / \psi$ veto is applied on events with same flavor and opposite sign leptons with invariant mass smaller than 5 GeV . Several criteria have been reoptimized, including the transverse momentum of the three leading leptons, the impact parameter significance of all leptons, the calorimeter and track isolation, and the angular separation between the leptons. In addition, a kinematic fit, taking into account the natural width of the $Z$ boson and the energy and momentum resolution, improves the reconstructed Higgs boson mass resolution by $\sim 10 \%$. For $m_{4 l}<190 \mathrm{GeV}$, the $Z$ boson mass constraint is only used for the di-lepton pair with highest invariant mass, as one pair must originate from an off-shell $Z$ boson. Each of the four combinations of lepton flavor are treated as independent sub-channels. The mass resolutions are approximately $1.5 \%$ in the four-muon channel and $2 \%$ in the four-electron channel for $m_{H} \sim 120 \mathrm{GeV}$. The four-lepton invariant mass is used as a discriminating variable. A detailed description of the analysis updates in this channel is given in Ref. [15].

### 2.3 Systematic Uncertainties

Systematic uncertainties and the treatment of their correlations are unchanged with respect to Ref. [1] for all channels other than $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$. The systematic uncertainties in the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$channels have been estimated for both the 2011 and 2012 LHC running conditions. The treatment of systematic uncertainties associated with electron and photon energy scales has been updated to a more detailed model improving the treatment of correlations between electrons, converted photons, and unconverted photons.

Individual sources of systematic uncertainty affecting both 2011 and 2012 data are taken as fully correlated. The $\pm 3.9 \%$ uncertainty on the measurement of the integrated luminosity for 2011 data is considered uncorrelated with the $\pm 3.6 \%$ uncertainty on the measurement of the integrated luminosity in the 2012 data. Furthermore, the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$analyses now use an updated measurement of the integrated luminosity in 2011, which is $1.5 \%$ lower than the previous measurement with an improved uncertainty of $\pm 1.8 \%$ [?]. Since the leading uncertainties in the two estimates of the 2011 integrated luminosity arise from different sources the two estimates are treated as uncorrelated. A detailed review of all systematic uncertainties in the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$analyses is given in Refs. [14, 15].

## 3 Results

For each Higgs boson mass hypothesis the parameter of interest is the overall signal strength factor $\mu$, which acts as a scale factor to the total rate of signal events. This global factor is used for all pairings of production cross sections and branching ratios. The signal strength is defined such that $\mu=0$ corresponds to the background-only model and $\mu=1$ corresponds to the SM Higgs boson signal. The combination procedure used herein and described in Refs. [1, 23, 25] is based on the profile likelihood ratio test statistic $\lambda(\mu)$ [26]. The test statistic extracts the information on the signal strength from the full likelihood including all the parameters describing the systematic uncertainties and their correlations, and is designed
to be powerful in the presence of a SM Higgs. Exclusion limits are based on the $C L_{s}$ prescription [27]; a value of $\mu$ is regarded as excluded at the $95 \% \mathrm{CL}$ when $C L_{s}$ is less than $5 \%$. The statistical procedures are performed in a scan over the hypothesized value of the Higgs boson mass, and $m_{H}$ is held fixed in the likelihood function.

The combined $95 \%$ CL exclusion limits on $\mu$ are shown in Fig. 1 as a function of $m_{H}$. These results are based on the asymptotic approximation [26]. This procedure has been validated using ensemble tests and a Bayesian calculation of the exclusion limits with a uniform prior on the signal cross section. Typically, these two alternative approaches agree with the expected results from asymptotic approximations to within a few percent.

The expected $95 \%$ CL exclusion region covers the $m_{H}$ range from 110 GeV to 582 GeV . The observed $95 \%$ CL exclusion regions are from 110 GeV to 122.6 GeV and 129.7 GeV to 558 GeV . The addition of the $2012 H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$analyses as well as the improvements to the analysis of 2011 data in these two channels bring a significant gain in sensitivity in the low-mass region with respect to the previous combined search [1]. Figure 2] shows the $C L_{s}$ values for $\mu=1$, where it can be seen that the regions between 111.7 GeV to 121.8 GeV and 130.7 GeV to 523 GeV are excluded at the $99 \% \mathrm{CL}$. The observed exclusion covers a large part of the expected exclusion range ( 113.0 GeV to 522 GeV ), with the exception of the low mass region between 121.8 GeV and 130.7 GeV .

An excess of events is observed near $m_{H} \sim 126.5 \mathrm{GeV}$ in the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$ channels, both of which provide fully reconstructed candidates with high resolution in invariant mass. The significance of an excess is quantified by the probability $\left(p_{0}\right)$ that a background-only experiment is more signal-like than that observed. The local $p_{0}$ probability is assessed for a fixed $m_{H}$ hypothesis and the equivalent formulation in terms of number of standard deviations is referred to as the local significance. The probability for a background-only experiment to produce a local significance of this size or larger anywhere in a given mass region is referred to as the global $p_{0}$. The corresponding reduction in the significance is referred to as the "trials factor" or "look-elsewhere effect" and is estimated using the prescription described in Refs. [24,28].

The observed local $p_{0}$ values calculated using the asymptotic approximation as a function of $m_{H}$ are shown in Fig. 3. The expected $p_{0}$ corresponds to the median $p_{0}$ in the presence of a SM Higgs boson signal at that mass. The corresponding significances are shown in Fig. 4. In order to validate the asymptotic approximation for such extremely small $p$-values, an importance sampling algorithm has been used.

The largest local significance for the combined 2011+2012 analysis is found for a SM Higgs boson mass hypothesis of $m_{H}=126.5 \mathrm{GeV}$, where it reaches $5.1 \sigma$, with an expected value in the presence of a SM Higgs boson signal at that mass of $4.6 \sigma$. For the 2012 data alone, the maximum local significance for the $H \rightarrow \gamma \gamma$ and $H \rightarrow \mathrm{ZZ}^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$channels combined is $4.0 \sigma$, which occurs at $m_{H}=127.0 \mathrm{GeV}$ (3.4 $\sigma$ expected).

The significance of the excess is mildly sensitive to energy scale systematic (ESS) uncertainties and resolution for photons and electrons. The muon energy scale systematic uncertainties are smaller and therefore neglected. The presence of these uncertainties, which affect the shape and position of the signal distributions, lead to a small deviation in the distribution of the test statistic from a chi-square distribution. Previously, the observed $p_{0}$ including these effects was estimated using ensemble tests; however, the very small $p_{0}$ values makes this impractical computationally.

Here, a new approach to correcting for the leading departure from the asymptotic chi-square distribution is employed. The procedure is motivated by the observation that in the limit of very large energy scale uncertainties, an invariant mass peak could occur almost anywhere with $m_{H}$ fixed. This is essentially equivalent to the situation where $m_{H}$ is allowed to float freely in the fit, which gives rise to the look-elsewhere effect. The procedure outlined in Ref. [24, 28], which follows from theoretical work in

Ref. [29], corrects the minimum local $p$-value to the global $p$-value via

$$
\begin{equation*}
p_{0}^{\text {global }}=p_{0}^{\min \text { local }}+N e^{-\left(q_{0}\left(m_{H}\right)-u\right) / 2} \tag{1}
\end{equation*}
$$

where $N$ is the average number of times the test statistic $q_{0}\left(m_{H}\right)$ crosses some fixed value $u$ while scanning $m_{H}$ in the range considered. This corresponds to replacing the fixed threshold $u$ in the equation above with $u\left(m_{H}\right)$, a parabolic form related to the assumed Gaussian distribution of the energy scale uncertainty. A generalization of the fixed $u$ result [30] can be used to find the expected number of times the test statistic $q_{0}\left(m_{H}\right)$ is greater than $u\left(m_{H}\right)$. In essence, the correction to the local $p$-value due to energy scale systematics is similar to a look-elsewhere effect correction in a small search range. The effective size of the range, however, depends on the details of how several components to the energy scale uncertainty affect the ten different $H \rightarrow \gamma \gamma$ channels and four $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$channels. The effective $N$ can be estimated by fitting the sum of a chi-square and a falling exponential to the distribution of the test statistic created with a large number of pseudo-experiments. This hybrid ensemble-asymptotic approach was validated with much larger samples of pseudo-experiments generated for the previous combination [1] and shown to accurately reproduce the $p$-values. The result of this procedure for the full combined $2011+2012$ model results in a local significance including energy scale systematics of $5.0 \sigma$.

The global significance for local excesses depends on the range of $m_{H}$ and the channels considered. The global significance for the combined search to have a $5.0 \sigma$ excess anywhere in the mass range $110-$ 600 GeV is estimated to be approximately $4.1 \sigma$, increasing to $4.3 \sigma$ in the range $110-150 \mathrm{GeV}$ which is the range of the $H \rightarrow \gamma \gamma$ search and approximately the mass range not excluded at the $99 \%$ CL by the LHC combined SM Higgs boson search [31] and the LEP electroweak limits on a Standard Model Higgs boson [4]. The global significance for the $4.0 \sigma$ excess in the 2012 combined search to occur in the range $110-130.7 \mathrm{GeV}$, which is not excluded by the 2011 combination at $99 \%$ confidence level, is approximately $3.1 \sigma$.

The best-fit value of $\mu$, denoted $\hat{\mu}$, is displayed for the combination of all channels in Fig. 5 as a function of the $m_{H}$ hypothesis. The bands around $\hat{\mu}$ illustrate the $\mu$ interval corresponding to $-2 \ln \lambda(\mu)<$ 1 and represent an approximate $\pm 1 \sigma$ variation. While the estimator $\hat{\mu}$ is allowed to be negative in Fig. 5 in order to illustrate the presence and extent of downward fluctuations, the $\mu$ parameter is bounded to ensure non-negative values of the probability density functions in the individual channels. Hence, for negative $\hat{\mu}$ values close to the boundary, the $-2 \ln \lambda(\mu)<1$ region does not reflect a calibrated $68 \%$ confidence interval. It should be noted that $\hat{\mu}$ does not directly provide information on the relative strength of the production modes, nor does its maximum value give an estimate of the mass of a potential signal.

The best fit values of the signal strength parameter for each channel independently and for the combination are illustrated in Fig. 7 for $m_{H}=126.5 \mathrm{GeV}$. The observed excess corresponds to $\hat{\mu}$ of approximately $1.2 \pm 0.3$ for $m_{H}=126.5 \mathrm{GeV}$ with all 2011 and 2012 channels combined. This signal strength is consistent with the SM Higgs boson hypothesis $\mu=1$.

Neither the $m_{H}$ value that minimizes $p_{0}$ nor the one that maximizes $\hat{\mu}$ are unbiased estimates of the SM Higgs boson mass $m_{H}$ as they are computed using a fixed $m_{H}$ hypothesis. The maximum likelihood estimate of $m_{H}$ from the combined likelihood remains subject to further studies; however, likelihood contours of $\left(\mu, m_{H}\right)$ in the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$channels are presented in Appendix A. The probability for a single Higgs boson-like resonance to produce mass peaks separated by larger than the amount observed in these two channels, allowing the signal strengths to vary independently, is about $20 \%$.

## 4 Conclusion

Searches for the SM Higgs boson have been performed in the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$ channels with the ATLAS experiment at the LHC using 5.8-5.9 $\mathrm{fb}^{-1}$ of $p p$ collisions collected at a center-
of-mass energy of 8 TeV . These 2012 results are combined with the earlier 2011 results [1] based on an integrated luminosity of 4.7-4.9 $\mathrm{fb}^{-1}$, including improved $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$ analyses.

The observed SM Higgs boson exclusion ranges at the $95 \% \mathrm{CL}$ are 110 GeV to 122.6 GeV and 129.7 GeV to 558 GeV , while masses between 110 GeV to 582 GeV are expected to be excluded at the 95\% CL.

A significant $5 \sigma$ excess of events is observed in the search for the Standard Model Higgs boson, dominated by the two channels with the highest mass resolutions. This observation provides evidence for a new, narrow resonance at a mass near 126.5 GeV . Although the combined result including all search channels is consistent with the production and decay of a Standard Model Higgs boson, more data are needed to assess the nature of this excess.

Figure 1: The observed (full line) and expected (dashed line) $95 \%$ CL combined upper limits on the SM Higgs boson production cross section divided by the Standard Model expectation as a function of $m_{H}$ in the full mass range considered in this analysis (a) and in the low mass range (b). The dashed curves show the median expected limit in the absence of a signal and the green and yellow bands indicate the corresponding $68 \%$ and $95 \%$ intervals.

Figure 2: The value of the combined $C L_{s}$ for $\mu=1$ (testing the Standard Model Higgs boson hypothesis) as a function of $m_{H}$ in the full mass range of this analysis (a) and in the low mass range (b). The expected $C L_{s}$ is shown in the dashed curves. The regions with $C L_{s}<\alpha$ are excluded at least at ( $1-\alpha$ ) CL. The $95 \%$ and $99 \%$ CL values are indicated as dashed horizontal lines.

Figure 3: The local probability $p_{0}$ for a background-only experiment to be more signal-like than the observation in the full mass range of this analysis (a) and in the low mass range (b) as a function of $m_{H}$. The dashed curves show the median expected local $p_{0}$ under the hypothesis of a Standard Model Higgs boson production signal at that mass. The horizontal dashed lines indicate the $p$-values corresponding to significances of $1 \sigma$ to $6 \sigma$. Energy scale systematics are not included; taking them into account leads to a small negative correction $\sim 0.1 \sigma$ near $m_{H}=126 \mathrm{GeV}$.

Figure 4: The same as Fig. 3 shown in terms of local significance. An excess (deficit) of events corresponds to a positive (negative) local significance. This presentation makes clear the magnitude of a local deficit of events, where the logarithmic scale in Fig. 3 compresses large values of $p_{0}$. The dashed curves show the median expected local $p_{0}$ under the hypothesis of a Standard Model Higgs boson production signal at that mass. The horizontal dashed lines indicate significances ranging from $-2 \sigma$ to $5 \sigma$. Energy scale systematics are not included; taking them into account leads to a small correction $\sim 0.1 \sigma$ near $m_{H}=126 \mathrm{GeV}$.

Figure 5: The combined best-fit signal strength $\hat{\mu}$ as a function of the Higgs boson mass hypothesis (a) in the full mass range of this analysis and (b) in the low mass range. The interval around $\hat{\mu}$ corresponds to a variation of $-2 \ln \lambda(\mu)<1$.

Figure 6: The evolution of the local probability $p_{0}$ and the best-fit signal strength $\hat{\mu}$ from the 2011 data, the 2012 data, and their combination.

Figure 7: Summary of the individual and combined best-fit values of the strength parameter for a Higgs boson mass hypothesis of 126.5 GeV .

Figure 8: Summary of the individual and combined best-fit values of the strength parameter for three sample Higgs boson mass hypotheses of $119 \mathrm{GeV}, 126.5 \mathrm{GeV}$ and 130 GeV .

Figure 9: Likelihood contours in ( $\mu, m_{H}$ ) for the $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$and $H \rightarrow \gamma \gamma$ channels including energy scale systematics are shown in panel (a). The comparison of the contours with (thick lines) and without (thin lines in lighter colors) energy scale systematics is shown in panel (b).

## Appendix A: Contours in $\left(\mu, m_{H}\right)$ for $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$

The results presented so far do not give any information about the range of masses consistent with a potential signal, because the statistical procedure is performed in a scan over $m_{H}$ with $m_{H}$ fixed in the likelihood as if it were known a priori. These shortcomings are addressed by considering various contours of the likelihood function.

In order to address the values of the signal strength and mass of a potential signal that are simultaneously consistent with the data, the following profile likelihood ratio is used:

$$
\begin{equation*}
\lambda\left(\mu, m_{H}\right)=\frac{L\left(\mu, m_{H}, \hat{\boldsymbol{\theta}}\left(\mu, m_{H}\right)\right)}{L\left(\hat{\mu}, \hat{m}_{H}, \hat{\boldsymbol{\theta}}\right)} \tag{2}
\end{equation*}
$$

were $\hat{\boldsymbol{\theta}}\left(\mu, m_{H}\right)$ is the conditional maximum likelihood estimate with $\mu$ and $m_{H}$ fixed. In the presence of a strong signal, this test statistic will produce closed contours about the best fit point $\left(\hat{\mu}, \hat{m}_{h}\right)$; while in the absence of a signal the contours will be upper limits on $\mu$ for all values of $m_{H}$.

Asymptotically, the test statistic $-2 \ln \lambda\left(\mu, m_{H}\right)$ is distributed as a $\chi^{2}$ distribution with two degrees of freedom. In particular, the $100(1-\alpha) \%$ confidence level contours are defined by $-2 \ln \lambda\left(\mu, m_{H}\right)<k_{\alpha}$, where $k_{\alpha}$ satisfies $P\left(\chi_{2}^{2}>k_{\alpha}\right)=\alpha$.

The $68 \%$ and $95 \%$ CL contours for the $H \rightarrow \gamma \gamma$ channel are shown in Fig 9 , where the asymptotic approximations have been validated with ensembles of pseudo-experiments. Similar contours for the $H \rightarrow \mathrm{ZZ}^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$channel are shown in Fig 9 , where the distribution of $-2 \ln \lambda\left(\mu, m_{H}\right)$ is not expected to have converged to the asymptotic distribution. These preliminary contours in the ( $\mu, m_{H}$ ) plane take into account uncertainty in the energy scale and resolution. The impact of these uncertainties is illustrated in Fig. 9 (b).

The probability for a single Higgs boson-like resonance to produce mass peaks separated by larger than the amount observed in these two channels, allowing the signal strengths to vary independently, is about $20 \%$.

## Appendix B: Individual Channels and Combined Results

The individual channels observed and expected results in terms of CL limits, local probability $p_{0}$ and the corresponding significance are shown in Fig. 10, Fig. 11, and Fig. 12. The expected only results are shown in Fig. 13, Fig. 14, and Fig. 15 ,

Figure 10: The observed (solid) and expected (dashed) $95 \%$ CL cross section upper limits for the individual search channels and the combination, normalized to the SM Higgs boson production cross section, as a function of the Higgs boson mass hypothesis; (a) for the full Higgs boson mass hypotheses range and (b) in the low mass range. The expected limits are those for the background-only hypothesis i.e. in the absence of a Higgs boson signal.

Figure 11: The local probability $p_{0}$ for a background-only experiment to be more signal-like than the observation, for individual channels and the combination; (a) in the full mass range of $110-600 \mathrm{GeV}$ and (b) in the low mass range of $110-150 \mathrm{GeV}$. The full curves give the observed individual and combined $p_{0}$. The dashed curves show the median expected value under the hypothesis of a SM Higgs boson signal at that mass. The horizontal dashed lines indicate the $p_{0}$ corresponding to significances of $1 \sigma, 2 \sigma, 3 \sigma$, $4 \sigma$ and $5 \sigma$.

Figure 12: The local significance in terms of standard deviations for individual channels and the combination; (a) in the full mass range of $110-600 \mathrm{GeV}$ and (b) in the low mass range of $110-150 \mathrm{GeV}$. The full curves give the observed individual and combined local significances. The dashed curves show the median expected value under the hypothesis of a SM Higgs boson signal at that mass.

Figure 13: The expected $95 \%$ CL cross section upper limits for the individual search channels and the combination, normalized to the SM Higgs boson production cross section, as a function of the Higgs boson mass hypothesis; (a) for the full Higgs boson mass hypotheses range and (b) in the low mass range. The expected limits are those for the background-only hypothesis i.e. in the absence of a Higgs boson signal.

Figure 14: The expected local probability $p_{0}$ for a background-only experiment to be more signal-like than the observation, for individual channels and the combination; (a) in the full mass range of 110600 GeV and (b) in the low mass range of $110-150 \mathrm{GeV}$. The horizontal dashed lines indicate the $p_{0}$ corresponding to significances of $1 \sigma$ to $5 \sigma$.

Figure 15: The expected local significance in terms of standard deviations for individual channels and the combination. (a) In the full mass range of $110-600 \mathrm{GeV}$ and (b) in the low mass range of $110-150 \mathrm{GeV}$.

## Appendix C: Results from 2012

The primary results are shown here for the combination of the $2012 H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$ search channels alone.

Figure 16: The observed (full line) and expected (dashed line) 95\% CL combined upper limits on the SM Higgs boson production cross section divided by the Standard Model expectation as a function of $m_{H}$ for the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$analysis on 2012 data. The dashed curve shows the median expected limit in the absence of a signal and the green and yellow bands indicate the corresponding $68 \%$ and $95 \%$ intervals.

Figure 17: The value of the combined $C L_{s}$ for $\mu=1$ (testing the Standard Model Higgs boson hypothesis) as a function of $m_{H}$ for the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$analysis on 2012 data. The regions with $C L_{s}<\alpha$ are excluded at least at $(1-\alpha) \mathrm{CL}$. The $95 \%$ and $99 \% \mathrm{CL}$ values are indicated as dashed lines.

Figure 18: The local probability $p_{0}$ for a background-only experiment to be more signal-like than the observation as a function of $m_{H}$ for the $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$analysis on 2012 data. The dashed curves show the median expected local $p_{0}$ under the hypothesis of a Standard Model Higgs boson production signal at that mass. The horizontal dashed lines indicate the $p$-values corresponding to significances of $1 \sigma$ to $5 \sigma$.

Figure 19: The same as Fig. 18 shown in terms of local significance. An excess (deficit) of events corresponds to a positive (negative) local significance. This presentation makes clear the magnitude of a local deficit of events, where the logarithmic scale in Fig. 18 compresses large values of $p_{0}$. The dashed curves show the median expected local $p_{0}$ under the hypothesis of a Standard Model Higgs boson production signal at that mass. The horizontal dashed lines indicate significances ranging from $-2 \sigma$ to $5 \sigma$. Energy scale systematics are not included.

Figure 20: The combined best-fit signal strength $\hat{\mu}$ as a function of the Higgs boson mass hypothesis for the combination of the $2012 H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$analysis. The interval around $\hat{\mu}$ corresponds to a variation of $-2 \ln \lambda(\mu)<1$.

## Appendix D: Alternative Combinations

In order to compare the results obtained in the high mass resolution channels, $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow$ $\ell^{+} \ell^{-} \ell^{+} \ell^{-}$, with those of low mass resolution $H \rightarrow W W^{(*)} \rightarrow \ell^{+} v \ell^{-} \bar{v}, H \rightarrow \tau^{+} \tau^{-}$and $H \rightarrow b \bar{b}$, a separate combination of these channels is performed. The results are illustrated in Fig. 21.

Figure 21: (a) The local probability $p_{0}$ for a background-only experiment to be more signal-like than the observation and (b) the $95 \%$ CL upper limit on the Standard Model Higgs boson production cross section divided by the SM expectation as a function of $m_{H}$ is indicated by the solid curves for the combination of the high mass resolution $H \rightarrow \gamma \gamma$ and $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{+} \ell^{-}$channels (red), the low mass resolution channels $H \rightarrow W W^{(*)} \rightarrow \ell^{+} v \ell^{-} \bar{v}, H \rightarrow \tau^{+} \tau^{-}$and $H \rightarrow b \bar{b}$ channels (blue), and all channels (black). The dashed curves show (a) the median expected $p_{0}$ value under the hypothesis of a SM Higgs boson signal at that mass and (b) the median expected limit in the absence of a signal. The green and yellow bands indicate the corresponding $68 \%$ and $95 \%$ intervals for the full combination.

## ATLAS NOTE

August 30, 2012

# Observation of an Excess of Events in the Search for the Standard Model Higgs Boson in the $\boldsymbol{H} \rightarrow \boldsymbol{W} \boldsymbol{W}^{(*)} \rightarrow \ell \nu \ell v$ Channel with the ATLAS <br> Detector 

The ATLAS Collaboration

#### Abstract

A Standard Model Higgs boson search in the $H \rightarrow W W^{(*)} \rightarrow e v \mu \nu$ decay mode has been performed using proton-proton collision data corresponding to an integrated luminosity of $5.8 \mathrm{fb}^{-1}$ at a centre-of-mass energy of 8 TeV collected during 2012 with the ATLAS detector at the Large Hadron Collider. The search focuses on the mass region around 125 GeV , not previously excluded, where an excess of events over the expected background is observed corresponding to a local $p_{0}$-value of $6 \times 10^{-4}$ or 3.2 standard deviations. In a combined analysis of the 2012 data with the $4.7 \mathrm{fb}^{-1}$ of data acquired at $\sqrt{s}=7 \mathrm{TeV}$ in 2011, the observed excess in the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channel corresponds to a minimum local $p_{0}$ of $3 \times 10^{-3}$ or 2.8 standard deviations.

This note has been modified from the original version dated 17 July to correct and improve the presentation. The results of the analysis are unchanged. The systematic uncertainties given in Table 4 were for the expected signal and backgrounds without upper and lower $m_{\mathrm{T}}$ thresholds, and have been changed to the uncertainties with the $m_{\mathrm{T}}$ thresholds applied. The systematic uncertainty on the muon fake factor was incorrectly stated as $60 \%$; it is $40 \%$ and has been corrected. The single top and $Z \rightarrow 4 \ell$ cross sections have been corrected in Table 1. The uncertainty on the normalisation factor for the top background in the $H+2$-jet analysis now includes the statistical uncertainty from the number of events in the control region. The best-fit $\mu$ value is quoted at $m_{H}=126 \mathrm{GeV}$, not 125 GeV , for consistency with the published results. Finally, there have been some small modifications to clarify the text.

## 1 Introduction

The Standard Model (SM) of particle physics [1-3] has been tested by many experiments over the last four decades and has been shown to successfully describe high energy phenomena. However, the mechanism that breaks electroweak symmetry in the SM still remains to be confirmed experimentally. This mechanism [4-6], which gives mass to all massive elementary particles, predicts the existence of a scalar particle, the Higgs boson. It is the only elementary particle in the SM that has not yet been observed and the search for the Higgs boson is a centrepiece of the LHC physics programme.

Indirect limits on the Higgs boson mass of $m_{H}<158 \mathrm{GeV}$ at $95 \%$ confidence level (CL) have been set using global fits to precision electroweak results [7]. Direct searches at LEP and the Tevatron have excluded at $95 \%$ CL a SM Higgs boson with a mass below 114.4 GeV [8] and in the regions $147 \mathrm{GeV}<m_{H}<180 \mathrm{GeV}$ and $100 \mathrm{GeV}<m_{H}<103 \mathrm{GeV}$ [9], respectively.

The results of searches in various channels using $\sqrt{s}=7 \mathrm{TeV}$ data corresponding to an integrated luminosity of approximately $5 \mathrm{fb}^{-1}$ have been reported recently by the ATLAS Collaboration, excluding the mass ranges $112.9 \mathrm{GeV}-115.5 \mathrm{GeV}, 131 \mathrm{GeV}-238 \mathrm{GeV}$, and $251 \mathrm{GeV}-466 \mathrm{GeV}$ [10]; and by the CMS Collaboration, excluding the mass range from 127 GeV to 600 GeV [11]. Due to the narrow region remaining in $m_{H}$ after the exclusions made from the 2011 data, the hypothesis of $m_{H}=125 \mathrm{GeV}$ is used to characterise the signal for many aspects of the search presented here.

The $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channel (with $\ell=e, \mu$ ) is particularly sensitive in the mass range $120<$ $m_{H}<200 \mathrm{GeV}$. This channel can play an important role in the determination of the coupling of the Higgs boson to $W$ bosons. The branching ratio to $W W$ falls off with decreasing $m_{H}$ below $m_{H}=2 m_{W}$ but is still just over $20 \%$ at $m_{H}=125 \mathrm{GeV}$ [12], and the dilepton final state allows the selection of events with a favourable signal-to-background ratio. The leading backgrounds are continuum $W W \rightarrow$ $\ell \nu \ell \nu$ production and $t \bar{t}$ events in which both $W$ bosons decay to $\ell \nu$. Additional sources of background include Drell-Yan ( $p p \rightarrow Z / \gamma^{*} \rightarrow \ell \ell$ ), $W+$ jets, single top, $W\left(Z / \gamma^{(*)}\right.$ ), and $Z Z$ events.

The previous $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell v$ search results reported by the ATLAS collaboration used the full 2011 dataset, corresponding to $4.7 \mathrm{fb}^{-1}$ of proton-proton $(p p)$ collisions at $\sqrt{s}=7 \mathrm{TeV}$, and excluded a SM Higgs boson in the mass range $133 \mathrm{GeV}<m_{H}<261 \mathrm{GeV}$ at $95 \%$ CL [13]. A similar search has been performed by the CMS Collaboration [14]. The analysis described here uses a dataset collected between the beginning of April to the middle of June 2012, which after requiring that all detector components are fully functional, corresponds to $5.8 \mathrm{fb}^{-1}$ of $p p$ collision data at a centre-of-mass of 8 TeV . The production cross section of a Higgs boson with $m_{H}=125 \mathrm{GeV}$ increases by about $30 \%$ with the increase of the centre-of-mass energy of the Large Hadron Collider from 7 TeV to 8 TeV . The analysis methodology reported in Ref. [13] is mostly unchanged, but some selection criteria have been modified to reduce background contributions while coping with the higher instantaneous luminosity of the LHC in 2012. In particular, the data are affected by the occurrence of multiple $p p$ collisions per bunch crossing, referred to as "pile-up". In the 2011 data the average number of interactions per bunch crossing was around 10. In 2012, the average has increased to around 20 . This results in significantly larger Drell-Yan background to the same-flavour final states, due to an increased rate of fake missing transverse energy. Since the $e \mu$ final state provides the large majority of the sensitivity of the search, only this final state has been used in the analysis reported here. Finally, more stringent isolation criteria are applied, to further reduce the $W+$ jets background.

Motivated by the 2011 combined Higgs searches [10], the analysis procedure was modified to blind the kinematic region where a signal might be expected. Events passing the kinematic selection designed to isolate a signal from a SM Higgs boson with a mass between 110 and 140 GeV were excluded during the development of the 2012 analysis. The signal region data were unblinded once the agreement between data and the background model in the control regions corresponding to the
dominant backgrounds was judged to be reasonable.
In the last part of this document, the results obtained at $\sqrt{s}=8 \mathrm{TeV}$ with $5.8 \mathrm{fb}^{-1}$ of data are combined with the published $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell v$ results from the 2011 dataset.

## 2 Data and simulated samples

The data used for this analysis were collected in 2012 using the ATLAS detector, a multi-purpose particle physics experiment with a forward-backward symmetric cylindrical geometry and near $4 \pi$ coverage in solid angle [15]. ATLAS consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadronic calorimeters, and an external muon spectrometer incorporating large superconducting air-core toroid magnets. The combination of these systems provides charged particle measurements together with efficient and precise lepton measurements over the pseudorapidity ${ }^{1}$ range $|\eta|<2.5$. Jets are reconstructed over the full coverage of the calorimeters, $|\eta|<4.9$; this calorimeter coverage also provides a measurement of the missing transverse momentum $E_{\mathrm{T}}^{\text {miss }}$.

The data used for this analysis were collected using inclusive single-muon and single-electron triggers. The two main triggers require the transverse momentum of the lepton with respect to the beam line, $p_{\mathrm{T}}$, to exceed 24 GeV and that the lepton be isolated: the scalar sum of the $p_{\mathrm{T}}$ of charged particles within $\Delta R=\sqrt{\Delta \phi^{2}+\Delta \eta^{2}}=0.2$ of the lepton direction is required to be less than 0.12 and 0.10 times the lepton $p_{\mathrm{T}}$ for the muon and electron, respectively. Because of the detector geometry, the acceptance of the muon trigger is limited to $|\eta|<2.4$. The trigger efficiencies are measured as a function of $p_{\mathrm{T}}, \eta$, and data-taking period using $Z$ events. The efficiencies are approximately $90 \%$ for electrons, and $90 \%$ ( $70 \%$ ) for muons in the endcap (barrel).

In this analysis, the signal contributions considered include the dominant gluon fusion production process ( $g g \rightarrow H$, denoted as $g g \mathrm{~F}$ ), the vector-boson fusion production process ( $q q^{\prime} \rightarrow q q^{\prime} H$, denoted as VBF) and the Higgs-strahlung process ( $q q^{\prime} \rightarrow W H, Z H$, denoted as $\left.W H / Z H\right)$. The $t \bar{t} H$ production mechanism is negligible due to its smaller cross section. For the decay of the Higgs boson, only the $H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ mode is considered, including the small contributions from leptonic $\tau$ decays. The branching fraction for this decay as a function of $m_{H}$ is calculated using the Prophecy 4 F [30,31] program, with HDECAY also used in calculating the total width [32].

The signal cross section is computed to next-to-next-to-leading order (NNLO) [33-38] in QCD for the ggF process using the MSTW2008 PDF set [39]. Next-to-leading order (NLO) electroweak (EW) corrections are also applied [40,41], as well as QCD soft-gluon resummations up to next-to-next-toleading $\log$ (NNLL) [42]. These calculations are detailed in Refs. [43,44], and assume factorisation between the QCD and EW corrections.

Approximate NNLO QCD corrections [45] and full NLO QCD and EW corrections [46-48] and are used to calculate the cross sections for VBF signal production. The cross sections of the associated $W H / Z H$ production processes are calculated up to NNLO QCD corrections [49, 50] and NLO EW corrections [51].

The Monte Carlo (MC) generators used to model signal and background processes are listed in Table 1. For most processes, separate programs are used to generate the hard scattering process and to model the parton showering, hadronisation, and the underlying event. PYTHIA [28] or PYTHIA8

[^70]Table 1: MC generators used to model the signal and background processes, and the corresponding cross sections at $\sqrt{s}=8 \mathrm{TeV}$ (given $m_{H}=125 \mathrm{GeV}$ in the case of the signal processes). The ggF Higgs boson $p_{\mathrm{T}}$ spectrum in POWHEG [12] is tuned to agree with the prediction from HqT [16]. Finite heavy quark mass effects in the gluon-gluon production are also included [17]. The relevant single-top production channels ( $s$-channel and $W t$ ) are included. The number quoted for the inclusive $Z / \gamma^{*}$ process (also referred to in the text as the Drell-Yan process) is for generated dilepton invariant masses greater than 10 GeV . Kinematic criteria are also applied in the generation of $W(\rightarrow \ell v) \gamma$ events (the photon must have $p_{\mathrm{T}}>8 \mathrm{GeV}$ and be separated from the charged lepton by $\left.\Delta R=\sqrt{\left(\Delta \eta^{2}\right)+\left(\Delta \phi^{2}\right)}>0.25\right)$ and $W(\rightarrow \ell v) \gamma^{*}\left(\rightarrow \ell^{\prime} \ell^{\prime}\right)$ events (at least two leptons have $p_{T}$ larger than 5 GeV and $|\eta|<3$ for the $e e$ and $\mu \mu$ case, and $|\eta|<5$ for the $\tau \tau$ case). The $Z^{(*)} Z^{(*)} \rightarrow 4 \ell$ samples are generated with an invariant mass cut of $m_{\ell \ell}>4 \mathrm{GeV}$. For the $W Z^{(*)}$ and $W \gamma^{*}$ processes, MADGRAPH includes the interference between the $Z^{(*)}$ and the $\gamma^{*}$, and the boundary between the samples is at $m_{\ell \ell}=7 \mathrm{GeV}$. For the $W \gamma^{*}$ a lower invariant mass cut of $m_{\ell \ell}>2 m_{e}$ is applied. Leptonic decays of $W / Z$ bosons are always assumed, and the quoted cross sections include the branching ratios and are summed over lepton flavours. The exception is top quark production; for which inclusive cross sections are quoted.

| Process | Generator | $m_{H}(\mathrm{GeV})$ | $\sigma \cdot \mathrm{Br}(\mathrm{pb})$ |
| :--- | :--- | ---: | ---: |
| ggF | POWHEG [18]+PYTHIA8 [19] | 125 | 0.441 |
| VBF | POWHEG [20]+PYTHIA8 | 125 | $35 \cdot 10^{-3}$ |
| $W H / Z H$ | PYTHIA8 | 125 | $25 \cdot 10^{-3}$ |
| $q \bar{q} / g \rightarrow W W$ | MC@NLO [21]+HERWIG [22] | 5.68 |  |
| $g g \rightarrow W W$ | GG2WW [23]+HERWIG | 0.16 |  |
| $t \bar{t}$ | MC@NLO+HERWIG | 238 |  |
| $t W / t b$ | MC@NLO+HERWIG | 28 |  |
| $t q b$ | AcerMC [24]+PYTHIA | 88 |  |
| inclusive $W$ | ALPGEN [25]+HERWIG | $37 \cdot 10^{3}$ |  |
| inclusive $Z / \gamma^{*}$ | ALPGEN+HERWIG | $16 \cdot 10^{3}$ |  |
| $Z^{(*)} Z^{(*)} \rightarrow 4 l$ | POWHEG+PYTHIA8 | 0.73 |  |
| $W Z^{(*)}$ | MADGRAPH [26,27]+PYTHIA [28] | 1.54 |  |
| $W \gamma^{*}$ | MADGRAPH [29]+PYTHIA | 9.26 |  |
| $W \gamma$ | ALPGEN+HERWIG | 369 |  |

[19] are used for these latter three steps for the signal and some of the background processes. When HERWIG [22] is used for the hadronisation and parton showering the underlying event is modelled using JIMMY [52]. The MLM matching scheme [53] is used for the description of the $W+$ jets, $Z / \gamma^{*}+$ jets and $W \gamma$ processes. The cross sections for the $W \gamma$ and $W \gamma^{*} / W Z^{(*)}$ processes are normalised to the MCFM [54] NLO predictions. These normalisation factors (K-factors) are calculated to be 1.15 for $W \gamma, 1.3$ for $W \gamma^{*}\left(m_{\ell \ell}<7 \mathrm{GeV}\right)$ and 1.51 for $W Z^{(*)}\left(m_{\ell \ell}>7 \mathrm{GeV}\right)$.

The CT10 parton distribution function (PDF) set [55] is used for the POWHEG and MC@NLO samples, and CTEQ6L1 [56] is used for the ALPGEN, MadGraph, and PYTHIA8 samples. Acceptances and efficiencies are obtained from a full simulation [57] of the ATLAS detector using GEANT4 [58]. The simulation incorporates a model of the pile-up conditions in the 2012 data, including both the effects of multiple $p p$ collisions in the same bunch crossing ("in-time" pile-up) and in nearby bunch crossings ("out-of-time" pile-up).

## 3 Event selection

Events are required to have a primary vertex consistent with the beam spot position, with at least three associated tracks with $p_{\mathrm{T}}>400 \mathrm{MeV}$. Data quality criteria are applied to events in order to suppress non-collision backgrounds such as cosmic-ray muons, beam-related backgrounds, or noise in the calorimeters.
$H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell v$ candidates (with $\ell=e, \mu$ ) are pre-selected by requiring exactly two oppositely charged leptons of different flavours, with $p_{\mathrm{T}}$ thresholds of 25 GeV and 15 GeV for the leading and sub-leading lepton, respectively. Events are classified into two exclusive lepton channels depending on the flavour of the leading lepton: in the following, $e \mu(\mu e)$ will refer to events with a leading electron (muon). The dilepton invariant mass is required to be greater than 10 GeV . For muons, the range $|\eta|<2.5$ is used; for electrons, the range $|\eta|<2.47$ is used, with the region $1.37<|\eta|<1.52$, corresponding to the boundary between barrel and end-cap calorimeters, excluded.

Electron candidates are selected by applying a set of tight identification criteria using a combination of tracking and calorimetric information. The fine lateral and longitudinal segmentation of the calorimeter and transition radiation capability of the ATLAS detector have allowed the previous levels of electron performance [59] to be retained in the increased pile-up environment of the 2012 data taking. Muon candidates are identified by matching tracks reconstructed in the inner detector and in the muon spectrometer [60]. Requirements on the number of hits in all three components of the inner detector (pixels, SCT, and TRT) provide background rejection, particularly against pion/kaon decays-in-flight.

At least one of the selected leptons is required to match a triggering object. Leptons from heavyflavour decays and jets satisfying the lepton identification criteria are suppressed by requiring the leptons to be isolated: the scalar sum of the $p_{T}$ of charged particles and of the calorimeter energy deposits within $\Delta R=\sqrt{\Delta \phi^{2}+\Delta \eta^{2}}=0.3$ of the lepton direction (excluding the lepton itself) are each required to be less than $0.12-0.20$ times the lepton $p_{\mathrm{T}}$. The exact value differs between the trackand calorimeter-based criteria, between electrons and muons, and depend on the lepton $p_{\mathrm{T}}$.

Drell-Yan and QCD multijet events are suppressed by requiring large $E_{\mathrm{T}}^{\mathrm{miss}}$ [61]. The $E_{\mathrm{T}}^{\mathrm{miss}}$ is the magnitude of $\mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}$, the opposite of the vector sum of the transverse momenta of the reconstructed objects, including muons, electrons, photons, jets, and clusters of calorimeter cells not associated with these objects. The quantity $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ used in this analysis is defined as: $E_{\mathrm{T}, \mathrm{rel}}^{\mathrm{miss}}=E_{\mathrm{T}}^{\mathrm{miss}} \sin \Delta \phi_{\mathrm{min}}$, with $\Delta \phi_{\min } \equiv \min \left(\Delta \phi, \frac{\pi}{2}\right)$. Here, $\Delta \phi$ is the minimum azimuthal angle between $\mathbf{E}_{\mathrm{T}}^{\text {miss }}$ and the leading lepton, the sub-leading lepton or any jet with $p_{\mathrm{T}}>25 \mathrm{GeV}$.

Compared to $E_{\mathrm{T}}^{\mathrm{miss}}$, the use of $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ increases the rejection of events with significant mismeasurement of a jet or a lepton, since in such events the direction in $\phi$ of the $\mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}$ is correlated with the direction of the mismeasured object. Figure 1 shows the distribution of $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ in dilepton events passing all of the selection above, up to but not including the $E_{\mathrm{T} \text {,rel }}^{\mathrm{miss}}$ threshold. The threshold applied in this analysis is 25 GeV . Any multijet background present at this stage is included in the $W+$ jets background estimate. After the lepton isolation and $E_{\mathrm{T}, \text { rel }}^{\mathrm{miss}}$ requirements, the multijet background is negligible and the Drell-Yan background is much reduced. The Drell-Yan contribution becomes negligible after the topological selections, described later in this section, are applied.

Figure 1 shows the multiplicity distribution of jets reconstructed using the anti- $k_{t}$ algorithm [62], with distance parameter $R=0.4$, for all events satisfying the pre-selection criteria described above including the $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ requirement. Only jets with $p_{\mathrm{T}}>25 \mathrm{GeV}$ and $|\eta|<4.5$ are considered. The jet $p_{\mathrm{T}}$ threshold is increased to 30 GeV in the forward region $2.5<|\eta|<4.5$ to reduce the contribution from jets produced by pile-up. In order to reject jets that are produced in the central part of the detector by

Figure 1: $E_{\mathrm{T}, \text { rel }}^{\mathrm{miss}}(\mathrm{left})$ and multiplicity of jets (right) for events satisfying the pre-selection criteria described in the text. (No $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ requirement is applied in the $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ distribution.) The jet selection applied is $p_{T}^{j e t}>25 \mathrm{GeV}$ for $\left|\eta^{j e t}\right|<2.5$ and $p_{T}^{j e t}>30 \mathrm{GeV}$ for $2.5<\left|\eta^{j e t}\right|<4.5$. The lepton channels are combined. The hashed area indicates the total uncertainty on the background prediction. The $W W$ and top backgrounds are scaled to use the normalisation derived from the corresponding control regions described in the text. The expected signal for a SM Higgs boson with $m_{H}=125 \mathrm{GeV}$ is superimposed.
pile-up interactions, a selection criterion is applied to each jet with $|\eta|<2.5$ on a quantity called the jet vertex fraction (JVF). The JVF is defined, using the charged tracks associated with a given jet, to be the $p_{\mathrm{T}}$ sum of the tracks originating from the primary vertex divided by the $p_{\mathrm{T}}$ sum of all of the tracks. Jets are required to have JVF $>0.5$. This selection was found to be robust against pile-up, based on studies of the dependence of the jet multiplicity on the number of reconstructed vertices in the $2012 Z+$ jet data. Figure 2 shows the ratio of $Z \rightarrow \mu \mu+1$-jet events to all $Z \rightarrow \mu \mu$ events as a function of the number of reconstructed primary vertices. The events are selected by applying the pre-selection criteria (excluding the $E_{\mathrm{T} \text {,rel }}^{\mathrm{miss}}$ requirement) with two muons and an additional requirement on the invariant mass ( $\left|m_{\mu \mu}-m_{Z}\right|<15 \mathrm{GeV}$ ) in order to select $Z$ events. No dependence is seen with the jet selection described above.

The background rate and composition depend significantly on the jet multiplicity, as does the signal topology. Without accompanying jets, the signal originates almost entirely from the ggF process and the background is dominated by $W W$ and Drell-Yan events. In contrast, when produced in association with two or more jets, the signal contains a much larger contribution from the VBF process and the background is dominated by $t \bar{t}$ production. To maximise the sensitivity, further selection criteria that depend on the jet multiplicity are applied to the pre-selected sample. The data are subdivided into $H+0$-jet, $H+1$-jet and $H+2$-jet channels according to the jet counting defined above (with the $H+2$-jet channel also including higher jet multiplicities at this stage). The different requirements for these channels are described in more detail below.

Due to spin correlations in the $W W^{(*)}$ system arising from the spin-0 nature of the SM Higgs boson and the V-A structure of the $W$ boson decay, the charged leptons tend to emerge from the interaction point in the same direction. This kinematic feature is exploited for all jet multiplicities by requiring that the azimuthal angular difference between the leptons, $\Delta \phi_{\ell \ell}$, be less than 1.8 radians, and that the dilepton invariant mass, $m_{\ell \ell}$, be less than 50 GeV for the $H+0$-jet and $H+1$-jet channels. For the $H+2$-jet channel, the $m_{\ell \ell}$ upper bound is increased to 80 GeV . The $m_{\ell \ell}$ distribution is somewhat harder

Figure 2: Ratio of $Z \rightarrow \mu \mu+1$-jet events to all $Z \rightarrow \mu \mu$ candidates as a function of the number of reconstructed primary vertices in the event. The selected events must pass the pre-selection criteria, excluding the $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ requirement, with the additional selection of $\left|m_{\mu \mu}-m_{Z}\right|<15 \mathrm{GeV}$. Only statistical uncertainties are included.
for the $H+2$-jet topology since the Higgs boson is more strongly boosted, reducing the alignment of the $W \mathrm{~s}$ and decorrelating the lepton directions.

In the $H+0$-jet channel, the magnitude $p_{\mathrm{T}}^{\ell \ell}$ of the transverse momentum of the dilepton system, $\mathbf{p}_{\mathrm{T}}^{\ell \ell}=\mathbf{p}_{\mathrm{T}}^{\ell 1}+\mathbf{p}_{\mathrm{T}}^{\ell 2}$, is required to be greater than 30 GeV . This improves the rejection of the Drell-Yan background.

In the $H+1$-jet channel, backgrounds from top quark decays are suppressed by rejecting events containing a jet identified as being consistent with originating from the decay of a $b$ or $c$ quark $(b-$ tagged jet), using a $b$-tagging algorithm based on a neural network that exploits the topology of weak decays of $b$ - and $c$-hadrons [63]. The algorithm is tuned to achieve an $85 \% b$-jet identification efficiency in $t \bar{t}$ events while yielding a light-jet tagging rate of approximately $11 \%$ [64]. The total transverse momentum, $p_{\mathrm{T}}^{\text {tot }}$, defined as the magnitude of the vector $\operatorname{sum} \mathbf{p}_{\mathrm{T}}^{\text {tot }}=\mathbf{p}_{\mathrm{T}}^{\ell 1}+\mathbf{p}_{\mathrm{T}}^{\ell 2}+\mathbf{p}_{\mathrm{T}}^{\mathrm{j}}+\mathbf{E}_{\mathrm{T}}^{\text {miss }}$, is required to be smaller than 30 GeV to suppress top background events that have additional jets with $p_{\mathrm{T}}$ below threshold. The $\tau \tau$ invariant mass, $m_{\tau \tau}$, is computed under the assumption that the reconstructed leptons are $\tau$ lepton decay products, that the neutrinos produced in the $\tau$ decays are collinear with the leptons [65], and that they are the only source of $E_{\mathrm{T}}^{\text {miss }}$. Events with $\left|m_{\tau \tau}-m_{Z}\right|<25 \mathrm{GeV}$ are rejected if the energy fractions carried by the putative visible decay products are positive (the collinear approximation does not always yield physical solutions).

The $H+2$-jet selection follows the $H+1$-jet selection described above (with the $p_{\mathrm{T}}^{\text {tot }}$ definition modified to include all selected jets). In addition, several additional jet-related criteria are applied to the two highest- $p_{\mathrm{T}}$ jets in the event, referred to as the "tag" jets. The tag jets must be separated in rapidity by a distance $\left|\Delta y_{\mathrm{jj}}\right|$ of at least 3.8. Events with an additional jet with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in between the tag jets $\left(y_{j 1}<y<y_{j 2}\right)$ are vetoed. Finally, the invariant mass of the two tag jets, $m_{\mathrm{jj}}$, must be at least 500 GeV .

A transverse mass variable, $m_{\mathrm{T}}$ [66], is used in this analysis to test for the presence of a signal for all jet multiplicities. This variable is defined as:

$$
m_{\mathrm{T}}=\sqrt{\left(E_{\mathrm{T}}^{\ell \ell}+E_{\mathrm{T}}^{\mathrm{miss}}\right)^{2}-\left|\mathbf{p}_{\mathrm{T}}^{\ell \ell}+\mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}\right|^{2}}
$$

where $E_{\mathrm{T}}^{\ell \ell}=\sqrt{\left|\mathbf{p}_{\mathrm{T}}^{\ell \ell}\right|^{2}+m_{\ell \ell}^{2}}$. The statistical analysis of the candidate data uses a fit to the $m_{T}$ shape in the signal region data after the $\Delta \phi_{\ell \ell}$ requirement (see Section 6). The signal sensitivity for a SM Higgs
mass hypothesis $m_{H}$ can also be enhanced by selecting events with $m_{T}$ in the range $0.75 m_{H}<m_{T}<$ $m_{H}$, and this additional selection is used later in this document to illustrate the background model and the observed excess. The signal-to-background ratios after this selection for a SM Higgs boson with $m_{H}=125 \mathrm{GeV}$, with the added $m_{T}$ requirement, are about $0.14,0.19$, and 1.0 for the $H+0$-jet, $H+1$-jet, and $H+2$-jet selections, respectively.

## 4 Background normalisation and control samples

For the $H+0$-jet and $H+1$-jet analyses, the leading backgrounds from SM processes producing two isolated high- $p_{\mathrm{T}}$ leptons are $W W$ and top (in this note, "top" background always includes both $t \bar{t}$ and single top ( $t W, t b$, and $t q b$ ) unless explicitly stated otherwise). These are estimated using partially data-driven techniques based on normalising the MC predictions to the data in control regions dominated by the relevant background source. The $W+$ jets background is fully estimated from data for all jet multiplicities. Only the backgrounds from Drell-Yan, diboson processes other than $W W$, and the $W W$ background for the $H+2$-jet analysis are estimated using simulation.

The control and validation regions are defined by selections similar to those used in the signal region but with some criteria reversed or modified to obtain signal-depleted samples enriched in a particular background. The control regions for $W W$ and top are used to normalise the corresponding backgrounds in the fit, which helps reduce the sensitivity of the background predictions to the systematic uncertainties detailed in Section 5. The normalisation and $m_{T}$ shape of the $W+$ jets background are also derived from a control region and extrapolated into the signal region using a "fake factor" defined below. Same-sign dilepton events are produced primarily by the $W+j$ jets, $W \gamma^{(*)} / W Z^{(*)}$ and $Z^{(*)} Z^{(*)}$ processes. These events are thus used as a validation region to check those background predictions. The term "validation region" distinguishes these regions from the control regions, which are used to directly normalise the corresponding backgrounds.

Some control regions have significant contributions from backgrounds other than the targeted one, which introduces dependencies among the background estimates. These correlations are fully incorporated in the profile likelihood used to test the background-only hypothesis (see Section 6). In the following subsections, each background estimate is described after any others on which it depends. Because of this, the largest background ( $W W$ ) is described last.

## 4.1 $W+$ jets estimation and the same-sign validation sample

The $W+$ jets background contribution is estimated using a control sample of events in which one of the two leptons satisfies the identification and isolation criteria described in Section 3, and the other lepton (denoted "anti-identified") fails these criteria but satisfies a loosened selection. Anti-identified electrons satisfy loosened isolation requirements and must fail at least one electron identification requirement, which may be on the shower shape or track quality. For anti-identified muons, the calorimeter isolation requirement is loosened and the track isolation and transverse impact parameter requirements are removed. Further, the muon must not pass all of the muon identification criteria. Otherwise, events in this sample are required to pass all of the signal selection requirements. The dominant contribution to this background comes from $W+$ jets events in which a jet produces an object which is reconstructed as a lepton. This object may be either a true electron or muon from the decay of a heavy quark, or else, in the case of electrons, a product of the fragmentation incorrectly reconstructed as an isolated electron candidate. The purity of $W+$ jets events in the control region is about $90 \%$ in the electron channel and $70 \%$ in the muon channel.

Figure 3: Distribution of $m_{T}$ (left) and $\Delta \phi_{\ell \ell}$ (right) in the same-sign validation region after the $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ and zero jet requirements. The lepton flavours are combined. The signal shown is for $m_{H}=125 \mathrm{GeV}$. The hashed area indicates the total uncertainty on the background prediction.

The $W+$ jets background in the signal region is obtained by scaling the number of events in the data control sample by a "fake factor". The fake factor is defined as the ratio of the number of fully identified lepton candidates passing all selections to the number which are anti-identified. It is estimated as a function of the anti-identified lepton $p_{\text {T }}$ using an inclusive dijet data sample, after subtracting the residual contributions from leptons produced by leptonic $W$ and $Z$ decays. For this subtraction, the $W$ candidates are identified by requiring the transverse mass $m_{\mathrm{T}}^{W}=\sqrt{2 p_{\mathrm{T}}^{\ell} E_{\mathrm{T}}^{\mathrm{miss}} \cdot(1-\cos \Delta \phi)}$ to satisfy $m_{\mathrm{T}}^{W}>30 \mathrm{GeV}$. In this expression, $p_{\mathrm{T}}^{\ell}$ is the lepton transverse momentum and $\Delta \phi$ is the difference in azimuth between the lepton and $\mathbf{E}_{\mathrm{T}}^{\text {miss }}$ directions. The $Z$ candidates are identified as two opposite-sign leptons of the same flavour with $\left|m_{\ell \ell}-m_{Z}\right|<15 \mathrm{GeV}$, and need to be subtracted as part of the fake factor calculation even though only $e \mu$ candidates are selected in the signal region. The remaining lepton contamination, which includes $W \gamma$ and $W \gamma^{*} / W Z^{(*)}$ events, is subtracted using MC simulation.

The fake factor uncertainty is the main uncertainty on the $W+$ jets background contribution. It is dominated by differences in jet composition between dijet and $W+$ jets samples as observed in MC simulation, accounting also for differences between the heavy-flavour ( $b$ and $c$ quark) content of the simulated $W+$ jets events and what has been measured in data. The total systematic uncertainty on the fake factor also includes smaller contributions originating from trigger effects and the subtraction of the contamination from leptonic $W$ and $Z$ decays. The total relative uncertainty on this background is approximately $40 \%$ for the electron fakes and $40 \%$ for the muon fakes.

The processes producing the majority of same-sign dilepton events, $W+$ jets, $W \gamma^{(*)}, W Z^{(*)}$, and $Z^{(*)} Z^{(*)}$ are all backgrounds to $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu . W+\mathrm{jets}$ and $W \gamma^{(*)}$ are particularly important for the analysis optimised for a low Higgs boson mass hypothesis. Therefore the normalisation and kinematic features of same-sign dilepton events are used to validate these background predictions. Satisfactory agreement is observed overall, and example distributions, the $m_{\mathrm{T}}$ and $\Delta \phi_{\ell \ell}$ distributions of same-sign zero-jet events passing the preselection requirements, are shown in Fig. 3. The observed number of events is somewhat smaller than the estimated background, although the differences seen are well within the statistical and systematic uncertainties.

The $W \gamma$ background arises from the photon converting into a electron-positron pair, while the $W$ decay provides the muon and the $E_{\mathrm{T}}^{\mathrm{miss}}$ signatures. The simulation of the $W \gamma$ background is tested in a modified same-sign validation region in which the electron criteria that remove photon conversions are reversed. In this region, a high $W \gamma$ purity is obtained (approximately $80 \%$ ). The final estimate is
taken from MC simulation since there are insufficient data in the $W \gamma$ validation region to derive an accurate normalisation, but the agreement between data and MC is good within the large statistical uncertainty.

### 4.2 Top-quark control sample

The number of background events from top quark production in the $H+0$-jet signal region is normalised to the number of events satisfying the pre-selection criteria described in Section 3, namely, the selection up to but not including the jet multiplicity requirements. This sample is dominated by top quark events, as shown in Fig. 1. The small contribution of non-top backgrounds to this sample is estimated from simulation, except for the $W+$ jets contribution, which is estimated from data. The fraction $f_{0-\text { jet }}^{\mathrm{MC}}$ of top events in the preselected sample which pass the jet veto is initially estimated in simulation and then corrected using kinematic information from a second, $b$-tagged, control sample. Specifically, the correction uses the probability $P_{1}^{\mathrm{b}-\mathrm{tag}}$ for an event in the control sample to have no jets reconstructed in addition to the one that is tagged. Because $b$-tagging selects a nearly pure sample of top events, $P_{1}^{\mathrm{b}-\mathrm{tag}}$ can be calculated in both data and simulation. Then $f_{0-\mathrm{jet}}^{\mathrm{data}}$ is estimated by multiplying $f_{0-\text { jet }}^{\mathrm{MC}}$ by the ratio $\left(P_{1}^{\mathrm{b}-\mathrm{tag}, \mathrm{data}}\right)^{2} /\left(P_{1}^{\mathrm{b}-\mathrm{tag}, \mathrm{MC}}\right)^{2}$, exploiting the stability of the ratio $f_{0-\text { jet }} /\left(P_{1}^{\mathrm{b}-\mathrm{tag}}\right)^{2}$ with respect to experimental uncertainties and, to a lesser extent, assumptions about top event kinematics [67]. The efficiency for the remaining requirements on $p_{\mathrm{T}}^{\ell \ell}, m_{\ell \ell}$, and $\Delta \phi_{\ell \ell}$ is taken from simulation. The ratio of the resulting prediction to the one from simulation alone is $1.11 \pm 0.06$ (stat). The total uncertainty on the estimate is $17 \%$, which includes both statistical and systematic uncertainties, which are described in Section 5.

In the $H+1$-jet and $H+2$-jet analyses, the top quark background prediction is normalised to the data in a control sample defined by reversing the $b$-jet veto and removing the requirements on $\Delta \phi_{\ell \ell}$ and $m_{\ell \ell}$. Note that the $\left|\Delta y_{\mathrm{jj}}\right|$ and $m_{\mathrm{jj}}$ requirements are included in the definition of the 2-jet control region. The resulting samples are primarily top events, and the small contribution from other sources is accounted for using simulation and the data-driven $W+$ jets estimate. The predicted and observed dilepton transverse mass distributions of events in these samples are shown in Fig. 4. In these plots, a modified 2 -jet control region, consisting of all events with two or more jets of which at least one is tagged, is used because there are not enough events in the full control region for a meaningful comparison of event kinematics. Good agreement is observed between data and MC for the numbers of events in the $H+1$-jet and $H+2$-jet control regions (see Table 2). The resulting normalisation factors are $1.11 \pm 0.05$ (stat) for the $H+1$-jet analysis and $1.01 \pm 0.26$ (stat) for the $H+2$-jet analysis. The total uncertainties on the estimated top-quark background in the $H+1$-jet and $H+2$-jet signal regions, including both statistical and systematic effects (which are described in Section 5), are 36\% and $70 \%$, respectively.

## 4.3 $W W$ control sample

The $W W$ background MC predictions in the $H+0$-jet and $H+1$-jet analyses, summed over lepton flavours, are normalised using control regions defined with the same selection as the signal region except that the $\Delta \phi_{\ell \ell}$ requirement is removed and the upper bound on $m_{\ell \ell}$ is replaced with a lower bound, $m_{\ell \ell}>80 \mathrm{GeV}$. The numbers of events in the $W W$ control regions in the data agree well with the MC predictions, as can be seen in Table 2. Figure 5 shows the $m_{T}$ shape predicted and observed for events in the $W W$ control regions. Events from $W W$ contribute about $70 \%$ of the total events in the zero jet control region and about $45 \%$ for the one jet control region. Good agreement

Figure 4: Distributions of the $m_{\mathrm{T}}$ variable in the $H+1$-jet (left) $H+2$-jet (right) top control regions. The lepton flavours are combined. The negligible signal shown is for $m_{H}=125 \mathrm{GeV}$. The $H+1$-jet top control region is identical to the $H+1$-jet signal region except that the veto on a $b$-tagged jet is reversed. The $H+2$-jet top control region used here is defined by the requirement of two or more jets, one of which is $b$-tagged jet, after the dilepton and $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ preselection. It is larger than but contains the sample used to normalise the top background in the $H+2$-jet analysis. No data-driven normalisation factors are applied to the simulated data. The hashed area indicates the total uncertainty on the background prediction.
is observed between the predicted and observed distributions. Contributions from sources other than $W W$ are derived as they are for the signal region, including the top and $W+$ jets backgrounds. The resulting $W W$ normalisation factors are $1.06 \pm 0.06$ (stat) for the $H+0$-jet channel and $0.99 \pm 0.15$ (stat) for the $H+1$-jet channel. The total uncertainty on the predicted $W W$ background in the signal region, including both statistical and systematic effects (which are described in Section 5), is 13\% for the $H+0$-jet analysis and $42 \%$ for the $H+1$-jet analysis. For the $H+2$-jet analysis, a signaldepleted region with a sufficient number of $W W$ events to make a statistically accurate estimate of this background cannot be isolated and it is therefore predicted using simulation alone.

## 5 Systematic uncertainties

Theoretical uncertainties on the signal production cross sections are determined following Refs. [12, 68]. QCD factorisation and renormalisation scales are independently varied up and down by a factor of two. Independent uncertainties on the ggF signal production are assumed for the inclusive cross section and the cross section for production with at least one or two jets. The resulting uncertainties on the cross sections in exclusive jet multiplicity final states are taken into account, as well as anticorrelations caused by migrations between different jet multiplicities. The sum in quadrature of those uncertainties for $m_{H}=125 \mathrm{GeV}$ amounts to $17 \%$ for the $H+0$-jet, and $36 \%$ for $H+1$-jet, final states $[12,68,69]$. The impact of the scale variations on both the VBF signal cross section and the jet veto acceptance, to which the $H+2$-jet analysis is mainly sensitive, is $4 \%$ [12]. Additional $7 \%$ uncertainties are included to account for the effect of the underlying event modelling on the signal acceptance for VBF signal events after jet tagging and central jet veto cuts. In the $H+2$-jet analysis, approximately $25 \%$ of the signal events are produced via $g g F$, with a relative uncertainty of around 25\%.

PDF uncertainties are evaluated, following Refs. [39, 55, 70, 71], using the envelopes of error sets

Figure 5: $m_{T}$ distributions in the $W W$ control region in the $H+0$-jet (left) and $H+1$-jet (right) analyses. The lepton flavours are combined. The signal shown is for $m_{H}=125 \mathrm{GeV}$. The top backgrounds are scaled using the normalisation derived from the corresponding control regions described in the text. The hashed area indicates the total uncertainty on the background prediction.
as well as different PDF sets, applied separately to quark-quark, quark-gluon, and gluon-gluon initiated processes. For $m_{H}=125 \mathrm{GeV}$ the relative PDF uncertainty is $8 \%$ for the ggF process and $2 \%$ for the VBF process. Uncertainties on the modelling of signal processes are estimated by using alternative generators, such as MC@NLO for the acceptance for the ggF process. As described in Section 4, the $W W$ background is normalised to signal-free control regions. The theoretical uncertainty on the extrapolation to the signal region from the control regions has been evaluated according to the prescription of [12]. An additional modelling uncertainty is added to take into account differences in the number of extrapolated events obtained with MC@NLO+HERWIG and POWHEG+PYTHIA8. The uncertainties associated with the underlying event and parton showering are included in the acceptance uncertainty, although they are negligible compared to the scale uncertainties on the cross sections for $H+0$-jet and $H+1$-jet.

Uncertainties on the $W \gamma$ background normalisation are evaluated for each jet bin using the procedure described in [68]. The uncertainty relative to the predicted $W \gamma$ background is $11 \%$ for the 0 -jet bin and $50 \%$ for the 1 -jet bin. For $W \gamma^{*}$ with $m_{\ell \ell}<7 \mathrm{GeV}$, a K-factor of $1.3 \pm 0.3$ is applied to the MadGraph LO prediction based on the comparison with the MCFM NLO calculation. The corresponding K-factor and uncertainty for $W Z^{(*)}$ with $m_{\ell \ell}>7 \mathrm{GeV}$ is $1.51 \pm 0.45$.

The main experimental uncertainties are related to the jet energy scale, which is determined from a combination of test beam, simulation, and in situ measurements. The uncertainty on the jet energy scale varies from $2 \%$ to $9 \%$ as a function of jet $p_{\mathrm{T}}$ and $\eta$ for jets with $p_{\mathrm{T}}>25 \mathrm{GeV}$ and $|\eta|<4.5$ [72]. An additional contribution to the jet energy scale uncertainty arises from pile-up, and is is estimated to vary between $1 \%$ and $5 \%$ for in-time pile-up, and up to $10 \%$ for out-of-time pile-up. The jet energy resolution varies from $7 \%$ to $22 \%$ as a function of jet $p_{\mathrm{T}}$ and $\eta$, and the relative systematic uncertainty on it, determined from in situ measurements, ranges from $17 \%$ to $25 \%$. The reconstruction, identification, and trigger efficiencies for electrons and muons, as well as their momentum scales and resolutions, are estimated using $Z \rightarrow \ell \ell, J / \psi \rightarrow \ell \ell$, and $W \rightarrow \ell v$ decays $(\ell=e, \mu)$. With the exception of the uncertainty on the electron selection efficiency, which varies between $2 \%$ and $5 \%$ as a function of $p_{\mathrm{T}}$ and $\eta$, the resulting uncertainties are all smaller than $1 \%$. Jet energy scale and lepton momentum scale uncertainties are propagated to the $E_{\mathrm{T}}^{\text {miss }}$ computation. Additional contributions arise from jets with $p_{\mathrm{T}}<20 \mathrm{GeV}$ as well as from low-energy calorimeter deposits not associated with reconstructed physics objects [61]; their effect on the total signal and background yields is about 3\%. The efficiency
of the $b$-tagging algorithm is calibrated using samples containing muons reconstructed in the vicinity of jets [64]. The resulting uncertainty on the $b$-jet tagging efficiency varies between $5 \%$ and $18 \%$ as a function of jet $p_{\mathrm{T}}$. The preliminary uncertainty on the integrated luminosity is $3.6 \%$, based on the calibration described in Ref. [73, 74].

For the backgrounds normalised using control regions, the systematic uncertainties are evaluated on the relative normalisation between the backgrounds in the signal and control regions and on the $m_{\mathrm{T}}$ shape in the signal region. The uncertainty on the top background in the $H+0$-jet analysis is dominated by the size of neglected interference effects between $t \bar{t}$ and single top and by the impact of the choice of jet thresholds on top event kinematics. Systematic uncertainties are evaluated for the control regions described in Section 4 in the same way as for the signal regions.

In this analysis, a fit to the $m_{\mathrm{T}}$ distribution is performed in order to obtain the signal yield for each mass hypothesis. The $m_{\mathrm{T}}$ shapes for the individual backgrounds and signal do not exhibit a statistically significant dependence on the majority of the theoretical and experimental uncertainties. The remaining uncertainties that do produce statistically significant variations of the $m_{\mathrm{T}}$ shape have no appreciable effect on the final results, with the exception of the $W W$ background, where an uncertainty is included to take into account differences in the $m_{T}$ shape observed between the MC@NLO and POWHEG generators. However, the uncertainty on the shape of the total background is dominated by the uncertainties on the normalisations of the individual backgrounds.

## 6 Results

### 6.1 Results from the 8 TeV data

The expected numbers of signal ( $m_{H}=125 \mathrm{GeV}$ ) and background events at several stages of the selection are presented in Table 2. The rightmost column shows the observed numbers of events in the data. The uncertainties shown include only the statistical uncertainties on the predictions from simulation. After all selection criteria, the dominant background in the $H+0$-jet channel comes from continuum $W W$ production, with smaller contributions from top, non- $W W$ diboson, and $W+$ jets events. In the $H+1$-jet and $H+2$-jet channels, the $W W$ and top backgrounds are comparable. Figure 6 shows the distributions of the transverse mass after all selection criteria in the $H+0$-jet and $H+1$-jet analyses, for both lepton channels combined. No distributions are shown for the $H+2$-jet channel because only two events in the data pass all of the selection through the $\Delta \phi_{\ell \ell}$ requirement.

Figure 7 shows the transverse mass distributions in data after all selection criteria have been applied, with the total estimated background subtracted. The $H+0$-jet and $H+1$-jet channels are summed and the predicted $m_{H}=125 \mathrm{GeV}$ signal is superimposed. No systematic uncertainties are included.

Table 3 shows the numbers of events expected from signal and background and observed in data, after application of all selection criteria. To reflect better the sensitivity of the analysis, additional thresholds on $m_{\mathrm{T}}$ have been applied: $0.75 m_{H}<m_{\mathrm{T}}<m_{H}$ for $m_{H}=125 \mathrm{GeV}$. The results are shown for the $e \mu$ and $\mu e$ channels combined. The uncertainties shown in Table 3 include the systematic uncertainties discussed in Section 5, constrained by the use of the control regions discussed in Section 4. The uncertainties are those that enter into the fitting procedure described below. An excess of events relative to the predicted background is observed in the data. Table 4 shows the magnitude of the main sources of systematic uncertainty on the signal ( $m_{H}=125 \mathrm{GeV}$ ) and background predictions for the $H+0$-jet and $H+1$-jet analyses. Similarly to Table 3 , the additional $m_{\mathrm{T}}$ cut is applied and the constraints from control regions are included.

The statistical analysis of the data employs a binned likelihood function $\mathcal{L}(\mu, \boldsymbol{\theta})$ constructed as the product of Poisson probability terms in each lepton flavour channel. The $m_{H}$-dependent $m_{\mathrm{T}}$ thresholds

Table 2: The expected numbers of signal and background events after the requirements listed in the first column, as well as the observed numbers of events. The signal is shown for $m_{H}=125 \mathrm{GeV}$. The $W+$ jets background is estimated entirely from data, whereas MC predictions normalised to data in control regions are used for the $W W, t \bar{t}$, and $t W / t b / t q b$ processes in all the stages of the selection. Contributions from other background sources are taken entirely from MC predictions. The expected numbers of signal and background events, and the observed numbers of events, are shown also in the control regions. For these rows, the $W+$ jets contribution is still taken from the data-driven estimate but no normalisation factors are applied, except that the top normalisation factor is applied for the top background estimate in the $W W$ control regions. The bottom part of the table lists the number of expected and observed events after the $\Delta \phi_{\ell \ell}$ cut separated by the flavour of the subleading lepton. Only statistical uncertainties associated with the number of events in the MC samples are shown.

Figure 6: Transverse mass, $m_{\mathrm{T}}$, distribution in the $H+0$-jet (top) and $H+1$-jet (bottom) channels, for events satisfying all criteria. The plots on the left show the events with a subleading muon, and the plots on the right show the events with a subleading electron. The expected signal for a SM Higgs boson with $m_{H}=125 \mathrm{GeV}$ is added on top of the estimated total background. The $W+$ jets background is estimated directly from data and $W W$ and top backgrounds are scaled to use the normalisation derived from the corresponding control regions described in the text. The hashed area indicates the total uncertainty on the background prediction.

Table 3: The expected numbers of signal ( $m_{H}=125 \mathrm{GeV}$ ) and background events after the full selections, including a cut on the transverse mass of $0.75 m_{H}<m_{\mathrm{T}}<m_{H}$ for $m_{H}=125 \mathrm{GeV}$. The observed numbers of events are also displayed. The uncertainties shown are the combination of the statistical and all systematic uncertainties, taking into account the constraints from control samples. These results differ from those given in Table 2 due to the application of the additional $m_{\mathrm{T}}$ cut. All numbers are summed over lepton flavours. For the $H+2$-jet analysis, backgrounds with fewer than 0.01 events expected are marked as negligible using a '-'.

described above are not used. Instead, the $m_{\mathrm{T}}$ distribution of events satisfying all of the criteria up to and including the $\Delta \phi_{\ell \ell}$ requirement is fit using the binned likelihood, with the $H+0$-jet $(H+$

Figure 7: The $m_{\mathrm{T}}$ distribution in data with the estimated background subtracted, overlaid with the predicted signal for $m_{H}=125 \mathrm{GeV}$. The distributions are summed for the $H+0$-jet and $H+1$-jet analyses. The statistical errors of both the data and the subtracted background are reflected in the data points. The systematic uncertainty on the background estimate is not included.

1-jet) signal regions subdivided into five (three) $m_{\mathrm{T}}$ bins. For the $H+2$-jet signal region, and the $W W$ and top control regions, only the results integrated over $m_{\mathrm{T}}$ are used; no shape information is used due to the small number of events remaining after the event selection. The use of the $m_{T}$ fit in place of a selection of events in a range of $m_{T}$ increases the sensitivity of the analysis but also incurs additional systematic uncertainties on the modelling of the shape of the $m_{T}$ distribution for the backgrounds. These additional uncertainties are not included in Table 3, but they are small in comparison to the uncertainties on the normalisation. The potential impact of the interference between $W W$ and Higgs diagrams [75] above a value of $m_{T}$ corresponding to the Higgs mass was investigated and found to be negligible. A "signal strength" parameter $\mu$ multiplies the expected Standard Model Higgs boson production signal in each bin. Signal and background predictions depend on systematic uncertainties that are parametrised by nuisance parameters $\boldsymbol{\theta}$, which in turn are constrained using Gaussian functions. The expected signal and background event counts in each bin are functions of $\boldsymbol{\theta}$. The parametrisation is chosen such that the rates in each channel are log-normally distributed for a normally distributed $\theta$. The test statistic $q_{\mu}$ is then constructed using the profile likelihood: $q_{\mu}=-2 \ln \left(\mathcal{L}\left(\mu, \hat{\boldsymbol{\theta}}_{\mu}\right) / \mathcal{L}(\hat{\mu}, \hat{\boldsymbol{\theta}})\right)$, where $\hat{\mu}$ and $\hat{\boldsymbol{\theta}}$ are the parameters that maximise the likelihood (with the constraint $0 \leq \hat{\mu} \leq \mu$ ), and $\hat{\boldsymbol{\theta}}_{\mu}$ are the nuisance parameter values that maximise the likelihood for a given $\mu$. This test statistic is used to compute the probability $\left(p_{0}\right)$ that a background fluctuation is more signal-like than the observed data, and to calculate the exclusion limits following the modified frequentist method known as $C L_{s}[76,77]$.

Figure 8 shows the expected and observed $p_{0}$ value and the fitted signal strength $\mu$ over the range $110<m_{H}<190 \mathrm{GeV}$, for the combined $H+0$-jet, $H+1$-jet and $H+2$-jet analyses. An excess of events is observed over the expected background, reflected by a low observed $p_{0}$ and a fitted $\mu$ which deviates from zero. Due to the limited mass resolution for this analysis, the $p_{0}$ distribution is rather flat around $m_{H}=125 \mathrm{GeV}$. The value of $p_{0}$ at $m_{H}=125 \mathrm{GeV}$ is $8 \times 10^{-4}$, corresponding to 3.1 standard deviations. The minimum value of $p_{0}$, found at $m_{H}=120 \mathrm{GeV}$, is $6 \times 10^{-4}$, which corresponds to 3.2 standard deviations. The significance exceeds three standard deviations for a possible signal within the mass range $110-130 \mathrm{GeV}$. The expected $p_{0}$ for a Higgs with $m_{H}=125 \mathrm{GeV}$ is 0.05

Table 4: Main systematic uncertainties on the predicted numbers of signal ( $m_{H}=125 \mathrm{GeV}$ ) and background events for the $H+0$-jet and $H+1$-jet analyses, relative to the total signal and background expectations. The same $m_{\mathrm{T}}$ criteria as in Table 3 are imposed. All numbers are summed over lepton flavours. The effect of the quoted inclusive signal cross section renormalisation and factorisation scale uncertainties on exclusive jet multiplicities is explained in Section 5. Sources of uncertainty that are negligible or not applicable in a particular column are marked with a '-'.

| Source (0-jet) | Signal (\%) | Bkg. (\%) |

or 1.6 standard deviations. The fitted signal strength is also shown in Figure 8 and is $\mu=1.9 \pm 0.7$ at $m_{H}=126 \mathrm{GeV}$, the location of the minimum observed $p_{0}$ in the most recent ATLAS combined results [78]. The increase of the fitted signal strength at lower $m_{H}$ is due to the decreasing expected $\sigma \cdot B r$ for the signal.

As a comparison, the $p_{0}$ was also evaluated using a counting experiment after applying a requirement on $0.75 m_{H}<m_{\mathrm{T}}<m_{H}$, rather than fitting the $m_{T}$ distribution (see Table 3 for event yields after the requirement on $m_{T}$ has been applied for $m_{H}=125 \mathrm{GeV}$ ). The resulting decrease in sensitivity reduces the expected significance at $m_{H}=125 \mathrm{GeV}$ to $p_{0}=0.07$ or 1.5 standard deviations. The observed significance in this variant of the analysis reaches a minimum of $p_{0}=2 \times 10^{-3}$, equivalent to 3.0 standard deviations, at $m_{H}=125 \mathrm{GeV}$.

The expected $95 \% C L_{S}$ limit on $\sigma / \sigma_{S M}$ excludes a SM Higgs boson with a mass down to 129 GeV . However, due to the observed excess of events the observed excluded $C L_{s}$ lower limit is only at 145 GeV .

### 6.2 Combination of the 7 TeV and 8 TeV results

The results obtained with the $5.8 \mathrm{fb}^{-1}$ of 8 TeV data acquired in 2012 are combined with the published $4.7 \mathrm{fb}^{-1}$ of 7 TeV results [13]. The 7 TeV analysis resulted in a signal strength of $\mu=0.5 \pm 0.6$ at $m_{H}=126 \mathrm{GeV}$. The signal strengths measured with the 7 TeV and 8 TeV analyses separately are compatible within 1.5 standard deviations. Figure 9 shows the distribution of the transverse mass after all selection criteria have been applied, summed for the 7 TeV and 8 TeV data, after subtracting the total estimated background. The $H+0$-jet and $H+1$-jet channels are added and the predicted $m_{H}=125 \mathrm{GeV}$ signal is superimposed. No systematic uncertainties are included. This figure is the equivalent of Figure 7 for the combined 2011 and 2012 datasets.

Figure 10 shows the expected and observed $p_{0}$ value and the fitted signal strength for the $H+0$-jet,

Figure 8: 2012 results, using $5.8 \mathrm{fb}^{-1}$ of 8 TeV data. Left: observed (solid line) probability for the background-only scenario as a function of $m_{H}$. The dashed line shows the corresponding expectation for the signal+background hypothesis at the given value of $m_{H}$. Right: fitted signal strength parameter $(\mu)$ as a function of $m_{H}$ for the low mass range.
$H+1$-jet and $H+2$-jet analyses with 7 TeV and 8 TeV data combined. Also shown is the expected distribution in the presence of a Higgs boson with $m_{H}=125 \mathrm{GeV}$. An excess of events is observed over the expected background, reflected by a low observed $p_{0}$ and a fitted $\mu$ which deviates from zero. The minimum value observed for $p_{0}$, found at $m_{H}=125 \mathrm{GeV}$, is $3 \times 10^{-3}$, corresponding to 2.8 standard deviations. The expected $p_{0}$ for a Higgs with $m_{H}=125 \mathrm{GeV}$ is 0.01 , or 2.3 standard deviations, for the combined 7 TeV and 8 TeV data. The fitted signal strength at $m_{H}=126 \mathrm{GeV}$ is $\mu$ $=1.3 \pm 0.5$.

Figure 11 shows the two-dimensional likelihood contours for a simultaneous scan of $\mu$ and $m_{H}$, for this analysis and also for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ [79] and $H \rightarrow \gamma \gamma$ [80] analyses. The lack of mass resolution in the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell v$ final state for low $m_{H}$ can be seen clearly in contrast to the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$ final states, but the best-fit values of $\mu$ and $m_{H}$ are in reasonable agreement for all three analyses.

Figure 12 shows the observed local $p_{0}$ from the combined 7 TeV and 8 TeV results, compared to the one expected in the presence of a signal at $m_{H}=125 \mathrm{GeV}$. The shape and normalisation of the $p_{0}$ curves as a function of $m_{H}$ are in agreement.

The $95 \% C L_{s}$ limit on $\sigma / \sigma_{S M}$ is expected to exclude a SM Higgs boson with a mass above 124 GeV with the combined 7 TeV and 8 TeV data in the absence of a signal. However, due to the observed excess of events the observed exclusion $C L_{s}$ lower limit is found at 137 GeV . The $C L_{s}$ limit is shown in Figure 12.

## 7 Conclusion

A search for the SM Higgs boson has been performed in the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell v$ channel in the mass range between 110 and 190 GeV using a data sample corresponding to $5.8 \mathrm{fb}^{-1}$ of $p p$ collision data from the Large Hadron Collider at $\sqrt{s}=8 \mathrm{TeV}$ recorded in 2012 with the ATLAS detector. For $m_{H} \lesssim 150 \mathrm{GeV}$, an excess of events over the expected background is observed, with a minimum local $p_{0}$-value of $6 \times 10^{-4}$ at $m_{H}=120 \mathrm{GeV}$, or 3.2 standard deviations. A combined analysis of the 2011 and 2012 data results in a minimum local $p_{0}$ at $m_{H}=125 \mathrm{GeV}$ of $3 \times 10^{-3}$, or 2.8 standard deviations. The best fit signal strength at $m_{H}=126 \mathrm{GeV}$, the location of the minimum observed $p_{0}$ in the most recent ATLAS combined results [78], cross section, is $1.3 \pm 0.5$. Given the observation of a new boson

Figure 9: The $m_{\mathrm{T}}$ distribution in data with the estimated background subtracted, overlaid with the predicted signal for $m_{H}=125 \mathrm{GeV}$. The distributions are summed for the $H+0$-jet and $H+1$-jet analyses and the 7 TeV and 8 TeV data. The statistical errors of both the data and the subtracted background are reflected in the data points. The systematic uncertainty on the background estimate is not included.

Figure 10: Combined 7 TeV and 8 TeV results. Left: observed (solid line) probability for the background-only scenario as a function of $m_{H}$. The dashed line shows the corresponding expectation for the signal+background hypothesis at the given value of $m_{H}$. Right: fitted signal strength parameter $(\mu)$ as a function of $m_{H}$ for the low mass range (solid black line with cyan band). The expected result for a signal hypothesis of $m_{H}=125 \mathrm{GeV}$ (red line) is included for comparison.
with mass close to 125 GeV in the $Z Z^{(*)}$ and $\gamma \gamma$ final states [79, 80], the excess observed in the $\ell \nu \ell$ final state is consistent with the decay of this new particle into a pair of $W$ bosons.

Figure 11: Approximate $68 \%$ and $95 \%$ two-dimensional likelihood $\left(\lambda\left(\mu, m_{H}\right)\right)$ contours in the best-fit signal strength $\mu$ and $m_{H}$ for the $W W^{(*)} \rightarrow \ell \nu \ell \nu, Z Z^{(*)} \rightarrow 4 \ell$, and $\gamma \gamma$ analyses using the 2011 and 2012 data [81]. The yellow shading shows the $-\ln \lambda\left(\mu, m_{H}\right)$ values for $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$.

Figure 12: Left: Observed (solid line) probability for the background-only scenario, $p_{0}$, as a function of $m_{H}$, for the combined 7 TeV and 8 TeV data. The dashed line shows the corresponding expectation for the $m_{H}=125 \mathrm{GeV}$ hypothesis. Right: Observed (solid) and expected (dashed) $95 \%$ CL upper limits on the cross section, normalised to the SM Higgs boson production cross section and as a function of $m_{H}$, over the full mass range considered in the 7 and 8 TeV combined data. Due to the excess of events observed in the low mass signal region, the corresponding mass points cannot be excluded as expected. The results at neighbouring mass points are highly correlated due to the limited mass resolution in this final state. The green and yellow regions indicate the $\pm 1 \sigma$ and $\pm 2 \sigma$ uncertainty bands on the expected $p_{0} /$ limit, respectively.

# Search for Charged Higgs Bosons in the $\tau+$ jets Final State in $t \bar{t}$ Decays with $1.03 \mathrm{fb}^{-1}$ of $p p$ Collision Data Recorded at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS Experiment 

The ATLAS Collaboration

#### Abstract

This note presents the results of a search for charged Higgs bosons, $H^{ \pm}$, in $1.03 \mathrm{fb}^{-1}$ of proton-proton collision data recorded at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS experiment at the LHC using the $\tau+$ jets channel in $t \bar{t}$ decays with a hadronically decaying $\tau$ lepton in the final state. The data agree with the Standard Model expectation leading to a limit on the product of branching ratios $\mathrm{BR}\left(t \rightarrow b H^{ \pm}\right) \times \mathrm{BR}\left(H^{ \pm} \rightarrow \tau v\right)$ of $0.03-0.10$ for $H^{ \pm}$masses in the range $90 \mathrm{GeV}<m_{H^{ \pm}}<160 \mathrm{GeV}$. In the context of the Minimal Supersymmetric Standard Model values of $\tan \beta$ larger than $22-30$ are excluded in the mass range $90 \mathrm{GeV}<m_{H^{ \pm}}<140 \mathrm{GeV}$.

## 1 Introduction

The charged Higgs boson is predicted by many non-minimal Higgs scenarios [1, 2], such as models containing Higgs triplets and Two-Higgs-Doublet Models (2HDM) [3]. The observation of charged Higgs bosons ${ }^{1}, H^{ \pm}$, would indicate physics beyond the Standard Model (SM). The analysis in this note considers the type II-2HDM [3], which is also the Higgs sector of the Minimal Supersymmetric Standard Model (MSSM) [4]. For charged Higgs boson masses, $m_{H^{+}}$, smaller than the top quark mass, $m_{t}$, the dominant production mode at the LHC for $H^{+}$is through top quark decay via $t \rightarrow H^{+} b$. The dominant source of top quarks at the LHC is through $t \bar{t}$ production; the cross section for charged Higgs boson production from top quark decays in single-top events is much smaller and not considered here. For $\tan \beta>3$, where $\tan \beta$ is the ratio of the vacuum expectation values of the two Higgs doublets, charged Higgs bosons decay mainly via $H^{+} \rightarrow \tau v$ [5]. Recent limits on light charged Higgs boson production come from the Tevatron [6], where the observed upper limit on $\operatorname{BR}\left(t \rightarrow H^{+} b\right)$ assuming $\operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)=1$ is 0.17 for $m_{H^{+}}=120 \mathrm{GeV}$. Direct searches at LEP [7] give a lower limit of $m_{H^{+}} \simeq 90 \mathrm{GeV}$ for $\operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)=1$. Preliminary results for charged Higgs boson searches in top quark decays have recently been made public by the CMS experiment [8].

This note describes the search for charged Higgs bosons in $t \bar{t}$ events in the topology shown in Fig. 1, for the case where both the $\tau$ lepton and the $W$ decay hadronically ( $\tau+\mathrm{jets}$ channel).

The $H^{+}$search uses proton-proton collision data collected with the ATLAS experiment [9] at the LHC at a center-of-mass energy of $\sqrt{s}=7 \mathrm{TeV}$ in 2011. The total integrated luminosity amounts to $1.03 \mathrm{fb}^{-1}$.

The background processes that enter these searches include the production of $t \bar{t}$, single-top, $W+$ jets, $Z / \gamma^{*}+$ jets, and multi-jet events where there is either a true $\tau$ lepton, or another object misidentified as a hadronically decaying $\tau$. In this note, all significant backgrounds, i.e. events with correctly identified hadronically decaying $\tau$ leptons (hereafter referred to as $\tau$ jets), or with jets or electrons misreconstructed as $\tau$ jets, are estimated using data-driven methods.

Figure 1: Example for a leading-order Feynman diagram for the production of a charged Higgs boson through gluon fusion in $t \bar{t}$ decays.

## 2 Physics processes and their cross sections

All relevant backgrounds are estimated using data-driven techniques. However, for backgrounds with intrinsic missing transverse energy and objects misidentified as $\tau$ jets, simulation is used to model any aspects not related to the probability of the object to be misidentified as a $\tau$ jet. For backgrounds without

[^71]intrinsic $E_{\mathrm{T}}^{\text {miss }}$ (multi-jet background), simulation is used to subtract the electroweak and $t \bar{t}$ contribution in the control region. Simulation is also used for comparison with the results of the data-driven estimates.

The Monte Carlo (MC) simulation of $t \bar{t}$ and single-top events is based on MC@NLO [10] using HERWIG [11] for the hadronization process and JIMMY [12] for simulating multi-parton interactions. Overlap between $t \bar{t}$ and single-top final states is taken into account [13]. A $t \bar{t}$ production cross section of 165 pb [14] obtained from approximate NNLO calculations [15] is used (both for SM $t \bar{t}$ decays and decays via a charged Higgs boson). The MC@NLO cross sections are used for single-top production. Throughout this note, a top quark mass of 172.5 GeV is assumed.

ALPGEN [16] is used for the generation of $W+$ jets and $Z / \gamma^{*}+$ jets events with up to five partons from the hard matrix element, again together with HERWIG/JIMMY. The ALPGEN cross sections are rescaled by a factor $1.20(W)$ and $1.25\left(Z / \gamma^{*}\right)$ to match NNLO calculations [17]. The $H^{+}$signal events are generated with PYTHIA [18], using TAUOLA [19] for $\tau$ lepton decays and PHOTOS [20] for photon radiation off charged leptons. Event generators are tuned to describe ATLAS data, and the parameter sets AMBT1 [21] and AUET1 [22] are used for this purpose for events hadronized with Pythia, and with HERWIG/JIMMY, respectively.

Table 1: Simulated events used in this study. The $W / Z+$ jets as well as the $s$ - and $t$-channel single-top events are only simulated for decays involving leptons ( $\ell$ denotes $e, \mu$, or $\tau$ ), and the cross section given includes this branching ratio. The NLO+NNLL cross section is used for $t \bar{t}$, NLO for single-top, and NNLO for $W / Z+$ jets. The $H^{+}$sample uses $m_{H^{+}}=130 \mathrm{GeV}, \operatorname{BR}\left(t \rightarrow b H^{+}\right)=0.1$ and $\operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$ is assumed to be 1 .

| Process | Generator | Cross section [pb] |
| :--- | :--- | ---: |
| $t \bar{t}$ with $\geq 1 \ell$ | MC@NLO | 89.4 |
| single-top $(s, t, W t$ channel $)$ | MC@NLO | $21.4,1.41,14.6$ |
| $W \rightarrow \ell v+$ jets | ALPGEN | $3.1 \cdot 10^{4}$ |
| $Z / \gamma^{*} \rightarrow \ell \ell+$ jets | ALPGEN | $3.2 \cdot 10^{3}$ |
| $t \bar{t} \rightarrow b H^{ \pm} b W$ with $H^{ \pm} \rightarrow \tau v$ | PYTHIA | 29.6 |

All events are propagated through a detailed GEANT4 [23, 24] simulation of the ATLAS detector and reconstructed by the same algorithms as the data. Cross sections and simulated event samples are summarized in Table 1.

## 3 Object reconstruction

A description of the ATLAS detector can be found elsewhere [9]. In this section, the criteria used to identify and reconstruct physics objects such as leptons or jets are described.

Data quality: For both the $H^{+}$event selection and the data-driven background estimates, the following requirements are applied [25]: The sub-detectors relevant to the analyses have been operational, the LHC delivered stable beams, and there are no jets in the event consistent with coming from instrumental effects such as coherent noise in the electromagnetic calorimeter, or non-collision backgrounds. To further reject non-collision backgrounds, only events with a reconstructed primary vertex with at least five associated tracks are considered.

Jets: Jets are reconstructed with the anti- $k_{t}$ algorithm [26,27] with a size parameter value of $R=0.4$. The jet finder uses three-dimensional noise-suppressed clusters [28] in the calorimeter, reconstructed at
the electromagnetic (EM) energy scale. Jets are then calibrated to the hadronic energy scale with Monte-Carlo-based correction factors which depend on their transverse momentum ( $p_{\mathrm{T}}$ ) and pseudorapidity $(\eta)$. The jet energy scale uncertainty is estimated to be $(2.5-14) \%$, depending on $p_{\mathrm{T}}$ and $\eta$, with methods described in Ref. [29] but based on a larger data set. Jets considered in this analysis are required to have $p_{\mathrm{T}}>20 \mathrm{GeV}$ and $|\eta|<2.5$.
$\boldsymbol{b}$ jets: To identify jets initiated by $b$ quarks, a combination of a 3D-impact-parameter-based discriminant and a secondary-vertex-tagger [30] with an identification efficiency of about $60 \%$ for $b$ jets with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $t \bar{t}$ events is applied.
$\boldsymbol{\tau}$ jets: For the reconstruction of $\tau$ jets, all anti- $k_{t}$ jets in the calorimeter with $E_{\mathrm{T}}>10 \mathrm{GeV}$ are considered as $\tau$ candidates [31]. A dedicated algorithm is used to reject electrons (called tight electron veto). Only candidates with 1 or 3 associated tracks reconstructed in the inner detector are considered. Hadronic $\tau$ decays are identified using a likelihood quality criterion (corresponding to an efficiency of about $30 \%$ for $\tau$ leptons with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $Z \rightarrow \tau \tau$ events, and a rejection factor of about 100-1000 for quarkand gluon-initiated jets, depending on $p_{\mathrm{T}}, \eta$, and the number of associated tracks). For this analysis, they are required to have a visible $p_{\mathrm{T}}>20 \mathrm{GeV}$ and to be within $|\eta|<2.3$. In some control regions, a loose $\tau$ identification is used instead; this corresponds to an efficiency of $60 \%$, and a jet rejection of about 10 , depending on $p_{\mathrm{T}}$ and $\eta$.

Electrons: Electrons are reconstructed by matching clustered energy deposits in the electromagnetic calorimeter to tracks reconstructed in the inner detector [32]. They are required to meet quality requirements based on the expected shower shape of electrons [33]. Electrons are required to have $E_{\mathrm{T}}>20 \mathrm{GeV}$, and be isolated (defined by requiring less than 3.5 GeV of transverse energy - after corrections for pileup and leakage - in a cone of $\Delta R=0.2$ around the electron ${ }^{2}$, excluding the electron itself). Electrons are required to be in the fiducial volume of the detector, $|\eta|<2.47$. Electrons in the transition region $1.37<|\eta|<1.52$ are excluded.

Muons: Muon candidates are required to have a match of an inner detector track with a track reconstructed in the muon spectrometer [34]. Candidates are required to have $p_{\mathrm{T}}>10 \mathrm{GeV}$ and $|\eta|<2.5$. Only isolated muons are accepted by requiring that in a cone of $\Delta R=0.3$ around the muon (excluding the muon itself), both the energy deposited in the calorimeters and the momentum of all inner detector tracks total less than 4 GeV of transverse energy.

Missing transverse energy, transverse energy sum: The reconstructed missing transverse energy, $E_{\mathrm{T}}^{\text {miss }}$, is based on the energy deposited in the calorimeter and the momentum of tracks identified as associated to muons. Only noise-suppressed clusters of cells are used, and corrections for unclustered cells are applied. The contribution of the calorimeter cells is calibrated differently depending on which object they are associated to. For all jets, the same hadronic calibration scheme as for jet reconstruction is used while electrons are calibrated at the electromagnetic energy scale [35].

The transverse energy sum, $\sum E_{\mathrm{T}}$, is defined as the sum of the transverse energy of all the objects which have been reconstructed as detailed in this section, including missing transverse energy.

[^72]Overlap removal: When candidates selected using the above criteria overlap geometrically with one another (within $\Delta R<0.2$ ), this conflict is resolved by only selecting one candidate in the following order of priority: muon, electron, $\tau$ jet, or jet.

General systematic uncertainties The main detector-related systematic uncertainties are listed in Table 2. These are mostly related to identification efficiencies and the energy/momentum resolution and scale of the physics objects described above. Uncertainties on trigger efficiency, luminosity, cross sections and acceptance are also listed.

To assess the impact of most sources of systematic uncertainty on the result of the analysis, selection cuts for each analysis are re-applied after shifting a particular parameter by its $\pm 1$ standard deviation uncertainty. The luminosity and the trigger uncertainty with respect to the offline efficiency serve directly as scale factors on the event yield.

Table 2: Systematic uncertainties. Uncertainties on the $t \bar{t}$ cross section include variations of the parton density functions (pdf) and of the factorization and renormalisation scale. A scale factor is the ratio of efficiencies in data and simulation, and is here denoted as "SF". The difference in acceptance for $t \bar{t}$ events at LO and NLO is used as systematic uncertainty on the signal acceptance.

| Quantity | Uncertainty |
| :--- | :--- |
| Luminosity [36] | $\pm 3.7 \%$ |
| Jet energy resolution (JER) | $\pm(10-30) \%$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| Jet energy scale (JES) | $\pm(2.5-14) \%$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $E_{\mathrm{T}}^{\text {miss }}$ | Uncertainty due to scale/resolution uncertainties (e.g. JES); |
|  | additional $10 \%$ of pile-up-related uncertainty |
| $b$-tagging efficiency SF unc. | $\pm(0.05-0.15)$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $b$-tagging mistag rate | $\pm(0.16-0.39)$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $b$ jets JES uncertainty | an additional $\pm 2.5 \%$ on top of the standard JES |
| $\tau$ identification efficiency | $\pm(8.5-9.9) \%$, depending on $p_{\mathrm{T}}$ |
| $\tau$ energy scale | $\pm(4.5-6.5) \%$, depending on $p_{\mathrm{T}}, \eta$, number of associated tracks |
| $\tau$ electron mis-id correction factors | $\pm(23-100) \%$, depending on $\eta$; for one-prong only |
| $\tau+E_{\mathrm{T}}^{\text {miss trigger }}$ | $\pm 9 \%$ |
| $e$ reco. efficiency SF | $\pm(0.7-1.8) \%$, depending on $\eta$ |
| $e$ identification efficiency SF | $\pm(2.2-3.8) \%$, depending on $E_{\mathrm{T}}$ and $\eta$ |
| $e$ energy scale | $\pm(0.3-1.8) \%$, depending on $p_{\mathrm{T}}$ and $\eta$ |
| $e$ energy resolution | $\pm(0.5-2.4) \%$ (additional constant term), depending on $p_{\mathrm{T}}$ and $\eta$ |
| $\mu$ reco. efficiency SF | $\pm(0.25-0.55) \%$, depending on the data-taking period |
| $\mu$ momentum scale and resolution | $\pm(0.4-0.7) \%$, depending on $\eta$ |
| Initial/final state radiation modelling | $-16 \% /+19 \%(t \bar{\tau}$ signal and background) |
| Acceptance | $\pm 4 \%$ (background), $\pm 10 \%$ (signal) |
| $t \bar{t}$ cross section | $165_{-9}^{+4}($ scale $)+7($ pdf $)$ pb |

## 4 Event selection

This study describes the search for a charged Higgs boson in the topology

$$
\begin{equation*}
t \bar{t} \rightarrow\left[H^{+} b\right]\left[W^{-} \bar{b}\right] \rightarrow\left[\left(\tau_{h a d}^{+}+v\right) b\right]\left[\left(q \bar{q}^{\prime}\right) \bar{b}\right] \tag{1}
\end{equation*}
$$

where both the $W$ boson and the $\tau$ lepton decay hadronically. This topology has the advantage that the $W$ boson can be fully reconstructed, the $H^{+}$candidate can be reconstructed in the transverse plane, and
the branching ratio of the $W$ boson decay to quarks is larger than that to leptons; but it needs to be distinguished from a large multi-jet background.

The following selection cuts are applied, based on the reconstructed physics objects described in Section 3:

1. Event preselection:
(a) Data quality cuts.
(b) $E_{\mathrm{T}}^{\text {miss }}$ plus tau trigger $[37,38]$, with a threshold of 29 GeV on the $\tau$ object, of 35 GeV on $E_{\mathrm{T}}^{\text {miss }}$, and no muon corrections on $E_{\mathrm{T}}^{\text {miss }}$. The signal efficiency is about $70 \%$, depending on $m_{H^{+}}$.
(c) At least 4 jets (excluding $\tau$ jets) with $p_{\mathrm{T}}>20 \mathrm{GeV}$ and $|\eta|<2.5$.
2. A $\tau$ jet with $p_{\mathrm{T}}^{\tau}>35 \mathrm{GeV}$ within $|\eta|<2.3$ is required. This $\tau$ jet must be matched to the $\tau$ trigger object within $\Delta R<0.1$. Events with a second identified $\tau$ jet with $p_{\mathrm{T}}^{\tau}>20 \mathrm{GeV}$ are vetoed.
3. Events are vetoed if any identified electrons $\left(E_{\mathrm{T}}>20 \mathrm{GeV}\right)$ or muons $\left(p_{\mathrm{T}}>10 \mathrm{GeV}\right)$ are present.
4. The missing transverse energy $E_{\mathrm{T}}^{\mathrm{miss}}$ is required to be larger than 40 GeV .
5. Events with large reconstructed $E_{\mathrm{T}}^{\mathrm{miss}}$ due to the limited resolution of the energy measurement are rejected with a cut on the ratio $\frac{E_{\mathrm{T}}^{\text {miss }}}{0.5 \cdot \sqrt{\sum E_{\mathrm{T}}}}>8 \mathrm{GeV}^{1 / 2}$, using the $\sum E_{\mathrm{T}}$ definition described in Section 3. Considering the minimum $\sum E_{\mathrm{T}}$ required to pass all other selection cuts, this also corresponds to raising the cut on $E_{\mathrm{T}}^{\text {miss }}$ to about 50 GeV .
6. At least one $b$-tagged jet is required.
7. Topologies consistent with a top decay are identified by requiring that the $q q b$ candidate with the highest $p_{\mathrm{T}}^{q q b}$ value must satisfy $m(q q b) \in[120,240] \mathrm{GeV}$.

For events passing the above selection cuts the transverse mass, $m_{\mathrm{T}}$, is defined as

$$
\begin{equation*}
m_{\mathrm{T}}=\sqrt{2 p_{\mathrm{T}}^{\tau} E_{\mathrm{T}}^{\mathrm{miss}}(1-\cos \Delta \phi)} \tag{2}
\end{equation*}
$$

where $\Delta \phi$ is the azimuthal angle between the $\tau$ jet and the missing energy direction. This final discriminating variable is related to the $W$ boson mass in the $W \rightarrow \tau v$ background case, and the $H^{+}$mass for the signal hypothesis.

At the end of the selection cut flow, after applying data-driven methods as detailed in the sections that follow, $37 \pm 7$ background events are expected for $m_{\mathrm{T}}>40 \mathrm{GeV}$. Of those, $21 \pm 5$ events are expected with a correctly identified $\tau$ jet; about 2 events each for the case where an electron or a jet have been misidentified as a hadronically decaying $\tau$ lepton in a $t \bar{t}$ or electroweak background process. The multijet contribution is expected to be $12 \pm 5$ events. A potential signal yield depends on the charged Higgs boson mass and the branching ratio $t \rightarrow b H^{+}$; for example, 70 events are expected for $m_{H^{+}}=130 \mathrm{GeV}$ and $\operatorname{BR}\left(t \rightarrow b H^{+}\right)=0.1$.

## 5 Data-driven background estimation

The main source of background events to charged Higgs boson searches at the LHC are those coming from production processes such as $t \bar{t}$, multi-jet, single top-quark, and $W+$ jets, in this order of relevance. The individual contributions from these backgrounds are determined in a data-driven way. They can
be divided into two categories: backgrounds with intrinsic $E_{\mathrm{T}}^{\text {miss }}$ from $W$ decays, and backgrounds with $E_{\mathrm{T}}^{\text {miss }}$ caused by detector effects (multi-jet events). For the first category, the contribution from events in which electrons or jets are misidentified as $\tau$ jets are predicted using appropriate control samples while events with correctly identified $\tau$ jets are studied with the embedding method. The multi-jet background can be estimated using the shape of its $E_{\mathrm{T}}^{\text {miss }}$ distribution in a suitable control region.

### 5.1 Methods based on measuring misidentification probabilities

The background from events where an electron or a jet is misidentified as a hadronically decaying $\tau$ lepton is estimated in a data-driven procedure from suitable control samples. The probability for an electron or jet to be misidentified as a $\tau$ jet is defined as
misidentification probability $=\frac{\text { number of } \tau \text { candidates passing event selection, } \tau \text { ID and electron veto }}{\text { number of } \tau \text { candidates passing event selection }}$.

### 5.1.1 Electron-to- $\tau$ misidentification probability with a tag-and-probe method

The Method A tag-and-probe method on $Z / \gamma^{*}$ events in collision data is used to measure the misidentification probability of electrons. The result is compared to simulation, and the ratio of the misidentification probability as measured in data to that determined in simulation is called a scale factor. This factor is then used to correct the description of the electron-to- $\tau$ misidentification probability in simulation. The method used is identical to that described in [39] though based on a larger data set. The process $Z / \gamma^{*} \rightarrow e e$ allows the selection of a clean sample of electrons from data. An electron trigger with a threshold on the electron $E_{\mathrm{T}}$ of 20 GeV is used. The tag electron is required to have a $p_{\mathrm{T}}>30 \mathrm{GeV}$ and to be located in the central region $(|\eta|<2.47)$ of the detector (but outside the transition region between the barrel and the end-cap, $1.37<|\eta|<1.52$ ). It must be isolated (the sum of the momenta of tracks in a cone of $\Delta R=0.4$ around the electron is required to be less than $6 \%$ of the electron momentum) and must pass tight electron identification criteria [33]. Furthermore, a match within $\Delta R=0.1$ to the trigger electron is required. The probe electron is considered for further analysis if it is reconstructed as a $\tau$ jet candidate with $p_{\mathrm{T}}>20 \mathrm{GeV}$ with exactly one associated track. The probability of electrons to be misidentified as 3-track $\tau$ jets is negligible. The pair with the highest scalar $E_{\mathrm{T}}$ sum is chosen from all possible $e-\tau$ pairs that are separated by $\Delta R>0.4$. Additionally, the tag and the probe objects are required to have opposite electric charges. Events with $E_{\mathrm{T}}^{\text {miss }}>20 \mathrm{GeV}$ are discarded to reduce the background contamination from $W \rightarrow e v$ decays, and the invariant mass of the $e-\tau$ pair is required to be between 80 and 100 GeV .

The selected probe sample of $\tau$ jet candidates then contains electrons originating from $Z$ bosons with a purity (estimated from simulation) of about $99 \%$. The main backgrounds are multi-jet events, $W \rightarrow e v$, and $Z / \gamma^{*} \rightarrow \tau \tau$, in that order. The multi-jet background is estimated using a two-dimensional sideband subtraction method [39], the electroweak backgrounds using simulation.

Results The misidentification probabilities (as defined in Eq. 3) are extracted for the $\tau$ candidates which pass the $\tau$ selection (including overlap removal with electron candidates) and the electron veto criteria as used in the $H^{+}$selection. In the denominator, the probe objects are not required to pass the $\tau$ jet identification, whereas the numerator contains the number of events with the probe objects both passing the identification and not being discarded by the electron veto. The results for the scale factor and misidentification probability are shown in Table 3 for the different calorimeter regions. Only the scale factors are used in the following. No significant dependence of the scale factor on the $p_{\mathrm{T}}$ of the $\tau$ lepton candidate is observed.

Application of the method to estimate the $e \rightarrow \tau$ misidentification background The misidentification probability from this study is applied by scaling simulated events in which the selected reconstructed $\tau$ jet originates from a true electron. The scale factor used is given by the ratio of the misidentification probability in data to that in Monte Carlo.

Table 3: Scale factors and measured $e \rightarrow \tau$ misidentification probabilities for $\tau$ candidates with $E_{\mathrm{T}}>20$ GeV in the barrel $(0<|\eta|<1.37)$, transition $(1.37<|\eta|<1.52)$ and end-cap $(1.52<|\eta|<2.5)$ regions passing the $\tau$ identification and a tight electron veto, for a $\tau$ identification efficiency of about $30 \%$. The scale factors are given with statistical and systematic uncertainties combined.

| Region | Scale factor | Misidentification probability (data) |
| :--- | ---: | ---: |
| $0<\|\eta\|<1.37$ | $1.1 \pm 0.3$ | $0.0028 \pm 0.0006$ |
| $1.37<\|\eta\|<1.52$ | $1.0 \pm 1.0$ | $0.0005 \pm 0.0004$ |
| $1.52<\|\eta\|<2.5$ | $1.6 \pm 0.5$ | $0.009 \pm 0.003$ |

Systematic uncertainties Five main sources of systematic uncertainties on the electron- $\tau$ jet misidentification probability are studied. The systematic uncertainty due to the subtraction of multi-jet and electroweak backgrounds is at the level of only $1 \%$, but can reach up to $25 \%$ in the transition region. Ideally, the measurement should be independent of the tag selection. To test any potential correlation, this selection has been varied (using medium electron identification criteria instead of tight ones in order to study the bias of only selecting very well-reconstructed tag electrons), leading to an estimate of a systematic uncertainty of $10 \%$. Other systematic uncertainties are negligible in comparison. The choice of the mass window size around $m_{Z}$ applied to the tag-and-probe objects which could result in a bias by only studying objects with well-reconstructed momentum and the uncertainty of the electron energy scale (via the cut on the tag electron energy) only give a small contribution. The total uncertainties on the scale factors (combining the statistical and systematic uncertainties of the measurement) are $24 \%$ in the barrel, $29 \%$ in the end-caps, and $100 \%$ in the transition region. Except for the end-cap, they are dominated by the statistical uncertainties.

In total, the expected contribution of events with electrons misidentified as $\tau$ jets in the signal region is about 2 events which is about $5 \%$ of the expected background. Thus reducing the relatively large uncertainties would only lead to a minor improvement of the $H^{+}$sensitivity.

### 5.1.2 Jet-to- $\tau$ misidentification probability from photon+jets

To study the probability for jets to be misidentified as hadronically decaying $\tau$ leptons, a $\gamma$-jet control sample is used. Like jets from the hard process in the dominant $H^{+}$background $t \bar{t}$, jets in this control sample originate predominantly from quarks as opposed to gluons. A measurement of the probability for a jet to be misidentified as a hadronically decaying $\tau$ lepton is performed using $1.03 \mathrm{fb}^{-1}$ of data and is used to predict the yield of jet-to- $\tau$ misidentification events from the most important SM backgrounds with intrinsic $E_{\mathrm{T}}^{\text {miss }}$. The main difference between $t \bar{t}$ and $\gamma$-jet events is the different fraction of $b$ jets which is smaller in $\gamma$-jet events. However, the probability for a $b$ jet to be misidentified as a $\tau$ jet is smaller than the corresponding probability for a light-quark jet: The average track multiplicity of $b$ jets is higher, and variables which measure the mass of the $\tau$ candidate allow a good discrimination. Hence using the $\gamma$-jet misidentification probability leads to a higher background estimate and is thus conservative.

Figure 2: Jet $\rightarrow \tau$ misidentification probability measured from $\gamma$-jet events for jets with 1 or 3 associated tracks as a function of $p_{\mathrm{T}}$ and $\eta$. The error bars indicate the size of the statistical uncertainties.

The Method Events are required to pass a single-photon trigger (with an $E_{\mathrm{T}}$ threshold of 15,20 or 40 GeV ). The photon candidate must be isolated (less than 6 GeV of $E_{\mathrm{T}}$ deposited in a $\Delta R=0.2$ cone around the photon), is required to match a trigger object, pass the photon selection [40], and have either zero or two associated tracks to include photon conversions. The photon candidate must have $|\eta|<2.37$, not be located in the transition region, and must have a transverse energy of at least 15 GeV . The selected $\gamma$-jet sample consists of events with one photon candidate and a jet with $p_{\mathrm{T}} \geq 20 \mathrm{GeV}$, separated in $\phi$ by at least 2.84 radians. The difference in transverse energy between the jet and the photon must be less than half of the total transverse energy of the photon. Any additional jets are required to have less than $20 \%$ of the photon transverse energy.

The misidentification probability is measured as a function of both $p_{\mathrm{T}}$ and $\eta$. The denominator of the calculated misidentification probability is the number of events with a $\tau$ candidate (i.e. no $\tau$ ID applied) with $p_{\mathrm{T}}$ greater than 20 GeV and $|\eta|<2.3$, which passes an electron veto. The misidentification probability is evaluated separately for the case of candidates with 1 or 3 associated tracks. Among all jets with $E_{\mathrm{T}}>20 \mathrm{GeV}$ and $|\eta|<2.3$, the fraction of light-quark jets which are considered as such $\tau$ candidates is about $27 \%$. The numerator in the calculated misidentification probability consists of events with objects which pass the full $\tau$ identification. They must not be within $\Delta R=0.2$ of any $e$ or $\mu$. The measured misidentification probabilities are shown in Fig. 2.

Systematic uncertainties The dominant systematic uncertainties on the misidentification probability are (the ranges given on each systematic uncertainty show the variation with the $p_{\mathrm{T}}$ and $\eta$ of the $\tau$ candidate):

- Contamination of the control sample with true $\tau$ jets from $Z \rightarrow \tau \tau$ and $W \rightarrow \tau v$ events, evaluated using simulation: $(1-3) \%$.
- Contamination of the control sample with multi-jet events which have a larger gluon-initiated jet fraction than $\gamma$-jet events. The associated systematic uncertainty is evaluated by modifying the photon ID requirements, in particular loosening the photon isolation which increases the impurity from multi-jet events in the control sample: $(5-9) \%$.
- Contamination of the control sample by three-jet events. The associated systematic uncertainty is evaluated by varying the selection cuts (vetoing events with additional jets with less than 0.1 of the
photon momentum), and by splitting the control sample in a part which fulfills even tighter requirements and one which does not, and then taking the variation of the misidentification probability due to these changes as the uncertainty: $(11-17) \%$.
- The measurement of the misidentification probability on the probe object is assumed to be uncorrelated from the selection of the tag object. To evaluate uncertainties from a violation of this assumption, correlations between the tag and the probe objects are studied by changing the requirements on the tag object (requiring a photon with a looser quality criterion) and studying the impact on the measurement of the misidentification probability on the probe object: $(7-14) \%$.

Additionally, the statistical uncertainty of the measurement of the misidentification probability enters as uncertainty on any application of the misidentification probability. The total systematic uncertainty is about $(15-24) \%$, depending on $p_{\mathrm{T}}$ and $\eta$. The systematic uncertainties on the misidentification probability are propagated into the background prediction for the baseline selection and enter the statistical evaluation as shape uncertainties.

Application to estimate the jet $\rightarrow \tau$ misidentification background To predict the background in $\mathrm{H}^{+}$ searches, the measured jet $\rightarrow \tau$ misidentification probability is applied to simulated $t \bar{t}$, single-top, and $W+$ jets events. These events are required to pass the full event selection except for the $\tau$ identification. For these events, $\tau$ candidates fulfilling the same requirements as in the misidentification probability definition which do not overlap with a true $\tau$ lepton are identified. Out of the remaining $\tau$ candidates, each one is considered to be potentially misidentified as a $\tau$ jet separately. The identified jet that corresponds to the $\tau$ candidate is removed from the event, affecting the number of reconstructed jets, the $E_{\mathrm{T}}^{\text {miss }}$ significance of the event, and the number of $b$-tagged jets. If, after taking this into consideration, the event still passes the selection, then the event is counted as background event with a weight given by the misidentification probability corresponding to the $p_{\mathrm{T}}$ and the $\eta$ of the $\tau$ candidate. The predicted number of events from the $t \bar{t}$ sample, together with a comparison to the MC prediction using truth information, is shown in Table 4. All other jet $\rightarrow \tau$ misidentification backgrounds with intrinsic $E_{\mathrm{T}}^{\text {miss }}$ are at least two orders of magnitude smaller than $t \bar{t}$.

Table 4: Application of the misidentification probability obtained from $\gamma$-jet events. The numbers shown are the expected number of events in collision data after the $H^{+}$selection. The prediction based on the misidentification probability measurement (statistical and systematic uncertainties), as well as the MC prediction (statistical uncertainties), are given.

| Sample | Data-driven prediction [number of events] | MC prediction [number of events] |
| :--- | :--- | :--- |
| $t \bar{t}$ | $2.8 \pm 1.0($ stat $) \pm 0.5($ syst $)$ | $3.8 \pm 0.6($ stat $)$ |

### 5.2 Multi-jet background estimate

As the uncertainties on the multi-jet expectation are large, it is necessary to avoid using any multi-jet simulation to estimate this background. Thus an approach different from estimating the jet $\rightarrow \tau$ misidentification contribution in events with intrinsic $E_{\mathrm{T}}^{\text {miss }}$, as described in the previous section, is chosen.

The Method The multi-jet background is estimated by fitting its $E_{\mathrm{T}}^{\text {miss }}$ shape (and the $E_{\mathrm{T}}^{\text {miss }}$ shape of other backgrounds) to data. In order to study this shape in a data-driven way, a control region is defined
where the $\tau$ identification and $b$-tagging requirements are inverted. The $\tau$ candidates must pass a loose $\tau$ identification but fail the tight $\tau$ identification used in the baseline selection. In addition, the event is required not to contain any $b$-tagged jets and therefore also the requirement on the $q q b$ mass (selection cut 7) is removed.

Assuming that the shapes of the $E_{\mathrm{T}}^{\text {miss }}$ and $m_{\mathrm{T}}$ distributions are the same in the control sample and signal regions (see Fig. 3 for a comparison early in the selection cut flow), the shape of the $E_{\mathrm{T}}^{\text {miss }}$ distribution is used to model the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution for the multi-jet background (after subtracting the background from other processes). The $E_{\mathrm{T}}^{\text {miss }}$ distribution measured in data (for the baseline selection) is then fitted using two shapes: this multi-jet model, and the sum of other processes (dominated by $t \bar{t}, W+\mathrm{jets}$ ) for which the shape and the relative normalisation are taken from MC simulation. The free parameters in the fit are the overall normalisation (to the one in data) and the multi-jet fraction.

Figure 3: Distribution of $E_{\mathrm{T}}^{\text {miss }}$, after subtracting the expectation from $t \bar{t}, W+\mathrm{jets}$, and single-top simulation; compared are the distributions after requirement 3 of the baseline selection as detailed in Section 4, with the exception that in the control region, the $\tau$ selection and the $b$-tagging requirements have been inverted. The shaded area indicates the size of the statistical uncertainties.

Systematic uncertainties The dominant systematic uncertainties are:

- The uncertainty on the assumption that the $E_{\mathrm{T}}^{\mathrm{miss}}$ shape is identical in the signal and control regions. This is studied by varying the number of entries in each bin separately within the maximum differences observed early in the selection cut flow (a factor of 0.5 and 2.0) and redoing the fit. Then, the largest downwards and upwards fluctuations are used as systematic uncertainty. This leads to an uncertainty on the multi-jet fraction of $-13 \% /+25 \%$.
- The uncertainty on the $t \bar{t}$ and $W+$ jets shapes and relative normalisation from Monte Carlo is dominated by uncertainties on the $t \bar{t}$ cross section. The scaling of the $t \bar{t}$ Monte Carlo is varied according to these uncertainties, leading to an uncertainty on the multi-jet fraction of $2.4 \%$.
- The uncertainty from backgrounds other than $t \bar{t}$ and $W+$ jets in the control region is found to be negligible.

The uncertainty on the multi-jet fraction is dominated by the statistical uncertainty of the data set on which the fit is performed.

Result of the data-driven estimate of the multi-jet background The multi-jet fraction is estimated to be $(23 \pm 10) \%$ using the fit to the $E_{\mathrm{T}}^{\text {miss }}$ distribution shown in Fig. 4. The $m_{\mathrm{T}}$ distribution for the same
events is shown in Fig. 5. Except for the multi-jet background, all other processes have $W$ bosons in the final state and their distributions drop off around the $W$ boson mass, as expected. Such behavior is neither expected nor observed for the multi-jet background as resulting shapes are mainly caused by detector effects. To probe the region with large $m_{\mathrm{T}}$, in which a potential $H^{+}$signal resides, it is thus important to suppress the multi-jet background as much as possible.

Figure 4: Multi-jet estimate: A fit to the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution in data after all selection cuts using two shapes (one for the multi-jet model, and one for all other background processes, dominated by $t \bar{t}$ and $W+$ jets) is shown. The multi-jet fraction estimated after all selection cuts is $(23 \pm 10) \%$.

Figure 5: Contribution of multi-jet events to the $m_{\mathrm{T}}$ distribution after all cuts of the $H^{+}$selection. The multi-jet fraction is estimated using the fit to the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution shown in Fig. 4.

### 5.3 Embedding method

Complementary to the methods based on misidentification probability, an embedding method is used for estimating the background from true $\tau$ jets, described below. The method consists of collecting a control sample of $t \bar{t}$, single-top, and $W+$ jets events with a muon in data, and replacing the detector signature of this muon with that of a simulated $\tau$ lepton. The reconstruction is re-applied to the new hybrid
events which are then used to estimate the background to the $H^{+}$selection. The advantage is that the whole event (except for the $\tau$ jet) is taken directly from data, including the underlying event and pile-up, missing energy, $b$-quark jets and light-quark jets. The method has been validated in $\tau+$ jets events using early ATLAS data [41].

### 5.3.1 The Method

Control sample selection To select the $t \bar{t}$-like $\mu+$ jets control sample from data, the following event selection is used:

- Event triggered by a single muon trigger ( $p_{\mathrm{T}}$ threshold of 18 GeV ),
- data quality cuts as described in Section 3,
- exactly one isolated muon with $p_{\mathrm{T}}>25 \mathrm{GeV}$,
- no isolated electron with $p_{\mathrm{T}}>20 \mathrm{GeV}$,
- at least four jets with $p_{\mathrm{T}}>20 \mathrm{GeV}$ in $|\eta|<2.5$,
- at least one of the jets is $b$-tagged (nominal efficiency of $65 \%$ ),
- missing transverse energy $E_{\mathrm{T}}^{\text {miss }}>30 \mathrm{GeV}$,
- scalar sum of energy of reconstructed objects $\sum E_{\mathrm{T}}>200 \mathrm{GeV}$.

This selection is looser than the selection defined in Section 4 in order not to bias the control sample. This also applies to the $\tau$ jet which carries the momentum of the selected muon minus the momentum of the neutrino in the $\tau$ lepton decay and its $p_{\mathrm{T}}$ is required to be larger than 35 GeV in the $H^{+}$selection. The impurity from the background with muons produced in $\tau$ decays, and non-isolated muons (dominantly $b \bar{b}$ and $c \bar{c}$ events) is at the level of $10 \%$ and biases the shape of embedded events. However, the bias is greatly reduced as these events are much less likely to pass the $H^{+}$selection.

Embedding step After events have been selected, the actual embedding step takes place. The muon in the event is selected and its vertex position and momentum are extracted. The momentum is then rescaled to account for the higher $\tau$ lepton mass and fed into TAUOLA to produce the $\tau$ lepton decay products and generate final state radiation. The result is propagated through ATLAS detector simulation, followed by reconstruction. In the next step, tracks, calorimeter deposits and segments in the muon spectrometer in the vicinity of the muon are replaced with those of the simulated $\tau$ lepton decay products.

Comparison of embedding method versus simulation To test the method, the embedded data events are compared to simulated $t \bar{t}$ events (hereafter referred to as 'reference') in which the $\tau$ lepton comes directly from simulation of the whole event, and is not added via the embedding method. To make sure the set of events is comparable, both for the embedded and the reference events, a reconstructed $\tau$ candidate which is matched to a true $\tau$ lepton is required (this can be performed using embedded events, as the $\tau$ part of the event is taken from simulation).

A comparison of distributions of variables relevant to this analysis is shown in Fig. 6. A good agreement is observed within the statistical uncertainties.

Figure 6: Validation plots for the embedding method used to estimate the background with true $\tau$ jets. Embedded data is compared to $t \bar{\tau}$ simulation after applying the $H^{+}$selection. The $\tau$ likelihood (TauLLH), the $\tau$ transverse momentum, the missing transverse energy, and the top quark transverse momentum on the $t \rightarrow b q q$ side are shown. The plots are normalized to unit area. The shaded area indicates the size of the statistical uncertainties on the MC simulation.

### 5.3.2 Application to estimate the true- $\tau$ background

The contribution of backgrounds with true $\tau$ jets to the final $m_{\mathrm{T}}$ distribution is estimated from this distribution for embedded events. The normalisation is taken from collision data events in the region $0-40 \mathrm{GeV}$ of this distribution, where any signal contamination would be low for the expected range of sensitivity $\left(\operatorname{BR}\left(t \rightarrow b H^{+} \approx 5 \%\right)\right)$. Such a contamination is dealt with in the limit-setting process by subtracting the expected signal from the observed data before normalizing the shape to the region $m_{\mathrm{T}}<40 \mathrm{GeV}$. This is done when evaluating the signal+background hypothesis and takes the tested $\mathrm{BR}\left(t \rightarrow b H^{+}\right)$into account. Effectively, this brings the signal+background expectation closer to the background-only expectation.

The following procedure is applied:

1. Apply the $\tau+$ jets event selection to embedded events to obtain the $m_{\mathrm{T}}$ shape.
2. From collision data, count the number of events in the $m_{\mathrm{T}}$ distribution between $0-40 \mathrm{GeV}$ after subtracting the background from objects misidentified as $\tau$ jets.
3. Using this number, normalize the $m_{\mathrm{T}}$ distribution from embedded events using the ratio of events in collision data and embedded data.

For technical reasons, the trigger simulation cannot be re-run for embedded events. As the number of events entering the embedding control sample and passing the whole event selection is still relatively small, the event selection applied to the embedded events is modified by requiring a $\tau$ identified using loose criteria. This can be done because the $m_{\mathrm{T}}$ distribution is normalized to data and, as Fig. 7 (left) shows, the looser cuts do not bias the shape significantly.

The result is shown in Fig. 7 (right). As can be seen, the uncertainty of the background estimate is currently limited by the statistical uncertainty due to the limited number of events in the $t \bar{t}$ control sample. In the range $40<m_{\mathrm{T}}<300 \mathrm{GeV}$, there are $21 \pm 5$ background events with true $\tau$ jets expected where the uncertainty is due to the limited number of events in the control sample, and of the data in the region to which the shape is normalized to. In data, 26 events are observed after subtracting the background predicted by the misidentification probability methods and the multi-jet estimate. Within statistical uncertainties, the background prediction and data agree well.

### 5.3.3 Systematic uncertainties

The following systematic uncertainties are associated with the background prediction:

- To study the effect of additional multi-jet background on the embedding and the control sample selection itself, the $\mu$ isolation requirement is varied. To study a potential bias introduced by the embedding method parameters chosen, alternative values are used for the inner and outer cone size in which calorimeter cell depositions are replaced or added. To account for the fact that a small amount of pile-up-related activity can be present in the calorimeter cells removed in a cone around the muon, the effect of only removing half of this energy before adding the $\tau$ jet is studied. This results in a systematic uncertainty of $7 \%$ on the background normalisation.
- The systematic uncertainty due to the difference in the $m_{\mathrm{T}}$ shape as a consequence of loosening the selection with respect to the $H^{+}$selection, as shown in Fig. 7, results in a $8 \%$ uncertainty on the background normalisation, and a shift of about 2 GeV in the $m_{\mathrm{T}}$ distribution.
- The impact of the incomplete treatment of the $\tau$ polarisation in embedded events results in an uncertainty on the $m_{\mathrm{T}}$ shape which is estimated by comparing bin by bin the difference in the number of events for simulated $t \bar{t}$ events with and without correct treatment of the $\tau$ polarisation.

Figure 7: Left: Comparison of the $m_{\mathrm{T}}$ shape for simulation and for embedded events (with loose $\tau$ identification) used to estimate the background with true $\tau$ jets. The distribution from simulation is shown both after the $H^{+}$baseline selection and after the same selection but without trigger requirement and loose $\tau$ identification. All distributions are normalized to unit area. Right: Comparison of the $m_{\mathrm{T}}$ shape for embedded events versus collision data. The prediction using the embedding method is stacked on top of the expected backgrounds with objects misidentified as $\tau$ jets: MC expectation for $t \bar{t}$ and electroweak processes, and the data-driven estimate for multi-jet events. The comparison is done after the $H^{+}$event selection and after normalizing the $m_{\mathrm{T}}$ distribution of embedded events to the data distribution in the range $0-40 \mathrm{GeV}$. The gray area indicates the size of the statistical and systematic uncertainties of the embedding method estimate.

This results in an uncertainty on the normalisation of $15 \%$, and the $m_{\mathrm{T}}$ distribution is shifted by about 7 GeV which corresponds to $14 \%$ of the average $m_{\mathrm{T}}$.

- The impact on the $m_{\mathrm{T}}$ distribution due to the uncertainty on the $\tau$ energy scale (Table 2 ) is evaluated, leading to a normalisation uncertainty of $+4 /-2 \%$, and a shift in the $m_{\mathrm{T}}$ distribution by $\pm 1 \mathrm{GeV}$.

The statistical uncertainty of the estimate is $8 \%$ due to the limited size of the control sample, and additionally $20 \%$ due to the normalisation to data (allowing data to fluctuate within one standard deviation for $m_{\mathrm{T}}<40 \mathrm{GeV}$ ). The numbers above are only indicative, for the limit calculation the full shape uncertainty is used.

## 6 Results

The results of the data-driven methods in estimating the contributions of the various categories of backgrounds after the baseline selection are summarized in Table 5, and the $m_{\mathrm{T}}$ distribution of the remaining events is shown in Fig. 8. The total systematic uncertainty on the background prediction is about $30 \%$ but can reach up to $70 \%$ for $m_{\mathrm{T}}>100 \mathrm{GeV}$. For the signal, the total systematic uncertainty on the yield is about $40 \%$ with a small dependence on $m_{H^{+}}$. The number of events with true $\tau$ jets has been estimated with the embedding method, the jet $\rightarrow \tau$ misidentification events with intrinsic $E_{\mathrm{T}}^{\text {miss }}$ with $\gamma+\mathrm{jets}$ control samples, the $e \rightarrow \tau$ misidentification events with $Z / \gamma^{*} \rightarrow e e$ control samples, and the multi-jet contribution by taking its shape from a sideband region and fitting it to the data. The number of events with $m_{\mathrm{T}}>40 \mathrm{GeV}$ is given which allows for a better comparison of data and expectation as the estimate from the embedding method is normalized to data in the range $m_{\mathrm{T}}<40 \mathrm{GeV}$. A good agreement between the estimated and the observed number of events is seen.

Table 5: Expected number of events from data-driven estimates with $m_{\mathrm{T}}>40 \mathrm{GeV}$, and as observed in data. Only statistical uncertainties are given.

|  | Events with/from |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | true $\tau$ jets | jet $\rightarrow \tau$ mis-id | $e \rightarrow \tau$ mis-id | multi-jet | expected (sum) | data |
| $m_{\mathrm{T}}>40 \mathrm{GeV}$ | $21 \pm 5$ | $2.4 \pm 0.7$ | $1.9 \pm 0.2$ | $12 \pm 5$ | $37 \pm 7$ | 43 |

Using data-driven background estimates, no statistically significant excess of events is observed in $1.03 \mathrm{fb}^{-1}$ of collision data. Exclusion limits are set on the branching ratio $t \rightarrow b H^{+}$, and in the $m_{H^{+}}-\tan \beta$ plane, by rejecting the signal hypothesis at the $95 \%$ confidence level applying the $\mathrm{CL}_{s}$ procedure [42, 43]. A profile likelihood ratio [44] is used with the $m_{\mathrm{T}}$ distribution as the discriminating variable. The statistical analysis is based on a binned likelihood function for the $m_{\mathrm{T}}$ distribution. Systematic uncertainties in shape and normalisation are incorporated via nuisance parameters and the one-sided profile likelihood ratio, $\tilde{q}_{\mu}$, is used as a test statistic. The final limits are based on the asymptotic distribution of the test statistic [44].

The resulting exclusion limit is shown in Fig. 9 in terms of $\operatorname{BR}\left(t \rightarrow H^{+} b\right) \times \operatorname{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$. Figure 10 shows the upper limit in the context of the $m_{h}^{\max }$ scenario of the MSSM [45] in the $m_{H^{+-}} \tan \beta$ plane. No exclusion limit is shown for charged Higgs boson masses close to 160 GeV as no reliable calculations for $\mathrm{BR}\left(t \rightarrow H^{+} b\right)$ exist for $\tan \beta$ values in the range of interest. The following relative uncertainties on $\mathrm{BR}\left(t \rightarrow b H^{+}\right)$are considered [46]: 5\% for one-loop electro-weak corrections missing in the calculations, $2 \%$ for missing two-loop QCD corrections, and about $1 \%$ (depending on $\tan \beta$ ) $\Delta_{b^{-}}$ induced uncertainties (where $\Delta_{b}$ is a correction factor to the running bottom quark mass [47]). These

Figure 8: The $m_{\mathrm{T}}$ distribution after event selection. The observation in collision data, and the estimates from data-driven methods are compared. The distribution of the $H^{+}$signal is given for a reference point in parameter space corresponding to $\mathrm{BR}\left(t \rightarrow b H^{+}\right)=10 \%$, thus the SM-like $t \bar{t}$ background is reduced correspondingly.
uncertainties are added linearly. This result constitutes a significant improvement compared to existing limits provided by the Tevatron experiments [6] over the whole investigated mass range, but in particular for charged Higgs boson masses close to the top quark mass.

## 7 Conclusions

Charged Higgs bosons are searched for in the decay mode $t \rightarrow b H^{+}, H^{+} \rightarrow \tau v$, with hadronically decaying $\tau$ leptons, using $t \bar{t}$ events reconstructed in a total of $1.03 \mathrm{fb}^{-1}$ of $\sqrt{s}=7 \mathrm{TeV} p p$ collision data recorded with the ATLAS experiment. Data-driven methods, employed to estimate the number of background events characterized by the presence of a $\tau$ jet, $E_{\mathrm{T}}^{\text {miss }}, b$ jets, and a hadronically decaying $W$ boson, predict $37 \pm 7$ (stat) events with $m_{\mathrm{T}}>40 \mathrm{GeV}$. A total of 43 such events are observed which is consistent with the prediction. The $\mathrm{CL}_{s}$ procedure is used to derive $95 \%$ CL exclusion limits. Values of the product of branching ratios, $\mathrm{BR}\left(t \rightarrow b H^{+}\right) \times \mathrm{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$, larger than $0.03-0.10$ have been excluded in the $H^{+}$mass range $90-160 \mathrm{GeV}$, significantly extending limits from other experiments. Interpreted in the context of the $m_{h}^{\max }$ scenario of the MSSM, values of $\tan \beta$ above $22-30$ (depending on $m_{H^{+}}$) can be excluded in the mass range $90 \mathrm{GeV}<m_{H^{ \pm}}<140 \mathrm{GeV}$.

## A Limit figure with PCL

Figure 11: Expected and observed $95 \%$ CL exclusion limits for charged Higgs boson production from top quark decays as a function of $m_{H^{+}}$in terms of $\mathrm{BR}\left(t \rightarrow H^{+} b\right) \times \mathrm{BR}\left(H^{+} \rightarrow \tau^{+} v\right)$ using the $\mathrm{CL}_{s}$ procedure. Power-Constrained limits (PCL) [48] with a $50 \%$ power constraint are shown as well. For comparison, the best limit provided by the Tevatron experiments is shown [6].

## 3. D0 Experiment at Tevatron

SMU joined the D0 Experiment in 2004, following a long D0 involvement by Kehoe since 1992. The primary thrust of the SMU project has been to study top quark physics ultimately to probe electroweak symmetry breaking, particularly in the period before a Higgs boson discovery. Kehoe's early efforts at SMU were to measure the top quark pair cross section, but have primarily focused on measuring the top quark mass. This activity was supported by work on the Level 1 Calorimeter upgrade for Run 2b (2004-2006), work by SMU postdoc Renkel to co-coordinate the Common Samples Group (20102011), and jet energy calibration efforts for the final data sample (2011-2013).

Recent activities by our group have involved postdocs Renkel and Amitabha Das, and Ph.D. students Yuriy Ilchenko and Huanzhao Liu. Our primary effort was top quark mass measurement and jet energy calibration. The effort has been productive, yielding conference and journal papers on top quark mass measurement, and on modelindependent searches for new physics. Ilchenko is now a postdoc at $U$. of Texas, Austin on ATLAS.
a) Jet Energy Scale (Liu, Ilchenko, Das, Kehoe): The JES is critical to the measurement of the top quark mass. The primary calibration is extracted using $\mathrm{E}_{\text {Tmiss }}$ in $\gamma+\mathrm{jet}$ events. SMU has major involvement in several elements of the standard D0 JES. In data, the $\gamma+$ jet signature has substantial instrumental background. To calibrate data to the same level as MC, we must evaluate the purity of the photon sample, correct the scale appropriately and establish a systematic uncertainty. Ilchenko studied the photon purity for data after the 2006 upgrade ('R2b') as it applies to the jet response ( $R_{j}$ ) measurement in the central region. The purity is evaluated with a template fit using an isolation variable from tracks near the photon. He determined a new efficiency for data and improved the statistical error calculation. He measured the purity for all of R2b and resolved a difficulty with poor $\chi^{2}$ in pre-shutdown data ('R2a').

D0 calibrates jets in data and MC independently using similar methods. He studied the ratio of the $R 2 a$ and $R 2 b$ MC jet responses vs. $E^{\prime}=\mathrm{p}_{\mathrm{T}^{* *}} \cosh \left(\eta_{\mathrm{j}}\right)$ in several $\eta$ bins and established agreement within quoted systematics. Liu and Kehoe continued with a study of $\Delta R=0.5$ cone jets and $M C$ simulating the luminosity profile of all $R 2 b$ run ranges. We observed excellent agreement within R 2 b and good agreement relative to R2a, although at low and very high energies a difference was observed that was still within the existing systematic uncertainty band. Liu observed no dependence on the number of primary vertices or on central preshower requirements for the photon. He also studied potential biases from the fitting method to develop a correction for data. He determined the absolute $R_{j}$ in MC for all R 2 b MC run ranges. The response is stable to within 1\% (see Figure 11).

The D0 detector is uniform in LAr calorimetry except for the inter-cryostat region occupied by scintillators (ICD). Liu derived $\eta$-dependence corrections for all run periods in data using $\gamma+$ jet and dijet events to maximize the energy reach out to $|\eta|=3.6$. He also used the $\chi^{2}$ to calculate the systematic uncertainty while avoiding double counting statistical uncertainties. The relative uncertainty is $<1.5 \%$ in most of the detector. This correction, and the purity and MC scale corrections, are now included in the final
corrections for the full data sample. Das performs the final data closure tests of the effectiveness of the overall calibration by computing the ratio of the corrected reconstructed jet energies between data and $\mathrm{MC} \gamma+$ jet events in photon $\mathrm{p}_{\mathrm{T}}$ bins. He sequentially identified and helped resolve several inconsistencies and bugs in the calibration software, and he established the ratio to be around 1 , with $\sim 2 \%$ uncertainty. The final jet energy scale step entails a post-calibration jet smearing and scaling correction. Das implemented this for the full data sample and worked to complete this final part of the jet energy scale analysis. Liu, Ilchenko, Das and Kehoe contributed to the final analysis note describing this work [1], and each wrote portions of the draft NIM paper currently in internal review.

### 3.4 D0 Physics Analysis:

The top quark mass, $m_{t}$, is a fundamental parameter of the SM and it provides sensitivity to the SM Higgs boson mass through radiative corrections. Its value indicates a Yukawa coupling near unity, which may point to new physics. Our effort on D0 has been focused on a precision measurement of the top mass in dilepton events. A model-independent search for new physics was also pursued.
a) Top Quark Mass in Dilepton Events (Renkel, Kehoe, Ilchenko, Liu, Das): Mass analysis in dilepton events is challenged by loss of kinematic information to two neutrinos and by the absence of $\mathrm{W} \rightarrow \mathrm{jj}$ in the final state. Since our result in $1 \mathrm{fb}^{-1}$ [2], we analyzed $4.3 \mathrm{fb}^{-1}$ of $\mathrm{R} 2 \mathrm{~b} e \mu$ events. We integrate over the expected neutrino $\eta$ distribution and compare the solved momenta to the observed $\mathrm{E}_{\text {Tmiss }}$ to obtain a relative weight vs. $m_{t}$. Ilchenko rewrote the weight calculation, and he and Kehoe fitted the $\eta$ distribution and optimized the binning of this distribution to balance CPU time with improvement in the statistical error expected in pseudo-experiments. He and undergraduate Jason South tested fitting the $\eta$ distribution with different functions, and developed a linear parametrization of the width of the $\eta$ distribution with $m_{t}$. We measure $m_{t}$ by fitting 3D templates relating the first two moments of the weight distribution with $m_{t}$. Liu and Kehoe optimized template binning to minimize the expected statistical error. Renkel estimated most systematic uncertainties and improved the treatment of statistical errors to better reflect MC samples. We obtained the world's most precise $m_{t}$ in dilepton events [3]. The results were shown at HCP 2010, and by Renkel at HQL 2010. Kehoe presented top and EWK at the Fermi User's Meeting, 2010.

This measurement was limited particularly by JES uncertainties. Renkel and Kehoe focused on a more accurate JES determination from analysis of $\mathrm{W} \rightarrow \mathrm{jj}$ in $t \bar{t}$ single lepton+jets (' $1+$ jets') events. We had to account for the different event topologies of dilepton and $1+$ jets events that can cause slight differences in JES. Renkel used single particle responses for data and MC to calculate their ratio in dilepton events, and in $1+$ jets events. The ratio of these ratios indicates agreement to within $0.3 \%$ (see Figure 11) and is taken as a systematic uncertainty. The shift is primarily because the b-jet particle multiplicity in the two samples differs by a few percent. Renkel implemented the $1+$ jets scale from $2.6 \mathrm{fb}^{-1}$ into the analysis, plus a time-dependent correction for aging of ICD since that analysis. Also for the first time in dilepton events, he implemented corrections to bring the flavor dependence of the MC JES into agreement with data. After several studies, only the overall calorimeter time-dependence was a significant ( $0.7 \%$ ) source of
uncertainty. Renkel also performed the residual JES uncertainty determinations for kinematic and flavor differences of dilepton b-jets relative to jets from $\mathrm{W} \rightarrow \mathrm{jj}$.

Figure 1: Central $\boldsymbol{R}_{\boldsymbol{j}}$ vs. $\mathrm{E}^{\prime}$ in MC for three different D0 run periods (left). Measured double ratio in the DO dilepton sample vs. $l+$ jets sample (right).

Ilchenko applied the new JES to $e e, e \mu$ and $\mu \mu$ channels. He also performed several studies to improve the statistical sensitivity of the analysis. While they did not reveal a clear improvement, they provided valuable insight motivating current studies by Liu. Ilchenko was primarily responsible for performing the full analysis, from selection, to moments calculation, fitting, testing and most systematics. He and Kehoe also performed a detailed analysis of high $\chi^{2}$ values in calibration plots, which were determined to arise from oversampling and varying Alpgen weights. Accounting for these caused no significant shift to the method's calibration. Our final result of $174.0 \pm 2.4($ stat $) \pm 1.4$ (syst) GeV in $5.3 \mathrm{fb}^{-1}$ [4] is included in the Tevatron $m_{t}$ average [5]. This was the first time the $\mathrm{W} \rightarrow \mathrm{jj}$ resonance has been used to calibrate jets outside the parent $1+$ jets sample. Ilchenko and Liu presented these results at Lake Louise and APS, respectively. Ilchenko is finishing his dissertation. Renkel presented top results at HQL and Aspen. Kehoe gave an invited talk on Top Quark Physics for Tevatron at APS. Das and Kehoe determined correlations between SMU and matrix-element approaches in R2a and R2b. Combining these analyses slightly improves our precision, giving the world's smallest uncertainty ( $1.4 \%$ ) in dilepton events [6]. This was published in fall.

With jet calibration and previous analysis finished, we have worked to analyze the full Run 2 b data sample of $8.7 \mathrm{fb}^{-1}$. Das set up the skimming software to extract this data sample. He worked through several difficulties particularly with the most recent data, and validated the output against previous results. He and Kehoe also worked with Liu in developing ideas to improve or modify the neutrino weighting approach to increase its statistical power. Liu has developed several techniques that improve the numerical integration, and more effectively identify correct jet-lepton assignments and neutrino solutions. He has run the full data sample with the old jet energy scale to verify results against our earlier measurement. Skimming with the new jet energy scale, and tests of the method sensitivity were also completed.
b) Model Independent Search for New Physics (Renkel): Renkel pursued a modelindependent search in over 120 channels in collaboration with Michigan State. He made substantial contributions, including his focus on applying MC corrections for tagging of
b-jets because many final states had b-jets. Space limitations preclude a more detailed discussion. He was integrally involved in EB and referee responses [7]. He presented results at DPF 2011 and SUSY 2011.
c) Other D0 Activities: Renkel was MC representative for the Top and JES groups, and co-convenor of DØ's Common Samples Group (CSG) in 2010-2011. The Top/JES job entailed developing MC requests within the groups, requesting and validating the samples, and developing infrastructure for special requests. As CSG convenor, a major D0 responsibility, Renkel's work included processing the data, maintaining databases, and calculating luminosity profiles for MC samples. Kehoe co-chaired the editorial board reviewing lifetime and CP -violation measurements in the $\mathrm{B}_{\mathrm{s}}$ system through 2011. Highlights were analyses of $\mathrm{B}_{\mathrm{s}} \rightarrow \mathrm{J} / \psi \phi[8]$ and $\mathrm{B}_{\mathrm{s}} \rightarrow \mathrm{J} / \psi \mathrm{f} 0$ [9]. Renkel, Ilchenko, Liu and Kehoe took calorimeter shifts during data-taking.

# Measurement of the Mass of the Top Quark in $e \mu+$ Jets Final States at DØ with $5.3 \mathrm{fb}^{-1}$ 

The DØ Collaboration<br>URL http://www-d0.fnal.gov<br>(Dated: August 25, 2010)

#### Abstract

We present a measurement of the mass of the top quark $\left(m_{\mathrm{t}}\right)$ in $e \mu+2$ jets final state using data corresponding to $5.3 \mathrm{fb}^{-1}$ collected by the $\mathrm{D} \varnothing$ experiment at the Fermilab Tevatron. The mass is extracted from an analysis of $t \bar{t} \rightarrow b W^{+} \bar{b} W^{-} \rightarrow b \bar{b} \mathrm{e}^{ \pm} \mu^{\mp} \nu_{\mathrm{e}} \nu_{\mu}$ candidate events. We employ a comparison of expected properties of the two unobserved neutrinos with the imbalance in transverse momentum in data, as a function of $m_{\mathrm{t}}$.

We measure $m_{\mathrm{t}}=173.3 \pm 2.4$ (stat.) $\pm 2.1$ (syst.) GeV by combining a Run2b top quark mass measurement with $4.3 \mathrm{fb}^{-1}$ and a Run2a measurement with $1.0 \mathrm{fb}^{-1}$.

## I. INTRODUCTION

In the standard model $(S M)$, the masses of vector bosons are generated from spontaneous breaking of electroweak symmetry, and masses of fermions arise from their Yukawa couplings to the scalar Higgs field [1]. In $S M$, we can use top quark mass, and $W$ boson mass to constraint the Higgs boson mass.

In this analysis, we measure $m_{\mathrm{t}}$ in $e \mu+$ jets decays of $t \bar{t}$ pairs. Each top quark decays to $W b$ with a branching fraction close to $\sim 100 \%$, and each $W$ boson decays into either a lepton and a neutrino, or two quarks. In the present analysis, we consider just those final states with one electron and one muon. They can arise from either $W \rightarrow e(\mu) \nu$, or from $W \rightarrow \tau \nu \rightarrow e(\mu) \nu \nu$ decays.

The value of $m_{\mathrm{t}}$ is measured in $4.3 \mathrm{fb}^{-1}$ of data collected at $\mathrm{D} \varnothing$ in Run 2 b of the Tevatron. The $\mathrm{D} \emptyset$ detector is described in Ref. [2]. The presented analysis is based on the Neutrino Weighting method used for $m_{\mathrm{t}}$ measurement in $1 \mathrm{fb}^{-1}$ of Run 2a data [3]. Assuming various top quark masses, the consistency of the observed event kinematics can be used to obtain weights for each event versus top quark mass using simulated neutrino pseudo-rapidity distributions. Weights are calculated for a range of assumed top quark masses based on the consistency of these momenta with the measured event $E_{T}$. We determine $m_{\mathrm{t}}$ using histograms of probability density of the first two moments of the weight distributions for different assumed $m_{\mathrm{t}}$.

## II. SELECTION OF EVENTS

The event selection used for this measurement is similar to the one used to measure the $t \bar{t}$ cross section in the same final state [4]. Basic requirements include one isolated electron and one isolated muon of opposite charge and transverse momenta of at least 15 GeV , exactly two jets that have transverse momenta of at least 20 GeV , and significant $H_{T}$, defined as the scalar sum of the transverse momenta of the two jets and the leading lepton. The only other requirement is that the events must pass the kinematic reconstruction of Section III. Table I shows the expected event yields for signal and backgrounds, as well as the number of events in data before and after kinematic reconstruction. The uncertainties are statistical only except for an uncertainty on signal yield, where it arises due to theoretical uncertainty on the $t \bar{t}$ cross section. The expected yields differ from those from Ref. [4] due to a different $H_{T}$ cut. For our measurement, the $H_{T}$ cut was slightly increased from $H_{T}>110 \mathrm{GeV}$ to $H_{T}>115 \mathrm{GeV}$ to reduce the expected statistical uncertainty on $m_{\mathrm{t}}$.

The signal and $Z \rightarrow \tau \tau$ background processes are generated with ALPGEN [5], followed by PYTHIA [6] for showering and hadronization, the diboson samples (WW,WZ,ZZ) are generated with PYTHIA. Instrumental effects can cause object misidentification, and mismeasurement of missing transverse energy. Instrumental background is modeled using data.

TABLE I: Expected and observed $e \mu$ event yield for background and signal ( $\sigma_{t \bar{t}}=7.45 \mathrm{pb}$ for $m_{\mathrm{t}}=172.5 \mathrm{GeV}$ ), after applying all selections. The numbers in the first six columns are given before the kinematic reconstruction.

| $t \bar{t} \rightarrow e \mu$ | $Z \rightarrow \tau \tau$ | diboson | instrumental | total | observed | after kinematic reconstruction |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $141.6_{-11.4}^{+11.4}$ | $10.9_{-1.3}^{+1.3}$ | $6.2_{-0.7}^{+0.7}$ | $10.8_{-3.8}^{+4.0}$ | $169.5_{-12.2}^{+12.2}$ | 202 | 197 |

## III. METHOD OF ANALYSIS

The kinematic reconstruction is based on the fact that the final state consists of the following six particles: two charged leptons, two jets from the $b$ quarks, and two neutrinos. After the assignments of the mass to each particle in the final state, a total of 18 independent kinematic quantities needed to fully measure the final state. Twelve of these quantities - the momenta of the charged leptons and jets - are measured directly in the detector. Five additional constraints are added by requiring that
(i) the two components of the observed imbalance in missing transverse momentum $\left(\mathbb{E}_{T}\right)$ equal the sum of the respective components of the two neutrinos;
(ii) the invariant mass of each pair of lepton and neutrino equals the $W$ boson mass; and
(iii) the mass of the top quark equals the mass of the antitop quark.

This leads to a total of seventeen constraints, which is one constraint short of providing a solution for the system.
A solution can be found by assuming a value of $m_{\mathrm{t}}$. We use the measured $E_{T}$ in each event to assign a weight to each solution. The weight is based on the agreement of the calculated transverse momentum of the neutrinos and the observed $E_{T}$ :

$$
\begin{equation*}
\omega=\frac{1}{N_{\text {iter }}} \sum_{i=1}^{N_{\text {iter }}} \exp \left(\frac{-\left(E_{x, i}^{\text {calc }}-\mathscr{E}_{x}^{\mathrm{obs}}\right)^{2}}{2 \sigma_{\mathbb{E}_{x}}^{2}}\right) \exp \left(\frac{-\left(E_{y, i}^{\mathrm{calc}}-Z_{y}^{\mathrm{obs}}\right)^{2}}{2 \sigma_{E_{y}}^{2}}\right) \tag{1}
\end{equation*}
$$

The calculated transverse momentum is found by ignoring the measured $E_{T}$, and, instead, assuming a pseudorapidity for each unobserved neutrino. From this input, the 3-momentum of each neutrino can be determined. This process is called a kinematic reconstruction. $N_{\text {iter }}$ indicates a sum over all assignments of jets to leptons and solutions for the kinematic reconstruction. An assigment of a jet to a lepton is an assumption that both of them are final decay products of the same top quark. There are two such assumptions per event. The resolutions for the two components of $E_{T}, \sigma_{E_{x, y}}$, are parameters of the method, and taken to be $6 \mathrm{GeV}[3]$. The top quark mass dependence on this parameter is very mild and does not create any systematic ncertainty. Integrating $\omega$ over the the distribution in $\eta$, $\rho(\eta)$, we obtain an overall weight $W\left(m_{\mathrm{t}}\right)$ as a function of assumed $m_{t}$ :

$$
\begin{equation*}
W\left(m_{\mathrm{t}}\right)=\int \omega\left(\eta_{1}, \eta_{2}\right) \rho\left(\eta_{1}\right) \rho\left(\eta_{2}\right) d \eta_{1} d \eta_{2} \tag{2}
\end{equation*}
$$

The distributions in neutrino pseudorapidity are all modeled as Gaussians, with root-mean-square (rms) of 1.0.
To kinematically reconstruct an event, we have to solve a system of two quadratic equations. If none of the solutions have real values, the event is said to fail kinematic reconstruction. The breakdown in efficiencies for kinematic reconstruction for different event sources is given in Table II. The efficiencies are defined as the ratio of expected event yield before the reconstruction and the yield after the reconstruction.

TABLE II: Efficiencies for kinematic reconstruction of events, with $H_{T}>115 \mathrm{GeV}$ cut.

| sample | $t \bar{t}(172.5 \mathrm{GeV})$ | $\mathrm{Z} \rightarrow \tau \tau$ | diboson | data |
| :---: | :---: | :---: | :---: | :---: |
| efficiency, $\%$ | $98.7 \pm 0.05$ | $96.6 \pm 2.3$ | $92.3 \pm 2.4$ | $97.5 \pm 1.1$ |

Weights calculated for different $m_{\mathrm{t}}$ yield a weight distribution for each event, which depends significantly on the number of sampling points used for each neutrino pseudorapidity distribution. In previous versions of this analysis, we used 10 sampling points. We have tested the analysis using 10 to 200 sampling points of neutrino $\eta$, and find that 29 such points ensure the optimal performance of the method. This sampling results in the desired gain in kinematic reconstruction efficiency and statistical uncertainty on $m_{\mathrm{t}}$ while balancing against CPU requirements. The overall weight $W\left(m_{\mathrm{t}}\right)$ is calculated in 1 GeV increments for $80<m_{\mathrm{t}}<330 \mathrm{GeV}$ by summing over all the weights for each chosen neutrino $\eta$.

## IV. PROBABILITY DENSITY HISTOGRAMS

For each event, $W\left(m_{\mathrm{t}}\right)$ is obtained as a function of the assumed $m_{\mathrm{t}}$. Two parameters are chosen to characterize this distribution for every event [3], namely the mean $\left(\mu_{w}\right)$ and root-mean-square ( $\sigma_{w}$ ) of the distribution. The normalized three-dimensional distribution of $\mu_{w}, \sigma_{w}$, and input $m_{\mathrm{t}}$ yields a signal probability histogram, $h_{s}\left(\mu_{w}, \sigma_{w}, m_{\mathrm{t}}\right)$. The background probability density histogram, $h_{b}\left(\mu_{w}, \sigma_{w}\right)$ which is not a function of $m_{\mathrm{t}}$, is obtained as the two-dimensional distribution of $\mu_{w}$ and $\sigma_{w}$ of simulated background events. Weights are assigned to events of different background sources that correspond to the their relative contributions. Probability density histograms scaled to expected event yields for background $h_{b}\left(\mu_{w}, \sigma_{w}\right)$ and signal $h_{s}\left(\mu_{w}, \sigma_{w}, 175 \mathrm{GeV}\right)$, and dependence of $\mu_{w}$ on $m_{t}$ for $25<\sigma_{w}<35$ are shown in Fig. 1.

## V. MAXIMUM LIKELIHOOD

After having modeled the signal probability histogram, $h_{s}\left(\mu_{w}, \sigma_{w} \mid m_{\mathrm{t}}\right)$, and background probability density histogram, $h_{b}\left(\mu_{w}, \sigma_{w}\right)$, the top quark mass is extracted by maximizing the likelihood:

$$
\begin{equation*}
\mathcal{L}\left(\mu_{\omega\{1 . . \mathrm{N}\}}, \sigma_{\omega\{1 . . \mathrm{N}\}}, N\left|\bar{n}_{b}, \bar{n}_{s}\right| m_{\mathrm{t}}\right)=\prod_{i=1}^{N} \frac{\bar{n}_{s} h_{s}\left(\mu_{\omega i}, \sigma_{\omega i} \mid m_{\mathrm{t}}\right)+\bar{n}_{b} h_{b}\left(\mu_{\omega_{i}}, \sigma_{\omega i}\right)}{\bar{n}_{s}+\bar{n}_{b}} \tag{3}
\end{equation*}
$$

FIG. 1: The calculated probability density histogram scaled to expected event yields for (a) background, (b) signal with $m_{\mathrm{t}}=175 \mathrm{GeV}$ as a function of $\mu_{w}$ and $\sigma_{w}$, and (c) dependence of $\mu_{w}$ on $m_{t}$ for signal.

Here $\bar{n}_{s}$ and $\bar{n}_{b}$ are the expected event yields for signal and background respectively, and $N$ is the total number of selected events. The parameters of the likelihood are broken into three groups: measured, expected, and fitted parameters. Uncertainties on the likelihood appear due to the finite statistics in our signal Monte Carlo samples. The distribution of $-\log \mathcal{L}$ vs. $\mathrm{m}_{\mathrm{t}}$ is fit by a parabola within an interval of $\pm 15 \mathrm{GeV}$ around the likelihood point with the lowest value. Signal sample corresponding to the top quark mass of 155 GeV was not used in the fits and ensemble tests for technical reasons. The value of $\mathrm{m}_{\mathrm{t}}$ at the minimum of the parabola defines our top quark mass estimate, $\hat{\mathrm{m}}_{\mathrm{t}}$. Half the width of the parabola where $-\log \mathcal{L}$ rises to 0.5 units more than its minimum value provides the statistical uncertainty, $\hat{\sigma}_{\mathrm{m}_{\mathrm{t}}}$.

The performance of the mass extraction technique is evaluated using ensemble testing techniques: the top quark mass $m_{\mathrm{t}}$ is extracted in ensembles of pseudoexperiments of 197 events. The events are chosen randomly from the signal and background Monte Carlo samples so that the average number of background events per source matches the expected yield. The actual number of events in a given pseudoexperiment is obtained according to a Poisson distribution. The mean of the Poisson distribution is taken from a Gaussian distribution centered at the expected event yield and with uncertainty equal to the total statistical uncertainty.

We employ two approaches for the ensemble tests. In the first approach, which is used for the measurement, we use the information about signal cross section from theory in Table I for all mass points. We fluctuate signal in the same way as the background processes and we select only those pseudoexperiments for which the total number of events exactly equals those observed in data. We employ 1000 pseudoexperiments in an ensemble, and we correct for the correlations among pseudoexperiments since the events are used in the pseudoexperiments more than once. However, the expected signal cross section may not accurately reflect the actual number of $t \bar{t}$ events in the selected sample. Consequently, the number of $t \bar{t}$ used for the ensemble tests can be incorrect. Also, this number depends on the assumed $m_{t}$. This might lead to a bias in the calibration of measured $m_{t}$. Therefore, we use a second approach [3] as a cross-check. We give up the information on the expected cross section, and the signal event yield in a pseudoexperiment is taken as the number of data events minus the total background event yield. Both approaches give consistent results.

Figure 2 shows a good agreement between the output and input top quark mass for the first approach and demonstrates the validity of the statistical error estimation, with widths of pull distributions near their expected value of 1.0. The linear fits in Fig. 2 are used to calibrate the results from data, mapping the output minimum to an input

FIG. 2: (a) shows the fitted top quark mass as a function of the generated MC input top quark mass with central value of the signal cross section taken from theory and with a correction for resampling MC events, and (b) pull width distributions with the same treatment.
top quark mass. The results of the fits are summarized in Table III. The neutrino pseudorapidity distribution is mass dependent, and our analysis assumes a mass-independent Gaussian of width 1.0. We tested the sensitivity of our analysis to this choice by repeating the analysis with a mass-dependent width fit in MC top samples with generator masses of 130 GeV to 210 GeV . The estimated expected statistical uncertainty changed by only 0.03 GeV . We also checked the stability of the result for variations in the range used in the fit, and the small dependence of the minimum on the width of the window for the fit is included in the calibration uncertainty on the final result.

|  | slope | offset $(\mathrm{GeV})$ | $\langle$ pull width $\rangle$ |
| :---: | :---: | :---: | :---: |
| signal cross section from theory | $0.99 \pm 0.006$ | $0.45 \pm 0.09$ | $1.0 \pm 0.007$ |

TABLE III: Slope and offset of the calibration curve in Fig. 2, and the pull width.

## VI. RESULTS

The top quark mass is estimated by maximizing the likelihood for the selected data. The top quark mass estimate and uncertainties are corrected to account for the calibration from ensemble tests (slope and offset, and pull widths) by using the calibration curves of Fig. 2. The measured top quark mass after calibration yields $m_{\mathrm{t}}=172.73 \pm$ 2.81 (stat.) GeV. The cross-check measurement is within 0.1 GeV of this result.

The negative log likelihood as a function of top quark mass before the calibration, together with the parabolic fit, are shown in Fig. 3. The distribution of expected statistical uncertainties is shown in Fig. 4, overlaid with the value observed in data.

## VII. SYSTEMATIC UNCERTAINTIES

A summary of the systematic uncertainties is given below.
(i) Jet energy scale: We evaluate this systematic uncertainty by shifting the jet energy scale by $+1 \sigma$ and $-1 \sigma$ and symmetrizing the errors. This uncertainty is found to be 1.35 GeV .
(ii) $b /$ light jet response: The calorimeter response is different for the light quark and $b$ - jets. To estimate this difference, particle jets in a $t \bar{t} l+$ jets sample were classified as $b$ - or light quark jets. Single particle response curves for both data and MC were then applied to the particle jets to predict the energy of a reconstructed jet in the calorimeter. The double ratio of jet transverse momenta in data and MC is estimated to be $1.8 \%$. We found the $b /$ light jet response systematic uncertainty by shifting the response down by $1.8 \%$ and remeasuring the top quark mass. We symmetrize this error and assign a systematic uncertainty of $\pm 0.8 \mathrm{GeV}$.

FIG. 3: Negative log likelihood distribution for data before calibration.

FIG. 4: Distribution of statistical uncertainties after correcting for the pull width and slope for $m_{\mathrm{t}}^{\mathrm{MC}}=170 \mathrm{GeV}$. Arrow indicates the measured statistical uncertainty on $m_{t}$.
(iii) Jet resolution: The jet resolution in Monte Carlo is smaller than in data. Therefore, an additional oversmearing is applied to the simulated jets. This additional oversmearing has some uncertainty. We evaluate the jet energy resolution by shifting the jet resolution by $+1 \sigma$ and $-1 \sigma$ and symmetrizing the errors. This systematic uncertainty is found to be 0.4 GeV .
(iv) Calibration uncertainty: The calibration uncertainty arises from the errors on the offset and slope of calibration curve. Using error propagation, we get an uncertainty of 0.1 GeV for the top quark mass.
(v) Template statistics: The templates have finite statistics. Local fluctuations in these templates can cause local fluctuations in the individual likelihood fits and the top quark mass. We obtain an uncertainty in $m_{\mathrm{t}}$ by varying the results of the negative likelihood fits from the data ensemble within their errors and repeating the fit to the distribution. The width of the $m_{\mathrm{t}}$ distribution provides the systematic uncertainty. It is found to be 0.35 GeV .
(vi) Initial state radiation (ISR) and final state radiation (FSR): We evaluate this systematic uncertainty by comparing Pythia with ISR and FSR parameters varied up and down [7]. After symmetrization of errors, we found this to be 0.55 GeV .
(vii) Hadronization and underlying events: We evaluate this systematic uncertainty by comparing ALPGEN + PYTHIA with HERWIG [8]. We conclude that hadronization and underlying event systematic uncertainty is 0.3 GeV .
(viii) Color reconnection: We evaluate this by comparing PYTHIA tuneACRpro [9] and tuneApro [10]. The uncertainty is found to be 0.7 GeV .
(ix) Higher order effects: We evaluate this systematic uncertainty [9] by comparing ALPGEN + PYTHIA with MC@NLO [11] + HERWIG. This is found to be 0.2 GeV .

| Source | Uncertainty (GeV) |  |  |
| :--- | :---: | :---: | :---: |
|  | $4.3 \mathrm{fb}^{-1}$ | $1 \mathrm{fb}^{-1}$ | combination |

| Electron energy resolution | $\pm 0.2$ | $\pm 0.2$ | $\pm 0.2$ |
| Jet identification | $\pm 0.5$ | $\pm 0.5$ | $\pm 0.5$ |
| Total systematic uncertainty | $\pm 2.1$ | $\pm 2.1$ | $\pm 2.1$ |

TABLE IV: Summary of uncertainties for the Run 2 b analysis, the Run2a analysis, and their combination. Run 2a systematic uncertainties marked with * are taken from Run 2 b .

A list of all evaluated systematic uncertainties is shown in Table IV. The systematic uncertainties are dominated by jet energy scale uncertainties. The combined systematic uncertainty is $\pm 2.1 \mathrm{GeV}$.

## VIII. COMBINATION WITH THE RUN 2A DILEPTON TOP QUARK MASS MEASUREMENT.

The $\mathrm{D} \emptyset$ Collaboration has published a measurement in the dilepton channel [3] using data corresponding to an integrated luminosity of $1 \mathrm{fb}^{-1}$ from Run 2 a yielding $m_{\mathrm{t}}=174.7 \pm 4.4$ (stat.) $\pm 2.0$ (syst.) GeV. This sample is statistically uncorrelated with the sample discussed in this note. The systematic uncertainties for MC calibration and template statistics are also uncorrelated between the two measurements. All other systematic uncertainties are taken to be $100 \%$ correlated. We do not assign a sample dependent systematic uncertainty in Run 2b because of improved simulation. Color reconnection and higher order effects systematics have been estimated for the current measurement, but not for the earlier one. We have applied the newer results to the older data. Combining the two measurements [12] and accounting for correlations between uncertainties, we obtain $m_{\mathrm{t}}=173.3 \pm 2.4$ (stat.) $\pm 2.1$ (syst.) GeV .

## IX. CONCLUSION

In proton-antiproton collision data corresponding to and integrated luminosity of $5.3 \mathrm{fb}^{-1}$, we have used the neutrino weighting method to measure a top quark mass from $t \bar{t}$ events in $e \mu$ final state. We measured the top quark masss to be:

$$
m_{\mathrm{t}}=173.3 \pm 2.4 \text { (stat.) } \pm 2.1 \text { (syst.) } \mathrm{GeV}
$$

by combining the Run2b $4.3 \mathrm{fb}^{-1}$ result

$$
m_{\mathrm{t}}=172.7 \pm 2.8 \text { (stat.) } \pm 2.1 \text { (syst.) } \mathrm{GeV}
$$

with the Run2a $1.0 \mathrm{fb}^{-1}[3]$ result

$$
m_{\mathrm{t}}=173.3 \pm 2.4(\text { stat. }) \pm 2.1 \text { (syst.) GeV. }
$$

This is the most precise single measurement in the dilepton channel.

#### Abstract

We present a measurement of the top-quark mass $\left(m_{t}\right)$ in $p \bar{p}$ collisions at $\sqrt{s}=1.96 \mathrm{TeV}$ using $t \bar{t}$ events with two leptons ( $e e, e \mu$, or $\mu \mu$ ) and accompanying jets in $4.3 \mathrm{fb}^{-1}$ of data collected with the D0 detector at the Fermilab Tevatron collider. We analyze the kinematically underconstrained dilepton events by integrating over their neutrino rapidity distributions. We reduce the dominant systematic uncertainties from the calibration of jet energy using a correction obtained from $t \bar{t}$ events with a final state of a single lepton plus jets. We also correct jets in simulated events to replicate the quark flavor dependence of the jet response in data. We measure $m_{t}=173.7 \pm 2.8$ (stat) $\pm 1.5$ (syst) GeV and combining with our analysis in $1 \mathrm{fb}^{-1}$ of preceding data we measure $m_{t}=174.0 \pm 2.4$ (stat) $\pm 1.4$ (syst) GeV . Taking into account statistical and systematic correlations, a combination with the D0 matrix element result from both data sets yields $m_{t}=173.9 \pm 1.9$ (stat) $\pm 1.6$ (syst) GeV .

The masses of fundamental fermions in the standard model are generated through their interaction with a hypothesized scalar Higgs field with a strength given by a Yukawa coupling specific to each fermion species. The

[^74]Yukawa coupling of the top quark corresponds to unity within uncertainties, and this value is constrained by a measurement of the top-quark mass $\left(m_{t}\right)$. In direct searches at the LHC for the standard model Higgs boson, both the CMS and ATLAS experiments observe local excesses above the background expectations for a Higgs boson mass $\left(m_{H}\right)$ of approximately $125 \mathrm{GeV} / c^{2}[1,2]$, decaying to diboson final states. Combined results in searches from the CDF and D0 experiments at the Tevatron show evidence for events above background expectation in $b \bar{b}$ final states [3]. It is therefore important to sharpen the measurement of $m_{t}$, as its precise value, along with the mass of the $W$ boson ( $m_{W}$ ), constrains the standard model prediction for $m_{H}$ through well defined radiative corrections.

In $p \bar{p}$ collisions, top quarks $(t)$ are primarily produced in $t \bar{t}$ pairs, with each top quark decaying with $B R(t \rightarrow W b) \sim$ $100 \%$. These events yield final states with either 0,1 , or 2 leptons from decays of the two $W$ bosons. We consider the
dilepton channels ( $2 \ell$ ) that contain either electrons or muons of large transverse momentum $\left(p_{T}\right)$ and at least two jets. We analyzed such events previously $[4,5]$ using the neutrinoweighting ( $\nu \mathrm{WT}$ ) approach [6]. While the $2 \ell$ channels have low background, the small decay branching ratio into leptons means that $m_{t}$ measurements from these events remained statistically limited unlike in channels with one lepton and four or more jets ( $\ell+$ jets). This situation has changed recently (e.g., Ref. [7]). Now, dominant systematic uncertainties from jet energy calibration, which have been larger [4] in the dilepton channel compared to $\ell+$ jets, are limiting precision of the $m_{t}$ measurement. In $\ell+$ jets events, two quarks originate from $W$ boson decay and yield a dijet mass signature that permits a precise calibration of jet energies for the measurement of $m_{t}$ in $t \bar{t}$ events [8]. While this calibration has greatly improved measurements in the $\ell+$ jets channels, it has not been carried over to the calibration in other analyses. This is primarily due to differences in event topologies that can affect the details of the jet energy scale.

We present a new measurement of $m_{t}$ using the D0 detector with $4.3 \mathrm{fb}^{-1}$ of $p \bar{p}$ collider data in the $e e, e \mu$, and $\mu \mu$ final states. We improve the jet energy calibration for the accompanying jets using the energy scale from $\ell+$ jets events [9]. Our approach differs from that of Ref. [10] in that we do not use the $\ell+$ jets scale as a constraint in a combined fit of $\ell+$ jets and dilepton events. Instead, we use this constraint as a calibration, and estimate the uncertainties of transferring that calibration to the dilepton event topology. This procedure demonstrates how the calibration obtained using the dijet constraint from $m_{W}$ can be applied to different final states, and has wide applicability beyond the measurement of $m_{t}$ in $2 \ell$ events. We also employ flavordependent corrections to jet energies for the first time in a dilepton analysis that substantially reduce the uncertainties on jet energy resulting from jet flavor. The presented $m_{t}$ measurement is performed using the same data as Ref. [7], and is correlated with it as discussed below.

The D0 detector [11] is a multipurpose detector operated at the Fermilab Tevatron $p \bar{p}$ collider. The inner detector consists of coaxial cylinders and disks of silicon microstrips for track and vertex reconstruction. Eight layers of scintillating fibers arranged in doublets surround the silicon microstrip tracker and extend tracking measurements to forward pseudorapidities $\eta$ [12]. A 1.9 T solenoid produces a magnetic field for the tracking detectors. Uranium-liquid argon calorimeters surround the tracking volume and perform both electromagnetic and hadronic shower energy measurements. Thin scintillation intercryostat detectors sample showers in the region between the central and end calorimeters. Three layers of proportional drift tubes and scintillation counters reside outside the calorimetry, with 1.8 T toroids that provide muon identification and independent measurement of muon momenta.

We simulate $t \bar{t}$ events using Monte Carlo (MC) samples for $140 \mathrm{GeV}<m_{t}<200 \mathrm{GeV}$ using the ALPGEN
generator [13] and PYTHIA [14] for parton fragmentation. Backgrounds originate from $Z / \gamma^{*} \rightarrow 2 \ell+$ jets and $W W / W Z / Z Z \rightarrow 2 \ell+$ jets production. For the former, we use ALPGEN combined with PYTHIA, while diboson backgrounds are simulated entirely with PYTHIA. We pass all MC events through a full detector simulation based on GEANT [15]. Backgrounds from instrumental effects that result in misidentified leptons are modeled using data.

We use single and two-lepton triggers to select events for this analysis. Data and simulated events are reconstructed to provide the momenta of tracks, jets, and lepton candidates. Charged leptons are required to be isolated from other calorimeter energy deposits, and to have an associated track in the inner detector. Calorimeter and tracking information are combined to identify electrons. Track parameters in the muon and inner detector system are used to identify muons. We reconstruct jets with an iterative, midpoint cone algorithm with radius $\mathcal{R}_{\text {cone }}=0.5$ [16]. Jets are calibrated with the standard D0 jet energy correction which is derived from data [17]. The method corrects the measured jet energy to the value obtained by applying the reconstruction cone algorithm to particles from jet fragmentation before they interact with the detector. We establish the efficacy of the method in the MC, where we compare the measured jet and the jet reconstructed from fragmentation particles. The jets in data and MC are calibrated independently so that their relative response is close to unity. This corrects for detector response, energy deposited outside of the jet cone, electronics noise, and pileup. The largest correction compensates for the detector response, and is extracted using $\gamma+$ jet events in data and MC. We also correct jets for the $p_{T}$ of any embedded muon and that of the associated neutrino. We initially apply this standard calibration [17] because it provides detailed $p_{T}$ and $\eta$ dependent corrections. It also provides distinct corrections to jets and the imbalance in event transverse momentum $\left(\boldsymbol{E}_{T}\right)$ because several components (e.g., noise and out-of-cone effects) result from the jet reconstruction algorithm rather than any undetected energy. In the $p_{T}$ range of jets found in $t \bar{t}$ events, the uncertainty of the standard D0 jet energy calibration averages $2 \%$, and is dominated by systematics. Because the flavor dependence of jet energy calibration can yield one of the largest systematic uncertainties on our measurement [4], we have improved our analysis by accounting for this dependence. We use responses of single particles from data and MC to determine the energy scale for different jet flavors. We correct MC jets by the ratio of data response to MC response according to their flavor to ensure that the MC reflects the flavor dependence in data, as in Ref. [9]. We calculate $\mathscr{L}_{T}$ as the negative of the vector sum of all transverse components of calorimeter cell energies and muon track momenta, corrected for the response to electrons and jets.

Events are selected to have two leptons ( $e e, e \mu, \mu \mu)$ and two or more jets. The leptons must have $p_{T}>15 \mathrm{GeV}$
and the jets must have $p_{T}>20 \mathrm{GeV}$. Electrons and jets are required to satisfy $|\eta|<2.5$, while muons must have $|\eta|<2$. We further require $\mathscr{E}_{T}>40 \mathrm{GeV}$ in the $\mu \mu$ channel. The $e \mu$ events must satisfy $H_{T}>120 \mathrm{GeV}$, where $H_{T}$ is defined to be the sum of the $p_{T}$ 's of jets and the leading lepton. In $\mu \mu$ and $e e$ events, we also require $\mathbb{E}_{T}$ to be significantly larger than typical values found in the distribution from $Z$ boson events. These and all other selections are detailed in Ref. [18]. We observe 50,198 , and 84 events with expected background yields of $10.4,28.1$, and 31.0 events in the $e e, e \mu$, and $\mu \mu$ channels, respectively.

In $\ell+$ jets events, one $W$ boson decays to two quarks that fragment to jets. The invariant mass of this jet pair can be used to improve the calibration for all jets in these events. Complications arise because the four jets in the $\ell+$ jets events can be incorrectly assigned to the initial four quarks. Energy from different partons is also mixed in the same jet due to a high jet multiplicity. Observed jet energies are also affected by color flow effects, which are different for the $b$-quark jets and for jets from the decay of color singlet $W$ bosons. These attributes are specific to a particular event topology such as $\ell+$ jets. Nevertheless, a scale factor based on the dijet invariant mass that is correlated with $m_{W}$ can be extracted. The most recent analysis of this kind by D0 used $2.6 \mathrm{fb}^{-1}$ of data and obtained a calibration factor of $1.013 \pm 0.008$ (stat) [9]. The uncertainty of $0.8 \%$ is smaller than that of the standard jet energy correction and will decrease with additional data. There are additional systematic effects on this energy scale that one must account for when applying it to $b$-quark jets in the $\ell+$ jets analysis. These also affect our analysis, and we similarly evaluate the flavor dependence and residual energy scale systematic uncertainties directly on the measured $m_{t}$ to avoid double counting. These are quoted in Table II and discussed below. Beyond this, we have the possible difference between $b$-quark jets in dilepton events and $b$-quark jets in $\ell+$ jets events and the effect of using a calibration based on a subset of the total data, each of which we discuss now in detail.

The event topology is different in $2 \ell$ and $\ell+$ jets events. This has prevented significant progress in reducing the large standard jet energy scale uncertainties in dilepton analyses. To overcome this challenge and carry over the $\ell+$ jets calibration, we must account for the possibility that the energy scale of the $b$-quark jets in the two channels can differ. We calculate the energy scale $R^{2 \ell}$ for $b$-quark jets in the dilepton sample using responses for single particles that fall within the reconstructed jet cone. This is done by scaling single particle responses in MC to reproduce the energy response of jets in data [19], giving $R_{\text {data }}^{2 \ell}$, and using particle responses from MC, giving $R_{\mathrm{MC}}^{2 \ell}$. We calculate the ratio of these two responses in the dilepton channel and the analogous ratio for $b$-quark jets in the $\ell+$ jets sample. The corresponding double ratio

$$
\begin{equation*}
\mathcal{R}_{2 \ell}^{b}\left(p_{T}^{b}\right)=\frac{R_{\text {data }}^{2 \ell}\left(p_{T}^{b}\right) / R_{\mathrm{MC}}^{2 \ell}\left(p_{T}^{b}\right)}{R_{\text {data }}^{\ell+\text { jets }}\left(p_{T}^{b}\right) / R_{\mathrm{MC}}^{\ell+\text { jets }}\left(p_{T}^{b}\right)} \tag{1}
\end{equation*}
$$

varies between 1.001 and 1.003 depending on $b$-quark jet $p_{T}, p_{T}^{b}$. The multiplicity of particles in $b$-quark jets in $\ell+$ jets events at the MC generator level is, after application of the offline jet algorithm, a few percent higher than in the dilepton sample, which is a sufficiently large difference to account for the observed value of $\mathcal{R}_{2 \ell}^{b}$. We therefore take $0.3 \%$, the maximum excursion of $\mathcal{R}_{2 \ell}^{b}$ from unity, as a systematic uncertainty on carrying over the $\ell+$ jets scale to the jets in our dilepton sample. The $\ell+$ jets scale is applied as a direct correction to the standard calibration.

The jet energy scale calibration obtained in Ref. [9] is based on a subset of the data, and we must therefore estimate the effect of using the calibration on a larger data set. The instantaneous luminosity of the dilepton sample is higher on average. We reweight the distribution of the number of primary vertices in the $\ell+$ jets sample to match the distribution in the $4.3 \mathrm{fb}^{-1} \ell+$ jets data and recalculate the $\ell+$ jets energy scale. This produces a negligible effect. To account for a possible shift in the energy scale of the liquid argon calorimeter, we apply a correction derived from $4.3 \mathrm{fb}^{-1}$ rather than $2.6 \mathrm{fb}^{-1}$, and this yields a $0.7 \%$ shift in jet energy scale. From these studies, we obtain a total uncertainty on the $\ell+$ jets energy scale as applied to our analysis as the sum in quadrature of the statistical uncertainty $(0.8 \%), \mathcal{R}_{2 \ell}^{b}(0.3 \%)$, and the calorimeter calibration ( $0.7 \%$ ). This yields a $1.1 \%$ uncertainty for applying the $\ell+$ jets energy scale.

The consequence of two neutrinos in dilepton events is an underconstrained kinematics. We employ the $\nu \mathrm{WT}$ technique to extract $m_{t}$ [6] due to its weak sensitivity to the modeling details of $t \bar{t}$ events. We integrate over the $\eta$ distributions predicted for both neutrinos, solve the event kinematics, and calculate $\mathbb{Z}_{T}$ from the neutrino momentum solutions. The expected neutrino $\eta$ distribution in the dilepton channel is symmetric around $\eta=0$ and found to be well described by a Gaussian distribution. The width of the distribution decreases gradually with increasing $m_{t}$ (i.e., as the neutrinos become more central). Hence, we model the neutrino $\eta$ distributions with a Gaussian probability distribution using a width parameterized as a linear function of $m_{t}$. Several more sophisticated parametrizations were tested, but provided negligible improvement in expected precision in pseudoexperiments. By comparing the calculated $\mathscr{E}_{T}$ to the measured $\mathscr{E}_{T}$ for each event, we calculate a weight for a given choice of $m_{t}$. For each neutrino rapidity sampling, we sum the weights calculated from all combinations of neutrino momentum solutions and jet assignments. We therefore arrive at a distribution of relative weight for a range of $m_{t}$ for each event. We found in Ref. [4] that most of the statistical sensitivity to $m_{t}$ is obtained from the first two moments of this weight distribution, the mean $\left(\mu_{w}\right)$ and $\mathrm{rms}\left(\sigma_{w}\right)$. A coarse
granularity of our sampling of the $\eta$ distribution causes these moments to be unstable. To reduce this variation, we have increased the sampling for this integration by an order of magnitude relative to our previous analysis [4]. This improves the expected statistical uncertainty on $m_{t}$ by $4 \%$. Requiring the integral of this distribution to be nonzero excludes events with a measured $\mathbb{E}_{T}$ that is incompatible with coming from neutrinos from $t \bar{t}$ decay. This introduces a small inefficiency for the $t \bar{t}$ signal and reduces the background contamination in the final sample. Our final kinematically reconstructed data sample consists of 49,190 , and 80 events in the $e e, e \mu$, and $\mu \mu$ channels, respectively.

Probability distributions for $\mu_{w}$ and $\sigma_{w}$ are constructed for background in each channel. Each background component is normalized to its expected event yield. We generate distributions of $t \bar{t}$ signal probability as a function of $\mu_{w}$, $\sigma_{w}$, and $m_{t}$. We use a binning that provides the minimum expected statistical uncertainty, as checked in pseudoexperiments. We perform a binned maximum likelihood fit to the probability distributions, fixing the total signal and background yields expected in our data. The signal is normalized to the cross section calculated for $t \bar{t}$ production [20], evaluated at $m_{t}=172.5 \mathrm{GeV}$. For all measurements, we obtain a likelihood $(L)$ vs $m_{t}$. We fit a parabola to the dependence of $-\ln L$ vs $m_{t}$, and the fitted mass $m_{t}^{\text {fit }}$ is defined as the lowest point of the parabola. Point-to-point fluctuations mean that the initial placement of the window may result in a nonconvergent fit. We therefore iterate the fit around the current fit minimum. This results in a significant improvement in fitting efficiency, particularly in the dimuon channel. The final $-\ln L$ vs $m_{t}$ for data is shown in Fig. 1. The statistical uncertainty for each measurement is taken as the half-width of the parabola at 0.5 units in $-\ln L$ above the minimum at $m_{t}^{\mathrm{fit}}$.

The above procedure is followed for the extraction of $m_{t}$ from data and is used to calibrate the result as follows. We construct pseudoexperiments from signal and background MC samples according to their expected yields and allow fluctuations in each such that the total equals the number of observed events. We perform 1000 pseudoexperiments for

FIG. 1. $\ln L$ as a function of $m_{t}$ for the combined $e e, e \mu$, and $\mu \mu$ channels. A parabolic fit is shown near the minimum value in $m_{t}$.
each channel, and measure $m_{t}^{\text {fit }}$ in each. A linear fit of $m_{t}^{\text {fit }}$ vs the input $m_{t}$ provides a calibration for our method. We also calculate the pull width of the average estimated statistical uncertainty vs the rms of $m_{t}^{\text {fit }}$ values. The resulting slopes, offsets, and pull widths are given in Table I. The $m_{t}^{\text {fit }}$ and estimated statistical uncertainty are corrected with these parameters. We obtain a calibrated mass measurement for the $4.3 \mathrm{fb}^{-1}$ sample in the $e e, e \mu$, and $\mu \mu$ channels.

The largest systematic uncertainties are associated with the jet calibration. We change the $\ell+$ jets energy scale factor by $\pm 1.1 \%$, and perform our analysis to obtain a systematic uncertainty on $m_{t}$ of 0.9 GeV . The result of the $\ell+$ jets analysis is a single scale factor averaged over all jet $p_{T}$ 's that are utilized in the dijet mass, i.e., dominated by light quark jets from $W$ boson decay. As in Ref. [9], we estimate an uncertainty due to the difference in $p_{T}$ distributions of $b$-quark jets, in our case in dilepton events, vs the calibrating jets from the $W \rightarrow j j$ sample. To estimate an uncertainty from this difference, we treat the $p_{T}$ and $\eta$ dependence of the uncertainty in the standard jet energy scale as a possible dependence of the residual energy scale following the calibration to $\ell+$ jets. We calculate the average of the energy scale uncertainty for jets in the $W \rightarrow j j$ sample. For each jet in the dilepton sample, we apply a shift corresponding to the difference between its uncertainty in energy scale and the $W \rightarrow j j$ sample's average uncertainty in energy scale. Propagating this difference through the mass analysis yields a 0.3 GeV uncertainty on $m_{t}$.

The flavor-dependent jet energy corrections described earlier provide MC-based mass templates that accurately reflect the data. As in [9], we propagate the uncertainty in these corrections and obtain a systematic uncertainty on $m_{t}$ of 0.5 GeV . The uncertainties due to flavor dependence and residual scale together with the uncertainty originating from the carry over of the jet energy scale from the $\ell+$ jets sample account for the difference between $b$-quark jets in dilepton events and jets from $W \rightarrow j j$ in $\ell+$ jets events.

We evaluate the effect of our uncertainty in modeling initial state radiation (ISR) and final state radiation (FSR) by comparing two PYTHIA samples having identical values of generated $m_{t}$ but different input parameters taken from a CDF study [21] corresponding to an increased or decreased amount of ISR/FSR. Color reconnection uncertainties are estimated by comparing the analysis with PYTHIA tune Apro and PYTHIA tune ACpro using [22]. Higher order

TABLE I. Parameters used to calibrate $m_{t}^{\mathrm{fit}}$ in the analysis of $e e, e \mu$, and $\mu \mu$ channels and their combination.

| Channel | Slope | Offset $[\mathrm{GeV}]$ | Pull width |
| :--- | :---: | :---: | :---: |
| $e e$ | $0.976 \pm 0.014$ | $0.03 \pm 0.16$ | $1.01 \pm 0.01$ |
| $e \mu$ | $0.973 \pm 0.012$ | $0.43 \pm 0.14$ | $1.03 \pm 0.01$ |
| $\mu \mu$ | $1.038 \pm 0.022$ | $0.49 \pm 0.23$ | $1.06 \pm 0.03$ |

TABLE II. Estimated systematic uncertainties on $m_{t}$ for the combined dilepton measurement in $4.3 \mathrm{fb}^{-1}$.

| Source | Uncertainty $(\mathrm{GeV})$ |
| :--- | :---: |
| Jet energy calibration |  |
| Overall scale | 0.9 |
| Flavor dependence | 0.5 |
| Residual scale | 0.3 |
| Signal modeling |  |
| ISR/FSR | 0.4 |
| Color reconnection | 0.5 |
| Higher order effects | 0.6 |
| $b$ quark fragmentation | 0.1 |
| Parton distribution function uncertainty | 0.5 |
| Object reconstruction |  |
| Muon $p_{T}$ resolution | 0.2 |
| Electron energy scale | 0.2 |
| Muon $p_{T}$ scale | 0.2 |
| Jet resolution | 0.3 |
| Jet identification | 0.3 |
| Method |  |
| Calibration | 0.1 |
| Template statistics | 0.5 |
| Signal fraction | 0.2 |
| Total systematic uncertainty | 1.5 |

QCD evolution is estimated by comparing ALPGEN configured with PYTHIA to MC@NLO with HERWIG [23] and this accounts for the uncertainty due to underlying event as well. To estimate sensitivity to uncertainties in the parton distribution functions, we use CTEQ6M, and employ the method described in Ref. [24].

We modify the jet energy resolution in MC events to reflect the resolution in data. We evaluate the effect of an uncertainty in this procedure on the extraction of $m_{t}$ by shifting the jet resolution by 1 standard deviation. We treat the electron and muon energy and momentum scales similarly and shift their calibrations within their uncertainties.

Pseudoexperiments are used similarly to account for the uncertainty in the method that arises from the uncertainties on the offset and slope in the calibration of the fitted $m_{t}$. We estimate the uncertainty due to the statistics employed in our templates of the $t \bar{t}$ probability distributions. We construct 1000 new templates, for both signal and background,
and vary their bin contents within their Gaussian uncertainties. With these templates, we obtain 1000 new measurements from data and quote the rms of these values as a systematic uncertainty. We assign a systematic uncertainty on the signal fraction by shifting the background contributions in pseudoexperiments within their total uncertainty.

We combine measurements in the three dilepton channels using the method of "best linear unbiased estimator" [25]. We calculate each systematic uncertainty for the combined result, as given in Table II, according to its correlation among channels. The resulting measurement gives $m_{t}=173.7 \pm 2.8$ (stat) $\pm 1.5$ (syst) GeV .

We combine this measurement with D0's measurement in the preceding $1 \mathrm{fb}^{-1}$ of data using the $\nu \mathrm{WT}$ and matrix weighting methods [4]. Some uncertainties evaluated in the $4.3 \mathrm{fb}^{-1}$ sample are not available for the $1.0 \mathrm{fb}^{-1}$ sample. We include the new uncertainties in the result from the previous analysis. We consider statistical uncertainties, as well as the following systematic uncertainties to be uncorrelated: calibration of method, template statistics, overall jet energy scale, and flavor dependence. We consider all other uncertainties to be fully correlated. The combined measurement yields $m_{t}=174.0 \pm 2.4$ (stat) $\pm 1.4$ (syst) GeV . This is consistent with measurements in other channels, and is the most precise single $m_{t}$ measurement in the dilepton channel to date. We have also improved the precision by combining the $\nu \mathrm{WT}$ results with the results of Ref. [7]. The statistical correlation of these two measurements is approximately $60 \%$, calculated from pseudoexperiments. Accounting for this correlation, and correlations appropriate to each source of systematic uncertainty, we obtain $m_{t}=173.9 \pm$ 1.9 (stat) $\pm 1.6$ (syst) GeV .

#### Abstract

The top quark is the heaviest known elementary particle, with a mass about 40 times larger than the mass of its isospin partner, the bottom quark. It decays almost $100 \%$ of the time to a $W$ boson and a bottom quark. Using top-antitop pairs at the Tevatron proton-antiproton collider, the CDF and D0 Collaborations have measured the top quark's mass in different final states for integrated luminosities of up to $5.8 \mathrm{fb}^{-1}$. This paper reports on a combination of these measurements that results in a more precise value of the mass than any individual decay channel can provide. It describes the treatment of the systematic uncertainties and their correlations. The mass value determined is $173.18 \pm 0.56$ (stat) $\pm 0.75$ (syst) GeV or $173.18 \pm 0.94 \mathrm{GeV}$, which has a precision of $\pm 0.54 \%$, making this the most precise determination of the top-quark mass.

## I. INTRODUCTION

## A. The top quark

The standard model (SM) of particle physics describes the elementary particles and their interactions. The top quark $(t)$ has a special place in the hierarchy of particles because it is far more massive than any of the other fundamental objects. It is the up-type quark, partnered with the down-type bottom quark ( $b$ ), forming the third generation of quarks that was predicted by Kobayashi and Maskawa in 1973 [1] to accommodate $C P$ violation in neutral kaon decays [2]. At particle colliders the top quark is produced mainly in top-antitop $(t \bar{t})$ pairs. The first evidence of top-quark production was reported by the CDF Collaboration [3], and the top quark was first observed in this production mode by the CDF [4] and D0 [5] Collaborations at the Tevatron proton-antiproton collider. Since then, great efforts have been focused on measuring its properties with ever higher precision. In addition to its large mass $\left(m_{t}\right)$, the top quark is also singular because it decays before it can hadronize: there are no mesons or baryons containing valence top quarks. The top quark decays almost exclusively to a $W$ boson and a $b$ quark, with the fraction determined by the near-unity value of the Cabibbo-Kobayashi-Maskawa (CKM) quark mixing matrix [1,6] element $V_{t b}(\approx 0.9992)$ [7]. Its other decays are limited by the small values of $V_{t s} \approx 0.0387$ and $V_{t d} \approx$ 0.0084 [7], assuming three-family unitarity of the CKM matrix. The $W$ boson decays to a charged lepton and its
associated neutrino, or to a quark-antiquark pair, and the final states of $t \bar{t}$ events are thus characterized as follows: "lepton + jets" $\left(t \bar{t} \rightarrow \ell^{+} \nu b q \bar{q}^{\prime} \bar{b}\right.$ and $\left.\bar{q} q^{\prime} b \ell^{-} \bar{\nu} \bar{b}\right)$; "alljets" $\left(t \bar{t} \rightarrow q \bar{q}^{\prime} b \bar{q} q^{\prime} \bar{b}\right)$, and "dileptons" $\left(t \bar{t} \rightarrow \ell^{+} \nu b \ell^{-} \bar{\nu} \bar{b}\right)$. In this notation the charged lepton $\ell$ represents an electron or muon, and $q$ is a first- or second-generation quark. The $W$ boson also decays to a $\tau$ lepton and a $\tau$ neutrino. If $\tau$ decays to an electron or muon, the event contributes to the lepton categories, and if the $\tau$ decays into hadrons, it contributes to the lepton + jets or alljets categories. A fourth category labeled " $\dot{E}_{T}+$ jets" is used to measure $m_{t}$ when there are jets and a large imbalance in transverse momentum in the event $\left(\mathbb{E}_{T}\right)$, but no identified lepton. It comprises $t \bar{t} \rightarrow \tau^{+} \nu b \tau^{-} \bar{\nu} \bar{b}, \tau^{+} \nu b q \bar{q}^{\prime} \bar{b}$, and $\bar{q} q^{\prime} b \tau^{-} \bar{\nu} \bar{b}$ final states, accounting for $40 \%$ of the $t \bar{t}$ signal events in the $\mathscr{E}_{T}+$ jets category, or $\ell^{+} \nu b q \bar{q}^{\prime} \bar{b}, \bar{q} q^{\prime} b \ell^{-} \bar{\nu} \bar{b}$, where the electron or muon are not reconstructed, accounting for $60 \%$ of the $t \bar{t}$ signal in this category. Additional contributions to $\mathscr{E}_{T}$ arise from the neutrino(s) produced in $\tau$ decays.

In dilepton events, there are typically two jets from the two $b$ quarks, one from each top-quark decay. In lepton + jets events, there are typically four jets, including two $b$ jets and two light-quark jets from $W$-boson decay. Alljets events most often contain six jets, the two $b$ jets and four light-quark jets. The $\mathbb{E}_{T}+$ jets events usually have four or five jets. Additional gluon or quark jets can arise owing to radiation from initial or final-state colored particles, including the top quarks. About $23 \%$ of the $t \bar{t}$ events have an extra jet with sufficient energy to pass the selection criteria,

FIG. 1 (color online). Examples of tree Feynman diagrams for $t \bar{t}$ production. At the Tevatron collider, the $q \bar{q}$ channel contributes $81 \%$ to the total $t \bar{t}$ inclusive cross section and the $g g$ channel the remaining $19 \%$ [69,96].

FIG. 2 (color online). Leading-order Feynman diagram for $t \bar{t}$ decay. The dilepton modes ( $e e, e \mu, \mu \mu$ ) have a combined branching fraction of $\approx 4 \%$, the electron + jets and muon + jets modes combined correspond to $\approx 30 \%$, and the alljets mode has a branching fraction of $\approx 46 \%$. The $\tau$ modes are shared among the $\mathscr{L}_{T}+$ jets and the other channels in the analyses.
and about $5 \%$ of the events have two additional jets. These extra jets complicate the measurement of $m_{t}$ and degrade its resolution. Figure 1 illustrates leading-order (LO) production of $t \bar{t}$ events at the Fermilab Tevatron Collider, and Fig. 2 shows the relevant $t \bar{t}$ decay modes.

## B. Top-quark mass origin and definitions

One of the fundamental properties of an elementary particle is its mass. In the SM, fermions acquire mass through interactions with the Higgs field [8]. Absolute values of these masses are not predicted by the SM. In theoretical calculations, a particle's mass can be defined in more than one way, and it depends on how higher-order terms in perturbative quantum chromodynamics (QCD) calculations are renormalized. In the modified minimal subtraction scheme ( $\overline{\mathrm{MS}}$ ), for example, the mass definition reflects short-distance effects, whereas in the pole-mass scheme the mass definition reflects long-distance effects [9]. The concept of the pole mass is not well defined since color confinement does not provide $S$-matrix poles at $m=m_{t}$ [10]. Direct mass measurements that are inputs to the combination described in this paper rely on Monte Carlo (MC) generators to extract $m_{t}$. Hence the measured mass corresponds in fact to the mass parameter in the MC. Work is proceeding to address the exact differ-
ence between the measured mass and the pole mass, as presented, for example, in Appendix C of Ref. [11]. One alternative way to address this problem is to extract $m_{t}$ from a measurement of the $t \bar{t}$ cross section [12]. The D0 Collaboration has recently shown that the directly measured mass of the top quark is closer to the pole mass extracted from a measurement of the $t \bar{t}$ cross section than to an $\overline{\mathrm{MS}}$ mass extracted in a similar way [12]. Hence, within the precision of theory and data, the directly measured $m_{t}$ is best interpreted as the top-quark pole mass.
$C P T$ invariance predicts that a particle and its antiparticle partner have the same mass. This has been checked for the top quark by the $\mathrm{D} 0, \mathrm{CDF}$, and CMS Collaborations, and the masses are found to hold within the measurement uncertainties, with $\Delta m_{t}=m_{t}-m_{\bar{t}}=0.84 \pm 1.87 \mathrm{GeV}$ [13], $\Delta m_{t}=-3.3 \pm 1.7 \mathrm{GeV}$ [14], and $\Delta m_{t}=-0.44 \pm$ 0.53 GeV [15], respectively. Thus, the top-quark mass combination in this paper assumes $m_{t}=m_{\bar{t}}$.

## C. Predictions based on the top-quark mass

The internal consistency of the SM can be tested by using different observables to predict the values of others and then to compare the expectations with their measured values. For example, the relation between the mass of the $W$ boson $\left(M_{W}\right)$ and $\sin ^{2} \theta_{W}$ (the electroweak mixing angle) includes higher-order radiative corrections involving $m_{t}$; hence the smaller the uncertainty on the measured $m_{t}$, the stronger is the test of consistency.

Since 1997, the LEP Electroweak Working Group has used the observed top-quark and the $W$ boson masses and other precision electroweak variables to extract constraints on the Higgs boson mass ( $M_{H}$ ) in the SM [16]. This has been extended to the minimal supersymmetric standard model [17], and the GFITTER Collaboration has applied the technique to set limits on a wide variety of theories beyond the SM [18]. Figure 3(a) shows the combined constraint attributable to $M_{W}$ and $m_{t}$ (as of March 2012) on the Higgs boson mass. Figure 3(b) shows the constraint from $M_{W}$ and $m_{t}$ separately (as of March 2012) on the Higgs boson mass, and a global constraint originating from all the other electroweak variables, showing the importance of the $M_{W}$ and $m_{t}$ variables to constrain the Higgs boson mass.

## D. History of measurement of $\boldsymbol{m}_{\boldsymbol{t}}$

Before 1995, global fits to electroweak data from the CERN and SLAC $e^{+} e^{-}$colliders (LEP and SLC) and from other experiments produced estimates of $m_{t}$ that ranged from $\approx 90 \mathrm{GeV}$ to $\approx 190 \mathrm{GeV}$ [19]. At the time of the first observation of the top quark in 1995, the fits indicated a mass close to the current Tevatron value of $m_{t}$, but with an uncertainty of $\approx \pm 10 \%$ and an assumption of 300 GeV mass of the Higgs boson [20]. CDF measured $m_{t}=176 \pm$ 8 (stat) $\pm 10$ (syst) GeV [4] (total uncertainty of $7 \%$ ) and

FIG. 3 (color online). (a) Constraints from LEP and Tevatron measurements of $M_{W}$ and $m_{t}$ (Tevatron only) on $M_{H}$ within the SM. The regions in the mass of the Higgs boson still allowed after the direct searches at LEP, Tevatron, and LHC are also shown. (b) From Ref. [18], the large countors (blue) indicate the constraints on the Higgs boson, from global fits to electroweak data without including the direct measurements of $M_{W}$ and $m_{t}$ from the Tevatron.

D0 measured $m_{t}=199_{-21}^{+19}($ stat $) \pm 22$ (syst) GeV [5] (total uncertainty of $15 \%$ ).

Since then, the CDF and D0 Collaborations have developed many novel measurement techniques and published nearly 50 journal papers on their measurements of $m_{t}$. Recently, the CMS Collaboration at the Large Hadron Collider (LHC) published a measurement using 102 dilepton events [21] and finds $m_{t}=175.5 \pm 4.6$ (stat) $\pm$ 4.6 (syst) GeV (total uncertainty of $3.7 \%$ ). The ATLAS Collaboration at the LHC has submitted a measurement of $m_{t}=174.5 \pm 0.6 \pm 2.3 \mathrm{GeV}$ (total uncertainty of $1.4 \%$ ) using nearly 12,000 lepton + jets events [22]. The most precise measurements from the Tevatron in a single decay channel use lepton + jets events, a matrix-element
method as introduced in Ref. [23], and an in situ calibration of the jet energy scale. CDF's matrix-element measurement [24] uses $5.6 \mathrm{fb}^{-1}$ of integrated luminosity to find $m_{t}=173.00 \pm 0.65$ (stat) $\pm 1.06$ (syst) GeV (total uncertainty of $0.72 \%$ ). D0's measurement [25] uses $3.6 \mathrm{fb}^{-1}$ of integrated luminosity to obtain $m_{t}=174.94 \pm 0.83$ (stat) $\pm$ 1.24 (syst) GeV (total uncertainty of $0.85 \%$ ). Figure 4 shows the publication history of the direct measurements of $m_{t}$ at the Tevatron.

## E. Overview of mass measurements

This paper reports on the combination of previously published measurements of $m_{t}$. Details of the analyses are therefore not repeated as this information is available in recent reviews [26], as well as in the publications of each of the results. We will, however, summarize the basic techniques used for the measurements.

The cross section for $t \bar{t}$ production in proton-antiproton $(p \bar{p})$ interactions at 1.96 TeV is $\approx 7.2 \mathrm{pb}[27,28]$. The mean transverse momentum ( $p_{T}$ ) of the $t \bar{t}$ system at parton level is $\approx 20 \mathrm{GeV}$, which is attributed to initial-state radiation (i.e., gluon emission). The mean transverse momentum of the top quarks at parton level is $\approx 95 \mathrm{GeV}$ [29]. Top quarks have a lifetime of $\approx 0.3 \times 10^{-24} \mathrm{~s}[30,31]$, which is an order of magnitude smaller than the time scale for parton evolution and hadronization. Hence, when top quarks decay, they transfer their kinematic characteristics to the $W$ boson and $b$ quark, and the measured energymomentum four-vectors of the final-state particles can be used to reconstruct the mass of the top quark, except for the presence of initial or final-state radiation.

In alljets events, the four-vector of every jet emerging from quarks can be reconstructed, but neutrinos emitted in semileptonic decays of $b$ quarks and jet energy resolution effects will lead to lost energy. In lepton + jets events, the momentum of the neutrino from the $W \rightarrow \ell \nu_{\ell}$ decay is not detected. The transverse component can be inferred from the negative of the vector sum of all transverse momenta of particles detected in the calorimeter and muon detectors. We estimate the longitudinal momentum of $\nu_{\ell}$ by constraining the mass of the charged lepton and neutrino system to the world average value of $M_{W}$ [7]. We also use $M_{W}$ to choose the two light jets from $W \rightarrow q \bar{q}^{\prime}$ decay, and we use that information for an in situ calibration of jet energies. In dilepton events, the analysis is more complicated because there are two final-state neutrinos from the leptonic decays of both $W$ bosons. Therefore, the longitudinal and transverse-momentum components of the neutrinos cannot be determined without the application of more sophisticated tools. These involve assuming a value for $m_{t}$ to solve the event kinematics and assigning a weight to each $m_{t}$ hypothesis to determine the most likely value of $m_{t}$ consistent with the hypothesis that the event is a $t \bar{t}$ event.

A major issue in $t \bar{t}$ final-state reconstruction is the correct mapping of the reconstructed objects to the partons

FIG. 4 (color online). The CDF and D0 published direct measurements of the top-quark mass as a function of time.
from the decays of the top quark and $W$ boson. The problem arises because often the jet charge and flavor cannot be uniquely determined. This creates combinatorial ambiguities in the $t \bar{t}$ event reconstruction that vary from 90 possible jet-to-parton assignments for the alljets final state to 2 in the dilepton channel. In the lepton + jets and dilepton final states, additional ambiguities may arise from multiple kinematical solutions for the longitudinal component of the neutrino momentum.

Two methods are used to measure the value of $m_{t}$. In the first method, the reconstructed mass distribution in data, or a variable correlated with $m_{t}$, such as the decay length of the $B$ hadron or the transverse momentum of a lepton, is compared to template distributions composed of contributions from background and simulation of $t \bar{t}$ events. One template is used to represent background and another for each putative value of $m_{t}$. The second method uses event probabilities based on the LO matrix element for the production of $t \bar{t}$. For each event, a probability is calculated as a function of $m_{t}$ that this event is from $t \bar{t}$ production, as based on the corresponding production and decay matrix element. Detector resolution is taken into account in the calculation of these probabilities through transfer functions that correlate parton-level energies and their measured values. The value of $m_{t}$ is then extracted from the joint probability calculated for all selected events, based on the probability for signal and background (also defined through its matrix element). This method produces the most accurate results, but the computations are time consuming.

## F. Combination overview

This paper describes the combination of statistically independent top-quark mass measurements from the

Fermilab Tevatron Collider. Measurements are independent if they are based on different data sets, e.g., from CDF and from D0, or from Tevatron Run I (1992-1996) and Run II (2001-2011). They are also independent within one data set if the event selections are designed to be exclusive; i.e., no event can pass more than one category of selections. At times, more than one measurement is published using the same data and decay channel. In this situation, the result with smallest overall uncertainty is chosen for the combination. Twelve measurements are used in the combination described here, eight from the CDF collaboration and four from D0. These comprise five lepton + jets measurements (CDF and D0, Run II and Run I, and a CDF Run II result based on the decay length of $B$ hadrons); two alljets measurements (CDF Run II and Run I); four dilepton measurements (CDF and D0, Run II and Run I); and a $\mathscr{E}_{T}+$ jets measurement (CDF Run II). We combine these measurements using an analytic method called the best linear unbiased estimator (BLUE) [32-34]. This technique forms a linear combination of the separate unbiased mass measurements to produce the best estimate of $m_{t}$ with the smallest uncertainty. This procedure follows a series of 11 such mass combinations presented in [35-45], updated each year since 2004 as new measurements of $m_{t}$ became available. The combination presented here is the first to be published in a peer-reviewed journal.

## II. INPUTS TO THE COMBINATION

## A. The independent mass measurements

The mass measurements included in the combination are shown in Table I [24,25,46-55]. These 12 channels are chosen because they are statistically independent, which

TABLE I. Top-quark mass measurements used as input to determine the combined value of $m_{t}$ from the Tevatron and the combined result.

| Decay channel or method | Tevatron period | Experiment | Integrated luminosity $\left[\mathrm{fb}^{-1}\right]$ | Number of events | Background [\%] | $m_{t}[\mathrm{GeV}]$ | Uncertainty on $m_{t}$ [\%] | Reference |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Lepton + jets | Run II | CDF | 5.6 | 1087 | 17 | $173.00 \pm 0.65 \pm 1.06$ | 0.72 | [24] |
| Lepton + jets | Run II | D0 | 3.6 | 615 | 27 | $174.94 \pm 0.83 \pm 1.24$ | 0.85 | [25] |
| Lepton + jets | Run I | CDF | 0.1 | 76 | 54 | $176.1 \pm 5.1 \pm 5.3$ | 4.2 | [46] |
| Lepton + jets | Run I | D0 | 0.1 | 22 | 22 | $180.1 \pm 3.6 \pm 3.9$ | 2.9 | [47] |
| Alljets | Run II | CDF | 5.8 | 2856 | 71 | $172.47 \pm 1.43 \pm 1.40$ | 1.2 | [48] |
| Alljets | Run I | CDF | 0.1 | 136 | 79 | $186.0 \pm 10.0 \pm 5.7$ | 6.2 | [49] |
| Dileptons | Run II | CDF | 5.6 | 392 | 23 | $170.28 \pm 1.95 \pm 3.13$ | 2.2 | [50] |
| Dileptons | Run II | D0 | 5.3 | 415 | 21 | $174.00 \pm 2.36 \pm 1.44$ | 1.6 | [51] |
| Dileptons | Run I | CDF | 0.1 | 8 | 16 | $167.4 \pm 10.3 \pm 4.9$ | 6.8 | [52] |
| Dileptons | Run I | D0 | 0.1 | 6 | 25 | $168.4 \pm 12.3 \pm 3.6$ | 7.6 | [53] |
| $\mathbb{E}_{T}+$ jets | Run II | CDF | 5.7 | 1432 | 32 | $172.32 \pm 1.80 \pm 1.82$ | 1.5 | [54] |
| Decay length | Run II | CDF | 1.9 | 375 | 30 | $166.90 \pm 9.00 \pm 2.82$ | 5.7 | [55] |
| Combination |  |  | $\leq 5.8$ | 7420 | 44 | $173.18 \pm 0.56 \pm 0.75$ | 0.54 |  |

maximizes the improvement in the combination, and because enough information is available to separate the components of systematic uncertainty for proper treatment in the combination.

The D0 measurement from 2005 in the alljets channel (Run I) [56] of $m_{t}=178.5 \pm 13.7$ (stat) $\pm 7.7$ (syst) GeV (total uncertainty of $8.8 \%$ ) is not included in the combination because some subcomponents of the systematic uncertainty are not available.

The CDF measurement from Run II based on decaylength analysis [55] differs from the others in that it uses the mean decay length of $B$ hadrons in $b$-tagged lepton + jets events as the $m_{t}$-sensitive variable. It is independent of energy information in the calorimeter, and its main source of systematic uncertainty is uncorrelated with the dominant ones from the jet energy scale calibration in other measurements. This measurement of $m_{t}$ is essentially uncorrelated with the higher precision CDF result from the lepton + jets channel. The overlap between the data samples used for the decay-length method and the lepton + jets sample has therefore no effect.

## B. Data

The data were collected with the CDF [57] and D0 [58,59] detectors at the Tevatron $p \bar{p}$ collider at Fermilab between 1992 and 2009. The Tevatron "center-of-mass" energy was 1.8 TeV in Run I from 1992 to 1996 and 1.96 TeV in Run II from 2001. A silicon microstrip tracker around the beam pipe at the center of each detector was used to reconstruct charged-particle tracks (only in Run II at D0). Tracks spatially matched to calorimeter jets are checked for originating from a secondary vertex, or for evidence that they originate from decays of long-lived heavy-flavor hadrons containing $b$ quarks from the decay of top quarks $[57,60]$. Electrons and jets produce particle
showers in the calorimeters, and the collected information is used to measure their energies. Muons traverse the calorimeters and outer muon detectors that are used to reconstruct their tracks. Both CDF and D0 have central axial magnetic fields in the tracking region (D0 only in Run II), in which the momenta of charged particles are determined from the curvature of their tracks. The CDF magnet has a diameter of 3 m and extends 4.8 m along the beam line, with a field strength of 1.4 T , and the D0 magnet has a diameter of 1.0 m and length of 2.7 m to fit inside the Run I calorimeter with a field strength of 2.0 T . The CDF detector's larger tracking volume with a higher density of measurements gives better transverse-momentum resolution for charged-particle tracks. The transverse-momentum resolution is $\approx 3.5 \%$ at CDF and $\approx 10 \%$ at D 0 for a muon with $p_{T}=50 \mathrm{GeV}$. The trigger and event-selection criteria depend on the $t \bar{t}$ final states, details of which appear in the publications listed in Table I. The experiments collected $\mathcal{O}\left(10^{14}\right)$ hard collisions, from which 7420 events are selected because they have the characteristics expected for $t \bar{t}$ pairs, of which $\approx 56 \%$ are expected to be true $t \bar{t}$ events.

## C. Models for $\boldsymbol{t} \overline{\boldsymbol{t}}$ signal

The $t \bar{t}$ signal in Run I was simulated using the LO generator HERWIG [61] with the $\mathrm{MRSD}_{0}^{\prime}$ [62] and CTEQ4M [63] parton distribution functions (PDF) used by CDF and D0, respectively. The HERWIG generator implements the hard-scattering processes $q \bar{q} \rightarrow t \bar{t}$ and $g g \rightarrow t \bar{t}$, adding initial-state and final-state radiation through leading-log QCD evolution [64]. The top quark and $W$ boson in HERWIG decay according to the branching fractions listed by the Particle Data Group [7], and the final-state partons are subsequently fragmented into jets. The MC events are then processed through a fast
simulation or a GEANT model [65] of the detectors and then through event reconstruction programs.

For the $t \bar{t}$ signal in Run II, CDF uses PYthia [66] with the CTEQ5L [67] PDF, and D0 uses the leading-log generator AlPGEN [68] with the CTEQ6L1 [69] PDF and PYTHIA for parton showering. ALPGEN contains more tree-level graphs in higher-order $\alpha_{s}$ than PYTHIA. ALPGEN has parton-jet matching [70], which avoids double counting of partons in overlapping regions of jet kinematics. CDF sets the event generation factorization and renormalization scales $Q^{2}$ to $m_{t}^{2}+p_{\perp}^{2}+\left(P_{1}^{2}+P_{2}^{2}\right) / 2$, where $p_{\perp}$ is the transverse momentum characterizing the scattering process, and $P_{1}^{2}$ and $P_{2}^{2}$ are the virtualities of the incoming partons. D0 sets the scales to $m_{t}^{2}+\left\langle p_{T}^{2}\right\rangle$, where $\left\langle p_{T}^{2}\right\rangle$ is the average of the square of transverse momentum of all other light partons produced in association with the $t \bar{t}$ pair. The PYTHIA model treats each step of the $t \bar{t}$ decay chain ( $t \rightarrow W b, W \rightarrow \ell \nu$ or $q \bar{q}^{\prime}$ ) separately and does not preserve spin correlations. ALPGEN uses exact matrix elements for each step and thereby correctly describes the spin information of the final-state partons. The fragments of the proton and antiproton or "underlying event" are added separately to each hard collision. CDF uses the "Tune A" settings [71] in PYTHIA while D0 uses a modified version of the tune. Both collaborations use angular ordering for modeling parton showering in PYTHIA, and not $p_{T}$-ordered models. The underlying event is therefore not interleaved with the parton showers as in models of color reconnection [72].

## D. Background models

In the lepton + jets channel, the dominant background is from $W+$ jets production. Smaller contributions arise from multijet events, $Z+$ jets, single top-quark ( $t q b$ and $t b$ ), and diboson production ( $W W, W Z$, and $Z Z$ ). The alljets channel has mainly multijet events as background. The largest background in the dilepton channel is from $Z+$ jets events, which include Drell-Yan production. Backgrounds from diboson production and from events with jets identified as leptons are very small in the dilepton channel. The $\mathscr{E}_{T}+$ jets channel has multijet events and $W+$ jets as main backgrounds.

In all channels contributions from multijet events are modeled using data. Most other background sources are modeled through MC simulation. In Run I, both collaborations used vecbos [73] to model $W+$ jets events. VECBOS is a precursor of ALPGEN and provides one of the first models of events with many high-momentum final-state partons. PYTHIA was used to model $Z+$ jets, Drell-Yan, and diboson processes. Background from events with a single top quark was negligible. In Run II, both collaborations used ALPGEN for the simulation of the $W+$ jets background. The treatment of heavy-flavor jets is implemented more accurately in ALPGEN, and parton-jet matching also improves the simulation. For the $Z+$ jets
background, CDF uses PYTHIA and D0 uses alpgen. For dibosons, both collaborations use PYTHIA. Processes with a single top quark are modeled by CDF using MADEVENT [74] (based on MADGRAPH [75]) and by D0 with SINGLETOP [76] (based on COMPHEP [77]).

The uncertainty in the description of the $W+$ jets background has three main components: (i) the uncertainty on the scale $Q^{2}$, which affects both the overall normalization and the differential jet distributions in pseudorapidity $\eta$ [78] and $p_{T}$; (ii) the uncertainty in the correction for flavor content of jets to higher order; and (iii) the limitation in the MC model we are using to reproduce the jet $p_{T}$ and $\eta$ distributions in data at low $p_{T}$ and large $|\eta|$.

## E. Jet properties

After the top quarks decay, the final-state quarks and gluons hadronize to produce multiple charged and neutral particles that traverse the central tracking systems into the calorimeters, where they produce many lower-momentum particles through interactions in the absorbers of the calorimeters. The observed particles tend to cluster in jets that can be assigned to the initial partons. For jet reconstruction, the CDF Collaboration uses a clustering algorithm in ( $\eta, \phi$ ) space [79] with a cone radius of

$$
\mathrm{CDF} \quad \mathcal{R}=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}=0.4,
$$

where $\phi$ is the azimuthal angle around the beam line, $\eta$ is the pseudorapidity, and $\Delta \eta$ or $\Delta \phi$ are the widths of the cone. D0 uses a midpoint iterative seed-based cone algorithm in ( $y, \phi$ ) space [80] with a radius defined by

$$
\text { D } 0 \quad \mathcal{R}=\sqrt{(\Delta y)^{2}+(\Delta \phi)^{2}}=0.5,
$$

where the rapidity $y=1 / 2 \ln \left(\left(E+p_{L}\right) /\left(E-p_{L}\right)\right), E$ is the jet energy, and $p_{L}$ is its longitudinal momentum component.

The jet energy resolution in the central region $(|\eta|<1)$ is approximately the same for CDF and D0; for CDF it is $\sigma\left(E_{T}\right) / E_{T}=50 \% / \sqrt{E_{T}(\mathrm{GeV})} \oplus 3 \%$. For jets in the forward region, however, the energy resolution at D0 is similar to that in the central region, while at CDF it is not as $\operatorname{good}\left[\sigma\left(E_{T}\right) / E_{T}=70 \% / \sqrt{E_{T}(\mathrm{GeV})} \oplus 4 \%\right]$. CDF's calorimeter covers $|\eta|<3.8$, whereas D0's calorimeter covers $|\eta|<4.2$. The D0 calorimeter is more homogeneous, so that the imbalance in transverse momentum (see Sec. II G) usually has better resolution at D0. For both CDF and D0, to reject jets with mismeasured energy, selections on energy deposition are required when clustering the energy from the calorimeter cells into jets. When a muon is reconstructed within the jet cone, a correction is applied to the jet energy to account for the muon and its associated neutrino assumed to arise from heavy-quark decay.

Jet energy scale calibrations are applied after jet reconstruction. CDF calibrates the transverse momentum using
test-beam data and single-particle simulated events and corrects the jet energy to the parton level. Consequently, CDF does not calibrate the jet energy scale in MC events. D0 calibrates the energy using photon + jets and two-jet data and calibrates jets in data as well as in MC to the observed particle level. Particle jets are clustered from stable particles after fragmentation, including particles from the underlying event, but excluding undetected energy from muons and neutrinos.

CDF's jet calibration [81] applies two scale factors and three offsets to convert the measured transverse momentum of a jet to that of the parton that initiated the jet. D0's jet calibration [82] applies three scale factors and one offset to the jet energy to convert to the particle jet energy scale. The calibrations are expressed as follows:

$$
\begin{aligned}
& \mathrm{CDF} p_{T}^{\mathrm{parton}} \\
&=\frac{p_{T}^{\mathrm{jet}} R_{\mathrm{rel}}-C_{\mathrm{MI}}}{R_{\mathrm{abs}}}-C_{\mathrm{UE}}+C_{\mathrm{OC}} \\
& \mathrm{D} 0 E^{\mathrm{particle}}
\end{aligned}=\frac{E^{\mathrm{jet}}-C_{\mathrm{MI}, \mathrm{UE}}}{R_{\mathrm{abs}} R_{\mathrm{rel}} F_{\mathrm{OC}}} .
$$

The absolute response $R_{\mathrm{abs}}$ corrects for energy lost in uninstrumented regions between calorimeter modules, for differences between electromagnetically and hadronically interacting particles, as well as for module-to-module irregularities. The relative response $R_{\text {rel }}$ is a scale factor that corrects forward relative to central jets and $C_{\mathrm{MI}}$ is a correction for multiple interactions in the same bunch crossing. The function $C_{\mathrm{UE}}$ is a correction for the jet energy added from the underlying event. D0 has one offset correction, $C_{\mathrm{MI}, \mathrm{UE}}$, which includes the effects of multiple interactions, the underlying event, noise from radioactive decays of the uranium absorber, and the effect of collisions from previous bunch crossings (pileup). The functions $C_{\mathrm{OC}}$ and $F_{\mathrm{OC}}$ are corrections for shower particles scattered in or out of the cone of radius $\mathcal{R}$. CDF's correction accounts for MC modeling that affects how the parton energy is translated into particle jet energy, whereas D0's correction accounts for a detector effect caused by the finite cell size in the calorimeter coupled with the cone size for the jet algorithm. The combined jet energy scale corrections increase the measured jet energies by about $20 \%-50 \%$, depending on $p_{T}$ and $\eta$.

The overall uncertainties on the jet energy scale corrections vary from about $2.7 \%$ for CDF and $1.1 \%$ for D0 for central jets of transverse energy of 100 GeV to $3.3 \%$ for CDF and $2.2 \%$ for D0 for forward jets. Central jets of 25 GeV have correction uncertainties of $5.9 \%$ for CDF and $1.4 \%$ for D0. For both experiments, the uncertainty on the corrections for absolute response $R_{\text {abs }}$ dominate these uncertainties.

At D0, the jet energy resolution in data is lower than predicted by the detector simulation. Therefore, the energies of MC jets are smeared so that the resulting resolution in MC matches that in data. Similarly, the reconstruction efficiency for jets in data is lower than is predicted by the
detector simulation, so an appropriate fraction of MC jets are randomly removed. Both effects are corrected for as functions of jet $p_{T}$ and pseudorapidity.

D0 Run II analyses include an energy correction to simulated jets that depends on jet flavor. There are corrections for $b$ jets, other-quark flavor jets ( $u, d, s$, and $c$ ), and gluon jets implemented in both the lepton + jets and dilepton analyses. Such corrections refine the simulation by improving the matching of jet energies in MC to data. The differences arise from the varying electromagnetic fractions and widths of the jets. The corrections depend on jet transverse energy and pseudorapidity and range from $-6 \%$ to $+2 \%$ [25].

Both collaborations perform an in situ jet energy scale calibration in lepton + jets events for the matrix-element mass extraction of $m_{t}$, and in CDF's alljets and $\mathscr{E}_{T}+$ jets measurements of $m_{t}$. The invariant mass of the two jets is constrained to a Breit-Wigner distribution for the $W \rightarrow q \bar{q}^{\prime}$ decay, set to the world average value for the $W$-boson mass [7]. The energies of all jets in the event are then rescaled to complete this calibration.

## F. $\boldsymbol{b}$-quark jet properties

To separate top-quark events from background and to decrease the ambiguity in jet-to-parton matching, it is important to identify $b$-quark jets. Every $t \bar{t}$ event has two $b$ jets, whereas such jets are rare in background. As $B$ hadrons have a mean lifetime of $\approx 10^{-12} \mathrm{~s}, b$ jets can be tagged through secondary vertices of the $B$ decay a few mm away from the primary $p \bar{p}$ interaction. CDF's $b$-tagging algorithm uses the significance of the displacement of the secondary vertex in the transverse $(r, \phi)$ plane for the lepton + jets and $\mathscr{E}_{T}+$ jets channels [57], as well as a jet-probability algorithm for $\mathscr{E}_{T}+$ jets events [83]. One parameter defines the significance of the separation of the primary and secondary vertices for events with one and two $b$ jets. For jets that are within the acceptance of the silicon microstrip tracker (i.e., "taggable" jets), this algorithm identifies $50 \%$ of real $b$ jets and $9 \%$ of real charm jets, while falsely tagging $1 \%$ of light jets. D0 tags jets by combining nine track and secondary-vertex-related variables using a neural network [60]. For jets within the acceptance of the silicon microstrip detector, this yields efficiencies of $65 \%$ and $20 \%$ for real $b$ and charm jets, respectively, while falsely tagging $3 \%$ of light jets.

To identify heavy-flavor jets in data and in MC events, the tagging algorithm is applied by CDF and D0 directly to the jets, except for simulated $W+$ light jets events, where CDF uses tag-rate functions measured in multijet data, since the rate for directly tagged MC events is very low. After applying direct tagging to $b$ and $c$ jets in MC events, D0 corrects the tagging efficiencies to match those observed in data by randomly dropping the tagging of $13 \%$ of such jets. For light-flavor jets, D0 assigns a per jet mistag weight.

## G. Properties of other event observables

The uncertainty on $m_{t}$ depends not only on an accurate measurement of jet energies and proper assignment of flavor but also on the reconstruction and calibration of the other elements of the event, including electrons, muons, and the imbalance in transverse momentum, taking into account the presence of any simultaneous $p \bar{p}$ interactions in the same bunch crossing.

The mean number of $p \bar{p}$ collisions per bunch crossing is $\approx 2$ in Run I and $\approx 5$ in Run II. Such additional collisions affect the observed characteristics of the hard scatter of interest and must be included in the MC simulation. These extra collisions result mostly in the production of low- $p_{T}$ particles. CDF simulates such additional interactions using the PYTHIA model of minimum-bias events and overlays them onto the hard scatters using a Poisson mean appropriate to the instantaneous luminosity of the data. In a similar manner D0 overlays randomly triggered data events with the same luminosity profile as the data onto the MC simulated events.

Electrons are identified by matching clusters of energy deposited in the electromagnetic layers of the calorimeters with tracks that point from the primary collision vertex to the clusters. The spatial shapes of the showers must agree with those expected for electrons, as studied in test-beam data. The energy of an electron is determined as a combination of the total energy of the cluster and the momentum measured from the curvature of the matching track. The reconstruction efficiency is determined using $Z \rightarrow e e$ data by identifying one tight charged lepton as a tag and using the other charged lepton as a probe (tag-and-probe method). The electron energy is also recalibrated using such $Z$ events.

Muons are reconstructed from a central track and matched to a track in the outer muon chambers. In D0, both the inner and outer trajectories pass through magnetic fields, and so the transverse momenta of the two are therefore required to match. The reconstruction efficiency and calibration of $p_{T}$ are determined using a tag-and-probe method applied on $J / \psi \rightarrow \mu \mu$ and $Z \rightarrow \mu \mu$ events in a manner similar to that used for electrons.

As indicated above, all $t \bar{t}$ decay channels except for alljets events have a large $\mathscr{E}_{T}$. All jet energy calibration corrections are also propagated to $\mathscr{E}_{T}$ in each event.

## III. COMBINATION OF MASS MEASUREMENTS

## A. BLUE combination method

The basic idea of the technique, called the best linear unbiased estimator (BLUE) method [32-34], used to obtain the combined mass $m_{t}^{\text {comb }}$, an "estimator" of the true mass $m_{t}^{\text {true }}$, is to calculate a linear weighted sum of the results from separate measurements:

$$
\begin{equation*}
m_{t}^{\mathrm{comb}}=\sum_{i=1}^{12} w_{i} m_{t}^{i} \tag{1}
\end{equation*}
$$

The $m_{t}^{i}$ are the 12 CDF and D 0 measurements $i$ of $m_{t}$ and

$$
\begin{equation*}
\sum_{i=1}^{12} w_{i}=1 \tag{2}
\end{equation*}
$$

The weights are determined using the value of $m_{t}^{\text {comb }}$ that minimizes the squared difference relative to the unknown true value $m_{t}^{\text {true }}$ :

$$
\begin{equation*}
\left(m_{t}^{\mathrm{comb}}-m_{t}^{\mathrm{true}}\right)^{2}=\operatorname{Variance}\left(m_{t}^{\mathrm{comb}}\right)+\left[\operatorname{Bias}\left(m_{t}^{\mathrm{comb}}\right)\right]^{2} \tag{3}
\end{equation*}
$$

where the two terms represent the weighted variance and bias in the 12 input $m_{t}$ values with

$$
\begin{equation*}
\operatorname{Variance}\left(m_{t}^{\mathrm{comb}}\right)=\sum_{i=1}^{12} w_{i}^{2} \operatorname{Variance}\left(m_{t}^{i}\right) \tag{4}
\end{equation*}
$$

and

$$
\begin{equation*}
\operatorname{Variance}\left(m_{t}^{i}\right)=\left[\sigma\left(m_{t}^{i}\right)\right]^{2} \tag{5}
\end{equation*}
$$

where $\sigma\left(m_{t}^{i}\right)$ are the uncertainties on the 12 input values given in Table I.

On average, we expect the input mass measurements to be unbiased, and we therefore assume

$$
\begin{equation*}
\operatorname{Bias}\left(m_{t}^{\mathrm{comb}}\right)=\sum_{i=1}^{12} w_{i} \operatorname{Bias}\left(m_{t}^{i}\right)=0 \tag{6}
\end{equation*}
$$

Equation (3) shows that the BLUE method defines the best estimate through a minimization of the variance of $m_{t}$ for an assumed unbiased set of measurements. The minimum corresponds to setting the weights to

$$
\begin{equation*}
w_{i}=\frac{1 / \operatorname{Variance}\left(m_{t}^{i}\right)}{\sum_{i=1}^{12} 1 / \operatorname{Variance}\left(m_{t}^{i}\right)} \tag{7}
\end{equation*}
$$

for uncorrelated input values. Since the input $m_{t}$ values are correlated, the variance in Eq. (4) has to be replaced with a covariance matrix:
$\operatorname{Variance}\left(m_{t}^{\mathrm{comb}}\right)=\sum_{i=1}^{12} \sum_{j=1}^{12} w_{i} w_{j} \operatorname{Covariance}\left(m_{t}^{i}, m_{t}^{j}\right)$,
which is defined as

$$
\begin{equation*}
\operatorname{Covariance}\left(m_{t}^{i}, m_{t}^{j}\right)=\left[\sigma\left(m_{t}^{i} m_{t}^{j}\right)\right]^{2}-\sigma\left(m_{t}^{i}\right) \sigma\left(m_{t}^{j}\right) \tag{9}
\end{equation*}
$$

Minimizing Eq. (3) yields

$$
\begin{equation*}
w_{i}=\frac{\sum_{j=1}^{12} \text { Covariance }^{-1}\left(m_{t}^{i}, m_{t}^{j}\right)}{\sum_{i=1}^{12} \sum_{j=1}^{12} \text { Covariance }^{-1}\left(m_{t}^{i}, m_{t}^{j}\right)}, \tag{10}
\end{equation*}
$$

where Covariance ${ }^{-1}\left(m_{t}^{i}, m_{t}^{j}\right)$ are the elements of the inverse of the covariance matrix (also known as the error matrix), and

Covariance $\left(m_{t}^{i}, m_{t}^{j}\right)=$ Correlation $\left(m_{t}^{i}, m_{t}^{j}\right) \sigma\left(m_{t}^{i}\right) \sigma\left(m_{t}^{j}\right)$
with Correlation $\left(m_{t}^{i}, m_{t}^{j}\right)$ the correlation coefficient between $m_{t}^{i}$ and $m_{t}^{j}$. The following sections show how the

TABLE II. The uncertainty in GeV from each component for the 12 measurements of $m_{t}$ and the resulting Tevatron combination. The total uncertainties are obtained by adding the components in quadrature. The entries " $\mathrm{n} / \mathrm{a}$ " stand for "not applicable" and " $\mathrm{n} / \mathrm{e}$ " for "not evaluated." The nonevaluated uncertainties were not considered as significant sources of uncertainty for Run I measurements.

correlation matrix is derived by examining the uncertainty components and their individual correlations.

## B. Measurement uncertainties

The uncertainty on any $m_{t}$ measurement has a statistical component from the limited number of events available for the measurement and a systematic component from the uncertainties assigned to the calibration of input quantities, to the model of the signal, and to the calibration of the mass extraction method. Since the first measurements of $m_{t}$ [4,5], the systematic component has been slightly larger than the statistical one. As more data became available, the statistical uncertainties on $m_{t}$ improved as did the calibrations of systematic uncertainty, and the two components therefore improved together.

The systematic uncertainty on each $m_{t}$ measurement in this combination is divided into 14 parts. Some of them have origin in only one source, whereas others include several related sources of uncertainties. For the latter the patterns of correlation among different channels, Tevatron Run I and Run II, or experiments are the same for all sources included in these systematic components. The uncertainty on jet energy scale (JES), on the other hand, is split into seven components, which do not apply to all measurements, given the significantly different approaches to jet energy calibration between CDF and D0 and the change in the D0 procedure between Run I and Run II.

Table II gives the uncertainty of each of the 12 top-quark mass measurements for the different contributions to uncertainty and their effect on the final combination. The components of uncertainty are defined in the following and can be classified as uncertainties in detector response (jet energy scale, jet and lepton modeling), uncertainties from modeling signal and background (signal modeling, multiple interactions model, background estimated from theory, and background based on data), uncertainties from method of mass extraction, and statistical uncertainties. A detailed description of the methods to evaluate these systematic uncertainties is presented in the Appendix.

## 1. Jet energy scale

## a. Light-jet response (1)

One subcomponent of the uncertainty in JES covers the absolute calibration for CDF's Run I and Run II measurements. It also includes small contributions from the uncertainties associated with modeling multiple interactions within a single bunch crossing and corrections for the underlying event.

## b. Light-jet response (2)

Another subcomponent of this uncertainty includes D0's Run I and Run II calibrations of absolute response (energy dependent), the relative response ( $\eta$ dependent), and the
out-of-cone showering correction that is a detector effect. This uncertainty term for CDF includes only the small relative response calibration ( $\eta$ dependent) for Run I and Run II.

## c. Out-of-cone correction

This subcomponent of the JES uncertainty quantifies the out-of-cone showering corrections to the MC showers for all of CDF's and for D0's Run I measurements that are obtained by varying the model for light-quark fragmentation.

## d. Offset

This subcomponent originates from the offset in D0's Run I calibration, which corrects for noise from uranium decay, pileup from previous collisions, and for multiple interactions and the model for the underlying event. In Run I, the uncertainties are large, but in Run II, owing to the smaller integration time for calorimeter electronics, they are negligible. CDF's calorimeter does not have the same sources of noise and sensitivity to pileup as D0, so CDF measurements do not have this term.

## e. Model for $b$ jets

This subcomponent comes from the uncertainty on the semileptonic branching fraction in $b$ decays and from differences between two models of $b$-jet hadronization.

## f. Response to $b / q / g$ jets

This subcomponent accounts for the difference in the electromagnetic versus hadronic response of $b$ jets, lightquark jets, and gluon jets. CDF corrects for jet flavor as part of the main calibration, and defines the uncertainty based on the remaining difference in response between $b$ jets and light-flavor jets, whereas D0 corrects the response for $b$, light-quark $(u, d, s$, and $c)$, and gluon jets as a function of jet $p_{T}$ and $\eta$.

## g. In situ light-jet calibration

The last part of the uncertainty in the jet energy scale is from the in situ calibration of $m_{t}$. It corresponds to the statistical uncertainty from the limited number of events used in the fit when using the $W$-boson mass to constrain the energies of the light quarks from the $W$ decay.

## 2. Jet modeling

The uncertainty in jet modeling has two components for D0. This uncertainty is negligible for CDF.
(i) The jet energy resolution is smeared for MC jets to match the resolution observed in data, and the uncertainty on the smearing functions is propagated to $m_{t}$.
(ii) The identification efficiency in MC events is corrected to match that found in data, and the uncertainty on the correction functions is propagated to $m_{t}$.

## 3. Lepton modeling

This uncertainty has two components:
(i) The electron and muon $p_{T}$ scales are calibrated to the $J / \psi$ and $Z$-boson mass by both CDF and D0. This uncertainty on the calibration is included in the measurements of $m_{t}$.
(ii) D0 smears the muon momentum resolution in MC events to match that in data, and the uncertainty on this correction is included in this term. The uncertainty on the electron resolution has a negligible impact on the measurements of $m_{t}$.

## 4. Signal modeling

There are six components to this uncertainty. They are combined into one term because the correlations between channels are similar for each component:
(i) Knowledge of the PDF parametrization.
(ii) The quark annihilation and gluon fusion fractions that differ significantly between leading-log and next-to-leading-order (NLO) QCD calculations (Run II).
(iii) The amount of initial- and final-state radiation in MC signal events differs from that in data and is adjusted through the value of $\Lambda_{\mathrm{QCD}}$ used in the shower and the scales of time and spacelike showers.
(iv) Higher-order QCD corrections to initial- and finalstate radiation differ from precise parton-level models, and this is not accounted for by the choice of scale for the calculations (Run II).
(v) Our model for jet hadronization is based on angular ordering in PYTHIA with Tune A underlyingevent tuning. Parton showering and the underlying event can also be simulated with HERWIG and JIMMY $[84,85]$. The effect of the difference on $m_{t}$ between the two models is included in this term.
(vi) Final-state partons and remnants of the protons and antiprotons are connected through color strings, which affect the distributions of jets. Since this effect is not included in the model for the $t \bar{t}$ signal, the value of $m_{t}$ has an uncertainty from this omission (Run II).

## 5. Multiple interactions model

The number of soft $p \bar{p}$ events overlaid on each MC event has a Poisson distribution. The mean number does not equal exactly the number seen in data since the luminosity increased as the Tevatron run progressed. The top-quark mass is measured as a function of the number of multiple interactions in signal events by CDF, the signal MC events are reweighted to match the distribution seen in data by D0, and the related uncertainties are included here.

## 6. Background from theory

There are four components in this uncertainty:
(i) Difference between NLO calculations of the fraction of heavy-flavor jets in $W+$ jets events. The ALPGEN model underestimates this fraction.
(ii) Impact of factorization and renormalization scales on the $W+$ jets simulation, which affects the background model for distributions characterizing jets.
(iii) The theoretical cross sections used to normalize all MC estimated background processes (except for $W+$ jets for CDF and D0 lepton + jets measurements, and Drell-Yan production for CDF dilepton measurements).
(iv) Impact of difference between the MC modeling of background kinematic distributions and those observed in data.

## 7. Background based on data

This refers primarily to uncertainties from the normalization of certain background components to data. These include multijet backgrounds in the lepton + jets, alljets, and $\mathscr{E}_{T}+$ jets analyses, the $W+$ jets background in the D0 lepton + jets analyses, and the Drell-Yan backgrounds in the CDF dilepton analyses.

D0 also considers the following four components of uncertainty:
(i) The uncertainty from correcting the MC events to match the trigger efficiency in data, which is based on the turn-on response for each trigger element.
(ii) The uncertainty from applying tag-rate and taggability corrections to MC events to make the efficiencies match the data for each jet flavor.
(iii) The uncertainty on the fraction of multijet events included in the pseudoexperiments used for calibration.

## 8. Calibration method

The extracted values of $m_{t}$ are calibrated using a straight-line fit to the relationship between input mass and measured mass in simulated pseudoexperiments. This term includes the systematic uncertainties from the slope and offset of this calibration.

## 9. Statistical uncertainty

The statistical uncertainties are determined from the number of data events in each of the 12 measurements.

Figure 5 shows the relative contribution for each major uncertainty to the analysis channels in Run II. The Appendix provides more detail on how each of the sources of the uncertainties is estimated.

## C. Uncertainty correlations

Tables III and IV indicate how uncertainties are correlated between measurements. There are seven patterns of correlation:

FIG. 5 (color online). The average uncertainties for CDF and D0 for each Run II measurement and for the Tevatron combination, separated according to major components. (See Table VIII in the Appendix for details on the systematic categories. In this figure, the jet and lepton modeling systematic uncertainties are grouped into the modeling background category.)
(i) Statistical uncertainty and calibration method uncertainty are not correlated among the measurements.
(ii) Correlations among D0 measurements that implement the same final jet energy corrections for the uncertainty from in situ light-jet calibration.
(iii) Correlations among CDF measurements that use the same data samples for the uncertainty from background based on data.
(iv) Correlations among all measurements in the same $t \bar{t}$ decay channel for the uncertainty from background estimated from theory.
(v) Correlations of measurements within the same experiment for a given run period for the uncertainties from light-jet response (2), offset, response to $b / q / g$ jets, jet modeling, lepton modeling, and multiple interactions model.
(vi) Correlations for measurements within the same experiment such as the uncertainty from light-jet response (1).
(vii) Correlations among all measurements such as the uncertainties from out-of-cone correction, model for $b$ jets, and signal modeling.
We assume that all sources correspond to either no or $100 \%$ correlation. A check of this assumption (see Sec. IV B) shows that it has a negligible effect on the combined value and uncertainty of $m_{t}$.

## D. Measurement correlations

The uncertainties shown in Table II and their correlations shown in Tables III and IV provide the correlations among the 12 input values of $m_{t}$. The correlation matrix for these measurements, as returned by the combination procedure, is shown in Table V. The inversion of the covariance matrix built with the correlation matrix defines the measurement weights, as described in Sec. III A.

TABLE III. Correlations in systematic uncertainties (in percent) among the different measurements of $m_{t}$.

## E. Measurement weights

As discussed in Sec. III A, the combined mass $m_{t}^{\text {comb }}$ is defined through the set of weights that minimize the squared difference between $m_{t}^{\text {comb }}$ and the true value of $m_{t}$, which is equivalent to minimizing the sum of the covariance matrix elements. Table V gives the weights $w_{i}$ for each of the input measurements as determined in this minimization. A weight of zero means that an input measurement has no effect on $m_{t}^{\text {comb }}$. The Run I measurement weights are negative, which reflects the fact that the correlations for these and other measurements are larger than the ratio of their total uncertainties [33]. In this case, the less precise measurement may acquire a negative weight. Input measurements with negative weights still affect the value of $m_{t}^{\text {comb }}$ and reduce the total uncertainty. By design, the sum of the weights is set to unity.

## IV. RESULTS OF THE COMBINATION

## A. Tevatron top-quark mass result

Combining the 12 independent measurements of $m_{t}$ from the CDF and D0 Collaborations yields

$$
\begin{aligned}
m_{t}^{\text {comb }} & =173.18 \pm 0.56(\text { stat }) \pm 0.75(\text { syst }) \mathrm{GeV} \\
& =173.18 \pm 0.94 \mathrm{GeV}
\end{aligned}
$$

The uncertainties are split into their components in Table II and Fig. 5. The jet energy scale contributes 0.49 GeV to the total systematic uncertainty. Of this, 0.39 GeV arises from limited statistics of the in situ JES calibration and 0.30 GeV
from the remaining contributions. Figure 6 summarizes the input $m_{t}$ values and the combined result.

We assess the consistency of the input $m_{t}$ measurements with their combination using a $\chi^{2}$ test statistic, defined as follows:

$$
\begin{aligned}
\chi_{\text {comb }}^{2}= & \left(\boldsymbol{m}_{\boldsymbol{t}}^{i}-\boldsymbol{m}_{\boldsymbol{t}}^{\text {comb }}\right)^{T} \text { Covariance }{ }^{-1} \\
& \times\left(m_{t}^{i}, m_{t}^{j}\right)\left(\boldsymbol{m}_{\boldsymbol{t}}^{j}-\boldsymbol{m}_{\boldsymbol{t}}^{\text {comb }}\right),
\end{aligned}
$$

where $\boldsymbol{m}_{t}^{i}$ is a column vector of the $12 m_{t}$ inputs, $\boldsymbol{m}_{\boldsymbol{t}}^{\text {comb }}$ is a matching column vector for the measurements adjusted in the previous minimization, and the superscript $T$ denotes the transpose. We find

$$
\chi_{\mathrm{comb}}^{2}=8.3 \text { for } 11 \text { degrees of freedom }
$$

which is equivalent to a $69 \%$ probability for agreement (i.e., $p$ value for the observed $\chi^{2}$ value) among the 12 input measurements.

## B. Consistency checks

We check one aspect of the assumption that biases in the input $m_{t}$ are on average zero (see Sec. III A) by calculating separately the combined $m_{t}^{\text {comb }}$ for each $t \bar{t}$ decay mode, each run period, and each experiment. The results are shown in Table VI. The resulting $m_{t}^{\text {comb }}$ values are calculated using all 12 input measurements and their correlations. The $\chi^{2}$ test statistic provides the compatibility of each subset with the others and is defined as
$\chi_{\mathrm{sub} 1, \mathrm{sub} 2}^{2},=\left(m_{t}^{\mathrm{sub} 1}-m_{t}^{\mathrm{sub} 2}\right)^{2}$ Covariance ${ }^{-1}\left(m_{t}^{\mathrm{sub} 1}-m_{t}^{\mathrm{sub} 2}\right)$.

FIG. 6 (color online). The 12 input measurements of $m_{t}$ from the Tevatron collider experiments along with the resulting combined value of $m_{t}^{\text {comb }}$. The gray region corresponds to $\pm 0.94 \mathrm{GeV}$.

The $\chi^{2}$ values in Table VI show that biases in the input measurements are not large.

To check the impact of the assumption that the systematic uncertainty terms are either $0 \%$ or $100 \%$ correlated between input measurements, we change all off-diagonal $100 \%$ values to $50 \%$ (see Tables III and IV) and recalculate the combined top-quark mass. This extreme change shifts the central mass value up by 0.17 GeV and reduces the uncertainty negligibly. The chosen approach is therefore conservative.

## C. Summary

We have combined 12 measurements of the mass of the top quark by the CDF and D0 collaborations at the Tevatron collider and find

$$
m_{t}^{\text {comb }}=173.18 \pm 0.56(\text { stat }) \pm 0.75(\text { syst }) \mathrm{GeV}
$$

which corresponds to a precision of $0.54 \%$. The result is shown in Table VII together with previous combined results for comparison. The input measurements for this combination use up to $5.8 \mathrm{fb}^{-1}$ of integrated luminosity for each experiment, while $10 \mathrm{fb}^{-1}$ are now available. We therefore expect the final combination to improve in precision with the use of all the data, but also from analyzing all $t \bar{t}$ decay channels in both experiments and from the application of improved measurement techniques, signal and background models, and calibration corrections to all channels that will reduce systematic uncertainties. Currently, there are also some overlaps of the systematic effects that are included in different uncertainty categories.

TABLE VII. Mass measurements of the top quark from 1999 until this publication at the Tevatron collider.

| Year | Integrated luminosity $\left[\mathrm{fb}^{-1}\right]$ | $m_{t}[\mathrm{GeV}]$ | Uncertainty on $m_{t}$ | Reference |
| :---: | :---: | :---: | :---: | :---: |
| 1999 | 0.1 | $174.3 \pm 3.2 \pm 4.0$ | $2.9 \%$ | $[35]$ |
| 2004 | 0.1 | $178.0 \pm 2.7 \pm 3.3$ | $2.4 \%$ | $[36]$ |
| 2005 | 0.3 | $172.7 \pm 1.7 \pm 2.4$ | $1.7 \%$ | $[37]$ |
| 2006 | 0.7 | $172.5 \pm 1.3 \pm 1.9$ | $1.3 \%$ | $[38]$ |
| 2006 | 1.0 | $171.4 \pm 1.2 \pm 1.8$ | $1.2 \%$ | $[39]$ |
| 2007 | 2.1 | $170.9 \pm 1.1 \pm 1.5$ | $1.1 \%$ | $[40]$ |
| 2008 | 2.1 | $172.6 \pm 0.8 \pm 1.1$ | $0.8 \%$ | $[41]$ |
| 2008 | 2.1 | $172.4 \pm 0.7 \pm 1.0$ | $0.7 \%$ | $[42]$ |
| 2009 | 3.6 | $173.1 \pm 0.6 \pm 1.1$ | $0.7 \%$ | $[43]$ |
| 2010 | 5.6 | $173.32 \pm 0.56 \pm 0.89$ | $0.61 \%$ | $[44]$ |
| 2011 | 5.8 | $173.18 \pm 0.56 \pm 0.75$ | $0.54 \%$ | [45] |
|  | 5.8 | $173.18 \pm 0.56 \pm 0.75$ | $0.54 \%$ | This paper |

In addition to the in situ light-jet calibration systematic uncertainty that will scale down with the increase of analyzed luminosity, these levels of double counting are expected to be reduced for the next combination. The combination presented here has a $0.54 \%$ precision on $m_{t}$, making the top quark the particle with the best known mass in the SM.

## ACKNOWLEDGMENTS

Sloan Foundation (USA).

## APPENDIX A: EVALUATION OF SYSTEMATIC UNCERTAINTIES

Systematic uncertainties arise from inadequate modeling of signal and backgrounds and from the inability to reproduce the detector response with simulated events. Systematic uncertainties also arise from ambiguities in reconstructing the top quarks from their jet and lepton remnants. We minimize such uncertainties by using independent data to calibrate the absolute response of the detector, and we use state-of-the-art input from theory for
modeling the signal and backgrounds. We use alternative models for signal and different parameters for modeling backgrounds to check our assumptions.

Table VIII lists the uncertainties from the Run II lepton + jets measurements for CDF and D0 that are based on the matrix-element technique [24,25]. These two measurements provide most of the sensitivity to the combined $m_{t}$ result and are discussed below. Before explaining how each individual systematic uncertainty is estimated, we will first discuss how the uncertainties from different sources are propagated to $m_{t}$ and how they are calculated using ensembles of pseudoexperiments.

Uncertainties related to the performance of the detector and calibration of the reconstructed objects, such as JES, the modeling of jets, leptons, and triggers, and calibration of the $b$-tagging algorithms, are evaluated by shifting the central values of their respective parameters by $\pm 1$ standard deviations $(\sigma)$ that correspond to the uncertainties on each value. This is done using MC $t \bar{t}$ events for $m_{t}=$ 172.5 GeV . The integrations over the matrix element are performed again for each shifted sample and define shifts in $m_{t}$ that correspond to each independent source of systematic uncertainty. These uncertainties are not determined at other $m_{t}$ values, and it is assumed that their dependence on $m_{t}$ is minimal.

For uncertainties that arise from ambiguities in the modeling of the $t \bar{t}$ signal, which include the uncertainties from initial- and final-state radiation, higher-order QCD corrections, $b$-jet hadronization, light-jet hadronization, the underlying-event model, and color reconnection, we generate simulated $t \bar{t}$ events using alternative models also at $m_{t}=172.5 \mathrm{GeV}$. These events are processed through detector simulation and are reconstructed, and the probability density is calculated by integration over the matrix elements.

For the uncertainties from the choice of parton distribution functions, the ratio of contribution from quark annihilation and gluon fusion, and models for overlapping

TABLE VIII. Individual components of uncertainty on CDF and D0 $m_{t}$ measurements in the lepton + jets channel for Run II data [24,25].

| Systematic | Uncertainty [GeV] |  |
| :---: | :---: | :---: |
|  | CDF ( $5.6 \mathrm{fb}^{-1}$ ) | D0 (3.6 fb ${ }^{-1}$ ) |

interactions, we reweight the fully reconstructed simulated $t \bar{t} \mathrm{MC}$ events at $m_{t}=165,170,172.5,175$, and 180 GeV to reflect the uncertainty on the $\pm 1 \sigma$ range on each parameter and extract its impact on $m_{t}$.

Each method used to measure $m_{t}$ is calibrated using $t \bar{t}$ MC events generated at $m_{t}=165,170,172.5,175$, 180 GeV , which provide the relationship between input and "measured" masses. A straight line is fitted to these
values, representing a response function that is used to correct the $m_{t}$ measurement in data.

Systematic uncertainties are evaluated using studies of ensembles of pseudoexperiments. For each of the shifted or reweighted sets of events, and those based on alternative models or different generated $m_{t}$, we create an ensemble of at least 1000 pseudoexperiments, by means of binomially smeared signal and background fractions that match the
expectation in the data sample and with the total number of events in each pseudoexperiment equal to the number of events observed in data. We use the ensembles of such pseudoexperiments to assess the difference between generated and measured mass and to calibrate the method of mass extraction.

For the uncertainty on background, we change the fraction of background events in the pseudoexperiments within their uncertainties and remeasure the top-quark mass.

For the BLUE combination method, the uncertainties must be defined symmetrically around the central mass value, and this requirement determines part of the following definitions of uncertainty.

For the uncertainties obtained in ensemble studies with shifted or reweighted parameters, $m_{t}^{+}$corresponds to the $+1 \sigma$ shift in the input parameter and $m_{t}^{-}$corresponds to the $-1 \sigma$ shift. The systematic uncertainty on the value of $m_{t}$ from these parameters is defined as $\pm\left|m_{t}^{+}-m_{t}^{-}\right| / 2$, unless both shifts are in the same direction relative to the nominal value, in which case the systematic uncertainty is defined as the larger of $\left|m_{t}^{+}-m_{t}\right|$ or $\left|m_{t}^{-}-m_{t}\right|$.

For the values obtained from a comparison between two or more models, the systematic uncertainty is taken as $\pm$ of the largest difference among the resulting masses (without dividing by two).

## 1. Jet energy scale

The following seven terms (1.1-1.7) refer to the jet energy scale.

## a. Light-jet response (1)

This uncertainty includes the absolute calibration of the CDF JES for Run I and Run II and the smaller effects on JES from overlapping interactions and the model for the underlying event.

CDF's calibration of the absolute jet energy scale uses the single-pion response to calibrate jets in data and to tune the model of the calorimeter in the simulation. Uncertainties of these processes form the greatest part of the JES uncertainty. Small constant terms are added to account for the model of jet fragmentation and for calorimeter simulation of electromagnetically decaying particles, and to take into account small variations of the absolute calorimeter response over time. The total resulting uncertainty on the absolute JES is $1.8 \%$ for 20 GeV jets rising to $2.5 \%$ for 150 GeV jets.

At high Tevatron instantaneous luminosities, more than one $p \bar{p}$ interaction occurs during the same bunch crossing, and the average number of interactions depends linearly on instantaneous luminosity and is changed from $\approx 1$ to 8 between the start and the end of Run II. If the final-state particles from these extra $p \bar{p}$ interactions overlap with the jets from a $t \bar{t}$ event, the energy of these jets is increased, thereby requiring the correction. The uncertainty on this correction depends on vertex-reconstruction efficiency and
the rate for misidentifying vertices. The impact of these effects is checked on data samples, including $W \rightarrow e \nu$, minimum bias, and multijet events with a trigger threshold of 100 GeV . CDF finds an uncertainty of 0.05 GeV per jet. This uncertainty was estimated early in Run II. With increasing instantaneous luminosity, this correction was insufficient, and another systematic uncertainty term was introduced through the "multiple-interactions-model" term, which is described later.

CDF includes the impact of the underlying event on JES in this component of uncertainty. The proton and antiproton remnants of the collision deposit energy in the calorimeter, and these can contribute to the energy of the jets from $t \bar{t}$ decay, which must be subtracted before $m_{t}$ can be measured accurately. CDF compares the "Tune A" underlying-event model [71] in PYTHIA [66] with the JIMMY model $[84,85]$ in HERWIG [86] using isolated tracks with $p_{T}>0.5 \mathrm{GeV}$. The data agree well with Tune A, which is expected since it was tuned to CDF data, but differ from JIMMY by about $30 \%$. This difference is propagated to the absolute calibration of JES and yields a $2 \%$ uncertainty for low- $p_{T}$ jets and less than $0.5 \%$ for 35 GeV jets.

MC $t \bar{t}$ events are generated by CDF with jet energies shifted by the above three uncertainties, and the resulting shifts in $m_{t}$ are used to estimate the uncertainty. The overall uncertainty on $m_{t}$ from these combined sources is $0.24 \%$ for lepton + jets, $0.22 \%$ for alljets, $1.18 \%$ for CDF Run II dilepton data, and $0.26 \%$ for $\mathscr{Z}_{T}+$ jets for Run II data of CDF.

## b. Light-jet response (2)

This uncertainty term represents almost all parts of D0 Run I and Run II calibrations of JES. The absolute energy scale for jets in data is calibrated using $\gamma+$ jet data with photon $p_{T}>7 \mathrm{GeV}$ and $\left|\eta_{\gamma}\right|<1.0$, and jet $p_{T}>15 \mathrm{GeV}$ and $\left|\eta_{\text {jet }}\right|<0.4$, using the " $E_{T}$ projection fraction" method [82]. Simulated samples of $\gamma+$ jets and $Z+$ jets events are compared to data and used to correct the energy scale for jets in MC events. The JES is also corrected as a function of $\eta$ for forward jets relative to the central jets using $\gamma+$ jets and dijets data. Out-of-cone particle scattering corrections are determined with $\gamma+$ jets data and simulated events, without using overlays of underlying events, to avoid double counting of this effect. Templates of deposited energy are formed for particles belonging to and not belonging to a jet using 23 annular rings around the jet axis for $\mathcal{R}(y, \phi)=\sqrt{(\Delta y)^{2}+(\Delta \phi)^{2}} \leq 3.5$. All of these calibration steps are combined, and the total uncertainty on JES is calculated for light jets and heavy-flavor jets (independent of the type of jet). The resulting D0 uncertainty on $m_{t}$ for Run II lepton + jets events is $0.36 \%$ and $0.86 \%$ for dilepton data.

This uncertainty term also includes the relative jet energy correction as a function of jet $\eta$ for CDF. This is
measured using dijet data, along with PYTHIA and HERWIG simulations of $t \bar{t}$ events generated with shifted jet energies, and lead to the following uncertainties on Run II measurements of $m_{t}: 0.01 \%$ for lepton + jets, $0.02 \%$ for alljets, $0.34 \%$ for dileptons, and $0.03 \%$ for $\mathbb{E}_{T}+$ jets.

## c. Out-of-cone corrections

For all CDF measurements and for D0 Run I, this uncertainty component accounts for energy lost outside the jet reconstruction cone and uses the difference between two models of light-quark and gluon fragmentation and simulation of the underlying event. D0 changed the way it measures the out-of-cone uncertainty between Run I and Run II, and this uncertainty for D0 Run II measurements is therefore included in the light-jet response (2) term, described previously.

Energy is lost from the cone of jet reconstruction when a quark or gluon is radiated at a large angle relative to the original parton direction, or when the fragmentation shower is wider than the cone, or when low momentum particles are bent out of the cone by the axial magnetic field of the detector. Energy is gained in the cone from initialstate radiation and from remnants of spectator partons, called collectively at CDF the underlying event. The two models compared by CDF in Run II are PYTHIA with Tune A for the underlying event and HERWIG with the JIMMY modeling of the underlying event. For the narrow cone size of $\mathcal{R}=0.4$ used in measurements of $m_{t}$, more energy is lost from the cone than gained. The correction is measured using PYTHIA dijet events and data in the region $0.4<$ $\mathcal{R} \leq 1.3$. A small constant is added to compensate for energy outside the $\mathcal{R}>1.3$ region ("splash out"). The correction is largest for jets at low transverse momentum: $+18 \%$ for $p_{T}=20 \mathrm{GeV}$ jets and $<4 \%$ for jets with $p_{T}>$ 70 GeV . A detailed description of the method can be found in Ref. [81].

The uncertainty on these corrections is measured by comparing $\gamma+$ jets data to the two simulations. The largest difference between either of the models and data is taken as the uncertainty (the difference between the two models is very small). For jets with $p_{T}=20 \mathrm{GeV}$, the uncertainty on the jet energy scale is $6 \%$, and for jets above 70 GeV , it is $1.5 \%$. These translate into uncertainties on CDF Run II $m_{t}$ measurements of $0.16 \%$ for the lepton + jets measurement, $0.14 \%$ for alljets, $1.25 \%$ for dileptons, and $0.12 \%$ for $\boldsymbol{E}_{T}+$ jets.

## d. Energy offset

This uncertainty term is specific to D0 Run I measurements. It includes the uncertainty arising from uranium decays noise in the calorimeter and from the correction for multiple interaction to JES. These lead to uncertainties in $m_{t}$ of $0.72 \%$ for lepton + jets and $0.77 \%$ for dilepton events. In Run II, the integration time for the calorimeter electronics is short, after the upgrade to shorter
bunch-crossing time ( $3.5 \mu$ s to 396 ns ). This effect results in a negligible uncertainty on the offset for D0 Run II measurements of $m_{t}$.

## e. Model for b jets

(i) Semileptonic b decay

The uncertainty on the semileptonic branching fraction ( $10.69 \pm 0.22$ ) $\times 10^{-2}$ (PDG 2007 values) of $B$ hadrons affects the value of $m_{t}$. Both collaborations reweight $t \bar{t}$ events by $\pm$ the uncertainty on the central value ( $\pm 2.1 \%$ ) and take half the resulting mass difference as the uncertainty on $m_{t}: 0.09 \%$ for CDF and $0.03 \%$ for D0.
(ii) $b$-jet hadronization

For its nominal $m_{t}$ measurements, CDF uses the default PYTHIA model of $b$-jet fragmentation based on the Bowler model [87] ( $r_{q}=1.0, a=0.3, b=$ 0.58), where $r_{q}$ is the Bowler fragmentationfunction parameter and $a$ and $b$ are Lund fragmentation-function parameters. D0 uses a model with these parameters tuned to data from ALEPH, DELPHI, and OPAL [88] ( $r_{q}=0.897 \pm$ $0.013, a=1.03 \pm 0.08, b=1.31 \pm 0.08)$. To measure the uncertainty on these models, CDF compares its $m_{t}$ values to those measured with the LEP parameters used by D0 and to those from the SLD experiment at SLC [88] ( $r_{q}=0.980 \pm 0.010, a=$ $1.30 \pm 0.09, b=1.58 \pm 0.09)$. D0 compares the measured $m_{t}$ with the LEP parameters to the one from SLC. The resulting uncertainties on the $m_{t}$ extracted from the lepton + jets channel are $0.09 \%$ for CDF and $0.03 \%$ for D0.
For some analyses, the determination of the uncertainties in (i) and (ii) may be affected by statistical fluctuations of the MC samples.

## f. Response to $b / q / g$ jets

The calibrations of JES described in the first two paragraphs of the Appendix are derived on samples dominated by "light-quark" and gluon jets and applied to all jets. However, the calorimeter response to heavy-flavor jets differs in that these particles often decay semileptonically, and the $b$ jet will have some energy lost through the escaping neutrino. Bottom quark jets can also contain an electron that showers in a pattern different than for hadronic particles, or the jet may contain a muon that neither produces a shower nor gets absorbed in the calorimeter. Bottom jets also differ from light jets in the distribution of their shower and particle content. Since every $t \bar{t}$ event contains two $b$ jets, it is important to understand their energy calibration after the application of the previous overall corrections.

CDF measures an uncertainty from the difference between the $b$-jets response and light-flavor jets response in

Run II. CDF takes sets of MC $t \bar{t}$ events and cluster particles into jets classifying each such particle jet as a $b$ jet or a light jet [79]. Single-particle response for data and for MC events are applied to the formed particle jets to predict the energy measured in the calorimeter. A double ratio is calculated: $\left(p_{T}^{\text {data }} / p_{T}^{\mathrm{MC}}\right)_{b j \text { jets }} /\left(p_{T}^{\text {data }} / p_{T}^{\mathrm{MC}}\right)_{\text {lightjets }}$, which is found to be 1.010. The uncertainty on $m_{t}$ is measured by generating new $t \bar{t}$ samples with the $b$-jet scale shifted by this $1 \%$ difference, which results in $0.1 \%$ uncertainty in $m_{t}$ for the lepton + jets measurement.

For Run II measurements, D0 corrects the transversemomentum distributions of jets differently in four regions of detector pseudorapidity to make the MC response match that in data (after the main JES calibration) as a function of jet flavor: $b$ jets, light-quark jets $(u, d, s, c)$, and gluon jets [25]. The correction functions are shifted up and down by their uncertainties, and the extracted shifts in $m_{t}$ are used to define the resulting uncertainty on $m_{t}$ of $0.15 \%$ for the lepton + jets measurement and $0.23 \%$ for the dilepton measurement.

## g. In situ light-jet calibration

In $t \bar{t}$ events where one or both $W$ bosons decay to $q \bar{q}^{\prime}$, the world average value of $M_{W}$ [7] is used to constrain the jet energy scale for light-quark jets in situ [89,90]. CDF and D0 perform simultaneous measurements of $m_{t}$ and $M_{W}$, and fit a linear function to the JES for light-quark jets that is applied to all the jets to improve precision of $m_{t}$.

CDF measures the in situ rescaling factor independently in their lepton + jets, alljets, and $\mathscr{E}_{T}+$ jets analyses, and so these terms are uncorrelated. D0 applies the rescaling derived from their lepton + jets measurement to dilepton events, and these uncertainties are therefore correlated.

The uncertainty from the in situ calibration is determined through a two-dimensional minimization of a likelihood that is a function of top-quark mass and JES. The extracted JES is then shifted relatively to its measured central value, and a one-dimensional fit is performed to the top-quark mass. The difference in quadrature between the uncertainty on $m_{t}$ from the first and second fits is taken as the uncertainty on $m_{t}$ from the in situ calibration, giving $0.34 \%$ for CDF's lepton + jets measurement, $0.27 \%$ for D0's lepton + jets result, $0.55 \%$ for CDF's alljets, $0.89 \%$ for their $\not_{T}+$ jets measurement, and $0.32 \%$ for D0's dilepton measurement.

## 2. Jet modeling

Applying jet algorithms to MC events, CDF finds that the resulting efficiencies and resolutions closely match those in data. The small differences propagated to $m_{t}$ lead to a negligible uncertainty of 0.005 GeV , which is then ignored. D0 proceeds as follows.
(i) Jet energy resolution

The modeling of the jet energy resolution is corrected in D 0 to match that in data. The value of $m_{t}$
is then remeasured using MC samples with jet energy resolution corrections shifted up and down by their uncertainties, resulting in an uncertainty on $m_{t}$ of $0.18 \%$.
(ii) Jet identification

D0 applies correction functions to MC events to match the jet identification efficiency in data. The uncertainty on $m_{t}$ is estimated by reducing the corrections by $1 \sigma$ and remeasuring the mass in the adjusted MC samples. The efficiency can only be shifted down and not up because jets can be removed from the simulated events but not added. The uncertainty on $m_{t}$ is therefore set to $\pm$ the single-sided shift and is $0.15 \%$.

## 3. Lepton modeling

(i) Momentum scale for leptons

In Run II, the electron and muon channels for CDF and the muon channels for D0 are used to calibrate the lepton momentum scales by comparing the invariant dilepton mass $m_{\ell 1 \ell 2}=$ $\sqrt{\left(E_{\ell 1}+E_{\ell 2}\right)^{2}-\left(p_{\ell 1}+p_{\ell 2}\right)^{2}}$ for $J / \psi \rightarrow \ell \ell$ and $Z \rightarrow \ell \ell$ decays in MC events with data. The positions of the resonances observed in the $m_{\ell \ell}$ distributions reflect the absolute momentum scales for the leptons. CDF and D0 perform a linear fit as a function of the mean value of transverse momentum to the two mass points $(3.0969 \mathrm{GeV}$ and 91.1876 GeV [7]), assuming that any mismatch is attributable to an uncertainty in the calibration of the magnetic field. D0 also fits a quadratic relation, assuming that the difference in scale arises from misalignment of the detector. The value of $m_{t}$ is measured using MC $t \bar{t}$ ensembles without rescaling lepton $p_{T}$ and with lepton $p_{T}$ values rescaled using these fitted relations. Half of the largest difference in extracting $m_{t}$ is taken as its systematic uncertainty resulting from the lepton $p_{T}$ scale. For muon measurements from D0, the largest shift is observed for the linear parametrization. In Run I, this source of uncertainty was neglected as it was negligible relative to other sources of uncertainty.
In D0 Run II measurement of the $W$-boson mass in the electron decay channel, it was found that 0.26 radiation length of material was left out in the GEANT modeling of the solenoid [91]. The Z-boson mass peak was used to calculate a quadratic correction to the electron energy by comparing MC events generated with additional solenoid material to data. This correction was then propagated to the $m_{t}$ measurement.
The uncertainties on the $m_{t}$ measurements from the lepton momentum scale are $0.08 \%$ for CDF lepton + jets measurements and $0.10 \%$ for D0, and $0.16 \%$ for

CDF dilepton measurements and $0.28 \%$ for D0 dilepton results.
(ii) Lepton momentum resolution

The muon momenta in simulated events at D0 are smeared to match the resolution in data. The uncertainty on this correction corresponds to an uncertainty on $m_{t}$ of $0.17 \%$.

## 4. Signal modeling

(i) Parton distribution functions

In Run I, the uncertainties from choice of PDF are determined by measuring the change in $m_{t}$ using the MRSA' set [92] instead of $\mathrm{MRSD}_{0}^{\prime}$ [62] or CTEQ4M [63], and are found to be negligible.
In Run II, the uncertainty is measured by CDF by comparing CTEQ5L results with MRST98L [93], by changing the value of $\alpha_{s}$ in the MRST98L model, and by varying the 20 eigenvectors in CTEQ6M [69]. The total uncertainty is obtained by combining these sources in quadrature. D0 measures this uncertainty by reweighting the PYTHIA model to match possible excursions in the parameters represented by the 20 CTEQ6M uncertainties and taking the quadratic sum of the differences. The resulting uncertainty on $m_{t}$ is $0.08 \%$ for CDF and $0.14 \%$ for D0.
(ii) Fractional contributions from quark annihilation and gluon fusion
In Run I, this source of uncertainty in $t \bar{t}$ production is not considered. In Run II, CDF estimates the effect on $m_{t}$ by reweighting the gluon fusion fraction in the PYTHIA model from 5\% to $20 \%$ [94]. The uncertainty on $m_{t}$ is found to be $0.02 \%$. This uncertainty is included by D 0 in the systematic component (iv) below, where the effects of higher-order QCD corrections are discussed.
(iii) Initial- and final-state radiation

Initial- and final-state radiation refers to additional gluons radiated from the incoming or outgoing partons or from the top quarks. Jets initiated by these gluons affect the measured value of $m_{t}$ because they can be misidentified as jets from the final-state partons in top-quark decay. Extensive checks were performed in Run I measurements to assess the effects of initial and final-state radiation by varying parameters in HERWIG.
In Run II, uncertainties from initial- and final-state radiation are assessed by both collaborations using a CDF measurement [95] in Drell-Yan dilepton events that have the same $q \bar{q}$ initial state as most $t \bar{t}$ events, but no final-state radiation. The mean $p_{T}$ of the produced dilepton pairs is measured as a function of the dilepton invariant mass, and the values of $\Lambda_{\mathrm{QCD}}$ and the $Q^{2}$ scale in the MC that matches best the data when extrapolated to the $t \bar{t}$
mass region are found. CDF's best-fit values are $\Lambda_{\mathrm{QCD}}(5$ flavors $)=292 \mathrm{MeV}$ with $0.5 \times Q^{2}$ and $\Lambda_{\mathrm{QCD}}(5$ flavors $)=73 \mathrm{MeV}$ with $2.0 \times Q^{2}$ for $\pm \sigma$ excursions around the mean dilepton $p_{T}$ values. Since the initial- and final-state shower algorithms are controlled by the same QCD evolution equation [64], the same variations of $\Lambda_{\mathrm{QCD}}$ and $Q^{2}$ scale are used to estimate the effect of final-state radiation. The resulting uncertainty for modeling of the initial- and final-state radiation is $0.09 \%$ for CDF and $0.15 \%$ for D0. The correction algorithm does not distinguish between "soft" (out-of-cone) and "hard" (separate jet) radiation, and there is therefore some overlap between the uncertainty on $m_{t}$ for the out-of-cone jet energy correction and for gluon radiation. There is also some overlap between the uncertainty for initial- and final-state radiation and the uncertainty on higher-order QCD corrections for high- $p_{T}$ radiation.
(iv) Higher-order QCD corrections

Higher-order QCD corrections to $t \bar{t}$ production are not used for Run I measurements, as only LO generators were available at that time. D0 measures higher-order jet-modeling uncertainties in Run II by comparing $m_{t}$ extracted with ALPGEN and HERWIG for evolution and fragmentation to the value obtained from events generated with MC@NLO [96], which uses HERWIG parton showering with a NLO model for the hard-scattering process. This component of uncertainty also includes (for D0) the uncertainty from the fraction of quark-antiquark to gluon-gluon contributions to the initial state. CDF also studies differences in $m_{t}$ using MC@NLO and finds that the uncertainties in distributions in the number of jets and the transverse momentum of the $t \bar{t}$ system overlap with the uncertainty from initialand final-state radiation. Future measurements of $m_{t}$ are expected to treat these uncertainties separately. The uncertainty on $m_{t}$ from higher-order contributions and initial-state $q \bar{q} / g g$ ratio is $0.14 \%$ for D 0 .
(v) Jet hadronization and underlying event

In Run I, CDF measured the uncertainty in the model for parton showering and hadronization and the underlying event by comparing the value of $m_{t}$ based on HERWIG to that on PYTHIA [97], and D0 compared HERWIG results to those from ISAJET [98]. In Run II, CDF estimates these uncertainties by comparing $m_{t}$ obtained using PYTHIA with Tune A of the underlying-event model to results from HERWIG with a tuned implementation of the underlying-event generator JIMMY. D0 estimates these uncertainties by comparing identical sets of hard-scatter events from ALPGEN coupled to HERWIG instead of to PYTHIA. For the uncertainty on $m_{t}$, this corresponds to $0.40 \%$ for CDF and $0.33 \%$ for D0.
(vi) Color reconnection

There are up to six final-state quarks in $t \bar{t}$ events, in addition to initial- and final-state radiation. When hadronization and fragmentation occur, there are color interactions among these partons and the color remnants of the proton and antiproton. This process is referred to as "color reconnection." It changes the directions and distributions of finalstate jets $[99,100]$, which affects the reconstructed value of $m_{t}$ [72].
The uncertainty on color reconnection was not evaluated for Run I because appropriate MC tools were not available at that time. Both collaborations estimate this effect in Run II by comparing the value of $m_{t}$ extracted from ensembles of $t \bar{t}$ events generated by PYTHIA using the difference between two parton shower simulations: (i) angular ordering for jet showers (same as used in the nominal $m_{t}$ measurements) using the A-PRO underlying-event model (Tune A but updated using the "Professor" tuning tool [101]), and (ii) ACR-PRO. ACR-PRO is identical to A-PRO except that it includes color reconnection in the model. The resulting uncertainties on $m_{t}$ are $0.32 \%$ for CDF and $0.16 \%$ for D0.

## 5. Multiple interactions model

Monte Carlo simulated events are overlaid with Poissondistributed low- $p_{T}$ events (PYTHIA MC events for CDF, "zero-bias" data for D0) to simulate the presence of simultaneous additional $p \bar{p}$ interactions. The mean number of overlaid events is chosen at the time of event generation, but in data, the number of such interactions changes with instantaneous luminosity of the Tevatron.

CDF measures $m_{t}$ as a function of the number of multiple interactions, finding a change of $0.07 \pm 0.10 \mathrm{GeV}$ per primary vertex. For CDF's measurements, the average number of primary vertices in data is 2.20 and for simulated events it is 1.85 , leading to an uncertainty on $m_{t}$ of $0.02 \%$. CDF adds to this in quadrature a term to cover the difference in jet energy response as a function of the number of multiple interactions of $0.06 \%$, giving a total uncertainty of $0.06 \%$.

D0 reweights the simulated events to make the instantaneous luminosity distribution match that in data. The resulting uncertainty on $m_{t}$ is $0.03 \%$.

## 6. Background from theory

(i) Higher-order correction for heavy flavor

D0 corrects the leading-log $W+$ jets cross section from ALPGEN to NLO precision before normalizing this background to data. This increases the fraction of $W b \bar{b}$ and $W c \bar{c}$ events in $W+$ jets by a factor of $1.47 \pm 0.50$. CDF normalizes the $W+$ heavy-flavor jets background to data independent of the other
components in $W+$ jets, which has a similar effect. The resulting uncertainties on $m_{t}$ are $0.11 \%$ for CDF and $0.04 \%$ for D0.
(ii) Factorization scale for $W+$ jets

The transverse momenta of the jets in $W+$ jets events are sensitive to the factorization and renormalization scales chosen for the calculations. These two scales are set equal to each other, with $Q^{2}=$ $M_{W}^{2}+\sum p_{T}^{2}$. To determine the uncertainty on $m_{t}$, the scale is changed from $(Q / 2)^{2}$ to $(2 \times Q)^{2}$, the MC events regenerated, and the mass remeasured. Changing the scale does not affect the fraction of $W+$ jets in the model but does affect the transversemomentum distributions of the jets. The uncertainties on $m_{t}$ are $0.02 \%$ for CDF and $0.09 \%$ for D0.
(iii) Normalization to predicted cross sections

CDF divides the background into seven independent parts: $W+$ heavy-flavor jets, $W+$ light-flavor jets, single-top $t q b$ and $t b, Z+$ jets, dibosons ( $W W, W Z$, and $Z Z$ ), and multijet contributions. This uncertainty term covers the normalization of the components modeled with MC simulated events (not multijets). The small backgrounds from single-top, $Z+$ jets, and diboson production are normalized to NLO calculations. The uncertainties on the cross sections are $10 \%$ for $t q b, 12 \%$ for $t b, 14 \%$ for $Z+$ jets, and $10 \%$ for dibosons. The $W+$ jets background is normalized to data before implementation of $b$ tagging, using a fit to the distribution for $\mathbb{E}_{T}$ in the event. The uncertainty on this normalization cannot easily be disentangled from the other sources, and so it is kept in this category. The combined uncertainty on $m_{t}$ from these normalizations is $0.09 \%$.
D0 also normalizes single-top, $Z+$ jets, and diboson contributions, in all analysis channels, and Drell-Yan in the dilepton channel, to next-to-leading-order cross sections, using values from the MCFM event generator [102]. The uncertainties on the cross sections take into account the uncertainty on th ePDF and on the choice of factorization and renormalization scales, which together propagate through to $m_{t}$ an uncertainty of $0.04 \%$.
(iv) Background differential distributions

For CDF, different methods were used to estimate the uncertainty attributable to the overall background shape. In the recent lepton + jets analysis, this uncertainty was assessed by dividing randomly the background events into subsets, building the background likelihood from one of the subsets, and reconstructing the $m_{t}$ from the second subset. In the next step, the difference in $m_{t}$ obtained from the second subset and the nominal $m_{t}$ value is evaluated. This contributes an uncertainty of $0.03 \%$. CDF also estimates an uncertainty from
the limited MC statistics used to measure the background. This yields an additional $0.03 \%$ uncertainty on $m_{t}$.
For D0, the $p_{T}$ and $\eta$ distributions of jets in $W+$ jets events do not fully reproduce those in data. An uncertainty to cover these deviations is based on the difference between the model for background and data in the $\eta$ distribution of the third jet in three-jet events. The resultant uncertainty on $m_{t}$ is $0.09 \%$.

## 7. Background based on data

(i) Normalization to data

In the lepton + jets, alljets, $\mathscr{E}_{T}+$ jets, and decaylength channels, backgrounds from multijet events are normalized to data. In the lepton + jets analyses at D 0 , the $W+$ jets background model is combined with the contribution from multijet events, and both are normalized simultaneously to data, so that their uncertainties in normalization are anticorrelated. In dilepton analyses at CDF, the Drell-Yan background is normalized to data. For the lepton + jets analyses, CDF uncertainty on $m_{t}$ from the normalization of the multijet backgrounds to data is $0.03 \%$, and D0's uncertainty for the normalization of $W+$ jets and multijets to data is $0.13 \%$.
(ii) Trigger modeling

CDF expects a negligible uncertainty on $m_{t}$ from the modeling of the trigger. D0 simulates the trigger turn-on efficiencies for MC events by applying weights as a function of the transverse momentum of each object in the trigger. The uncertainty is measured by setting all the trigger efficiencies to unity and recalculating the value of $m_{t}$, which shifts $m_{t}$ by $0.03 \%$.
(iii) $b$-tagging modeling

CDF applies the $b$-tagging algorithm directly to MC events and finds that any difference between the $b$-tagging behavior in MC and data has a negligible impact on the measurement of $m_{t}$. D0 applies the $b$-tagging algorithm directly to

MC events for recent Run II measurements. Previously $b$-tagging was simulated with tag probability, and in Run I, as D0 did not have a silicon tracker, nonisolated muons were used to identify $b$ jets. The tagging efficiency for simulated events is made to match that in data by randomly dropping $b$ tags for $b$ and $c$ jets, while assigning a per jet weight for tagging light-flavor jets as $b$ jets. The uncertainties for these corrections are determined by shifting the efficiencies for tagging $b$ and $c$ jets by $5 \%$ and by $20 \%$ for light jets, which introduces an uncertainty on $m_{t}$ of $0.06 \%$.
(iv) Signal fraction for calibration

D0 measures the impact of the uncertainty in the ratio of signal to background events, which affects the calibration of $m_{t}$. Changing the signal fraction within uncertainty results in an uncertainty on $m_{t}$ of $0.06 \%$.
(v) Impact of multijet background on the calibration Multijet background events are not used in D0 samples that determine the calibration of $m_{t}$ for the lepton + jets measurement since the background probability for such events is much larger than the signal probability. The assumption that this has a small effect on $m_{t}$ is tested by selecting a multijetenriched sample of events from data (by inverting the lepton isolation criteria) and adding these events when deriving the calibration. Applying this alternative calibration to data indicates that $m_{t}$ can shift by an uncertainty of $0.08 \%$.

## 8. Calibration method

Monte Carlo $t \bar{t}$ ensembles are generated at different values of input $m_{t} \quad\left(m_{t}=165,170,172.5,175\right.$, 180 GeV ), and calibrations relate the input masses for $t \bar{t}$ events to the extracted masses using a straight line. For some of the $m_{t}$ measurements, there is an additional in situ calibration of the JES to the light quarks in $W$-boson decay, which is then applied to all jets. The uncertainties from both calibrations are propagated to the uncertainty on $m_{t}$, which for CDF are $0.04 \%$ and $0.05 \%$, respectively, giving a total of $0.06 \%$. For D0, the uncertainty on $m_{t}$ is $0.13 \%$.

We describe a model-independent search for physics beyond the standard model in lepton final states. We examine 117 final states using $1.1 \mathrm{fb}^{-1}$ of $p \bar{p}$ collisions data at $\sqrt{s}=1.96 \mathrm{TeV}$ collected with the D 0 detector. We conclude that all observed discrepancies between data and model can be attributed to uncertainties in the standard model background modeling, and hence we do not see any evidence for physics beyond the standard model.

## I. INTRODUCTION

The standard model (SM) has been remarkably successful in accommodating all the interactions between the fundamental particles [1]. Despite this success, there are strong motivations to expect new phenomena at energies at the order of the electroweak scale. For example, the Higgs boson [2] receives quantum corrections to its mass through loop diagrams. The scalar nature of the Higgs boson leads to a quadratic divergence, with an upper limit of the integral set by the highest scale, i.e., the Planck mass $\left(10^{19} \mathrm{GeV}\right)$. To maintain the Higgs mass close to the

[^78]electroweak scale, it is necessary to fine-tune a parameter in the theory to within $M_{W} / M_{\text {Planck }} \approx 10^{-16}$ [3].

There are few logical options for overcoming this problem. If the Higgs boson does not exist, then there must be a new contribution to the physics at the electroweak scale. If the Higgs boson does exist, then the theory must be either fine-tuned or a generalized Higgs scheme, beyond the SM, is present at the electroweak scale.

Assuming that beyond standard model physics exists, we do not know how it appears, rendering its search difficult. While there are many theories that predict observable differences with the SM, these models usually depend on additional unspecified parameters which broaden the possible range of results.

Motivated by uncertainty and expectations of physics beyond the SM, we examine data from many channels in $p \bar{p}$ collisions at $\sqrt{s}=1.96 \mathrm{TeV}$ at the Tevatron Collider at Fermilab, collected by the D0 experiment, for deviations from the SM. After this, we focus on events with objects with high transverse momentum $\left(p_{T}\right)$ in a quasi-modelindependent search for new phenomena effects. Similar approaches have been applied to data from the D0

Collaboration [4-6], the H1 Collaboration at the HERA ep collider at DESY [7], and the CDF Collaboration at the Tevatron [8,9].

Our technique trades the sensitivity of specific searches for breadth of coverage: we do not design selections focused on a particular model and neglect systematic uncertainties. This way, we can incorporate many channels without developing a detailed modeling for each individual channel. This approach limits sensitivity for physics beyond the SM in individual final states, but it helps identify global differences relative to the SM expectations. If any particular final state or distribution found discrepant with the SM remains significantly discrepant after systematic uncertainties are considered, then it warrants claim for the presence of physics beyond the SM. The benefit of this approach is that we can look in a coordinated way at many channels, applying expectations from the SM and a model of the detector in a relatively straightforward manner, to search for discrepancies between data and the SM.

The data for this search consists of events containing high $p_{T}$ objects. The SM background estimates are based on Monte Carlo (MC) predictions supplemented with datadriven estimates of backgrounds where a jet fakes a lepton (multijet backgrounds). We apply corrections to the MC simulation, determined either from previous D0 studies based on well-understood regions of phase space or from higher-order MC simulations. These corrections are discussed further in Sec. IV.

We divide the data and the selected MC simulated events into seven inclusive subsets based on the number and types of leptons identified in each event. Unlike the search conducted by the CDF Collaboration [8,9], only events with at least one electron or muon are considered. To account for any incorrect normalizations in the absence of higher-order corrections to the cross section calculations, and for experimental systematic uncertainties, we determine scale factors for the MC contributions by fitting kinematic distributions in each of the seven inclusive subsets, as discussed in Sec. V.

The seven nonoverlapping inclusive subsets are merged to provide input for the analyses employing algorithms called VISTA and SLEUTH [8], as discussed in Sec. VII. In brief, VISTA searches for deviations in bulk distributions, while SLEUTH looks for excesses of data in the high- $p_{T}$ tails.

## II. D0 DETECTOR

The data correspond to $1.07 \pm 0.07 \mathrm{fb}^{-1}$ of integrated luminosity from $p \bar{p}$ collisions at the Tevatron Collider at Fermilab, collected with the D0 detector at $\sqrt{s}=$ 1.96 TeV during 2002-2006.

The D0 detector is described in detail elsewhere [10]. The central tracking, calorimetry, and muon systems are the components most important to this analysis. The central tracking system consists of a silicon microstrip tracker (SMT) and a central fiber tracker, both located within a 2 T
superconducting solenoidal magnet, and provides charged particle tracking for pseudorapidities $|\eta|<3$, where $\eta=$ $-\ln [\tan (\theta / 2)]$, and $\theta$ is the polar angle relative to the center of the detector with respect to the proton beam direction.
