The three liquid-argon/uranium calorimeters are housed in separate cryostats. Outside of the tracking system, a central section covers up to $|\eta|=1.1$. Two end calorimeters extend coverage to $|\eta|=4.2$. The calorimeter is highly segmented with four electromagnetic (EM) and four to five hadronic longitudinal layers; transverse to the particle direction, typical segmentation is $\Delta \eta=\Delta \phi=$ 0.1 , where $\phi$ is the azimuthal angle.

Beyond the calorimeter, a muon system consists of a layer of tracking detectors and scintillation trigger counters in front of 1.8 T iron toroids, followed by two similar layers after the toroids, all at pseudorapidities $|\eta|<2.0$ [11].

A three-level trigger system selects events, recording data at about 100 Hz . Our sample was collected using triggers that select events with at least one electron or one muon. The same trigger requirements are applied in the selection of the data samples used for the estimation of the multijet backgrounds.

## III. OBJECT ID AND EVENT SELECTION

In this section, we describe the identification criteria used to select energetic objects isolated from other event activity, viz., electrons ( $e^{ \pm}$), muons ( $\mu^{ \pm}$), tau leptons ( $\tau^{ \pm}$), missing transverse energy $\left(\mathscr{E}_{T}\right)$, jets, and $b$-quark jets. In addition, we discuss the criteria used to select samples of nonisolated electrons and muons. These objects are used to estimate the contribution of instrumental backgrounds to our final states. Objects that pass very loose isolation criteria but fail the tighter isolation criteria used for our signal events are primarily from jets. Events with these objects passing very loose isolation criteria are kinematically similar to events where the jet successfully mimics an isolated lepton. The number of these events in each final state is determined as part of the inclusive normalization fits, detailed in Sec. VI.

## A. Vertices

Only $p \bar{p}$ interaction vertices reconstructed from at least three tracks are allowed in this analysis. Based on the $p_{T}$ of the tracks associated with that vertex, we define the primary $p \bar{p}$ interaction vertex (PV), as the one with smallest probability of originating from a minimum-bias interaction [12]. The $z$ coordinate of the $\mathrm{PV}\left(z_{\mathrm{PV}}\right)$ is required to be $\left|z_{\mathrm{PV}}\right|<$ 60 cm (where the positive $z$ axis is oriented along the proton beam direction, with origin at the center of the detector).

## B. Electrons

Electrons are characterized by an isolated shower in the calorimeter and an isolated track in the central tracker.

Starting with a seed cell, a calorimeter cluster is formed using cells within a cone of radius $\Delta \mathcal{R}<0.4$ where $\Delta \mathcal{R}=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}$. Such clusters are required to pass the calorimeter isolation criterion $\left(E_{\text {tot }}(\Delta \mathcal{R}<0.4)-\right.$ $\left.E_{\mathrm{EM}}(\Delta \mathcal{R}<0.2)\right) / E_{\mathrm{EM}}(\Delta \mathcal{R}<0.2)<0.2$, where $E_{\mathrm{tot}}$ is the total energy of the shower, summing the EM and hadronic calorimeter cells, and $E_{\text {Ем }}$ is the energy in the EM calorimeter only. Every accepted cluster must have $90 \%$ of $E_{\text {tot }}$ within the EM calorimeter, pass a $\chi^{2}$-based selection on the spatial distribution of the shower, and be matched with a track extrapolated from the central tracker. An electron likelihood ( $L_{e}$ ), based on seven tracking and calorimetric parameters, is used to enhance signal purity of the candidate electrons. Different selection criteria on $L_{e}$ are used for different final states, as discussed in Sec. V.

In this analysis, we use only electrons that are found in the central calorimeter, with $|\eta|<1.1$ and $p_{T}>15 \mathrm{GeV}$. Typical electron detection efficiencies are $70 \%$ to $80 \%$.

To estimate the contribution from nonisolated electrons (e.g., from multijet background), we use the same selection as for signal, but with a reversed $L_{e}$ likelihood criterion.

## C. Muons

Muons are identified in the muon system, and then matched to tracks. They are required to have $|\eta|<1.5$ and $p_{T}>15 \mathrm{GeV}$. The track requirements include a selection on DCA $<0.02$ ( 0.2 ) cm for tracks with (without) hits in the SMT, where DCA is the distance of closest approach of the track to the PV in the transverse plane.

We require muons to be isolated, meaning that the sum of the transverse energies in calorimeter cells in an annular region $(0.1<\Delta \mathcal{R}<0.4)$ around the muon track, and the sum of the tracks $p_{T}$ in a cone of $\Delta \mathcal{R}<0.5$ around the muon track must both be less than 2.5 GeV .

To estimate the multijet background in the single muon sample, we use control samples where the isolation variables are required to be between 2.5 GeV and 8 GeV . All other criteria are the same as in the signal data sample.

Because the muon $p_{T}$ is estimated by the $p_{T}$ of the matching track in the central tracker, the momentum resolution decreases with increasing $p_{T}$. To restrict the analysis to muons with well measured momenta, we require the significance of its $p_{T}$ measurement to be $\left(1 / p_{T}\right) / \sigma\left(1 / p_{T}\right)>3$, where $\sigma\left(1 / p_{T}\right)$ is the uncertainty on the measurement of the track curvature (inverse of the muon track's $p_{T}$ ). This effectively limits muons to $p_{T}<200 \mathrm{GeV}$.

## D. Tau leptons

Tau leptons can decay to $e \nu_{e} \nu_{\tau}, \mu \nu_{\mu} \nu_{\tau}$, or hadrons $h \nu_{\tau}$ $\left(\tau_{h}\right)$. It is difficult to determine whether a light lepton in an event originated from a $\tau$, but the signature from $\tau_{h} \rightarrow h \nu_{\tau}$ differs significantly from that of a jet. The decays $\tau \rightarrow \pi \nu_{\tau}$ are referred to as Type-1. Decays corresponding to $\tau^{ \pm} \rightarrow$ $\pi^{ \pm} n \pi^{0} \nu_{\tau}$ are referred to as Type-2 ( $n$ is an integer $\geq 1$ ),
and decays to multiple charged pions are referred to as Type-3 decays. Type-3 decays differ from Type-1 ( $\tau_{1}$ ) and Type-2 $\left(\tau_{2}\right)$ by being matched to multiple tracks, and are not used in this analysis. Type-1 and Type-2 decays are required to have $|\eta|<1.1$ and a track with at least one SMT hit, as well as $p_{T}>10 \mathrm{GeV}$ for Type-1, and $p_{T}>$ 5 GeV for Type-2 tau leptons. There are also requirements concerning overlaps of objects: $\Delta \mathcal{R}(\mu, \tau)>0.4$ and $\Delta \mathcal{R}(e, \tau)>0.4$, where $\tau, \mu$ and $e$ are as defined above, except that muons that pass the overlap criterion do not have to pass the additional isolation requirement. To distinguish $\tau_{h}$ decays from jets, we use a neural network discriminant [13], $\mathrm{NN}_{h}$, and to distinguish Type-2 $\tau_{h}$ from electrons, we use an additional neural network, $\mathrm{NN}_{e}$. We require $\mathrm{NN}_{h}>0.9$ for $\tau_{1}$ and $\tau_{2}$, and $\mathrm{NN}_{e}>0.2$ for $\tau_{2}$.

To model the multijet contribution to final states with $\tau_{h}$ decays, we select events with $\tau_{h}$ candidates as above, but with $0.3<\mathrm{NN}_{h}<0.8$.

## E. Jets

We reconstruct jets within $|\eta|<2.5$, using an iterative midpoint cone algorithm [14] with cone radius of 0.5 and a minimum $p_{T}$ requirement of 20 GeV after applying a jet energy scale (JES) correction as discussed in Sec. IV B 3. Jets separated from a $\tau_{h}$ or an electron by $\Delta \mathcal{R}<0.5$ are removed from consideration.

## F. $b$-jets

Bottom and charm quarks can travel measurable distances from the PV before decaying, so that their decay products originate from an identifiable secondary vertex. This provides a way of tagging jets coming from a $b(c)$-quark decay by examining the associated tracks [15]. Before applying any $b$-tagging criteria, the jets are required to pass both calorimeter criteria outlined in Sec. IIIE and the taggability criteria. A jet is taggable if it is matched to a track jet, which is a jet formed from tracks, reconstructed using a simple cone-clustering algorithm of $\Delta \mathcal{R}<0.5$. At least two tracks are required, with at least one having $p_{T}>1 \mathrm{GeV}$ and another with $p_{T}>0.5 \mathrm{GeV}$. Every track in the jet is required to have at least one hit in the SMT detector, a DCA $<0.2 \mathrm{~cm}$, and a distance of closest approach along the $z$ axis of $<0.4 \mathrm{~cm}$.

All taggable jets are subjected to a neural network $b$ tagging algorithm [15] whose input variables include the DCA of each track in a jet and information on secondary vertices in the jet. We define $b$-jet candidates by requiring that the neural network output be greater than 0.775 . This algorithm selects about $60 \%$ of $b$ jets with $p_{T}=50 \mathrm{GeV}$, and only $1 \%$ of light flavor ( $u, d, s$ quarks or gluon) jets.

## G. Missing transverse energy

Neutrinos or other weakly-interacting neutral particles do not leave energy deposits in the detector. Their presence
is inferred from the measurement of significant $\mathbb{E}_{T}$ in the event. The missing transverse energy is determined from energies deposited in all calorimeter cells. The $\mathscr{E}_{T}$ is corrected for JES, measured muon $p_{T}$, electron and $\tau_{h}$ energy scales. The JES-corrected $\mathbb{E}_{T}$ vector is obtained by adding the difference between the vector sums of uncorrected and JES-corrected jet momenta to the uncorrected $\mathscr{E}_{T}$ vector. The muon correction reflects the fact that muons deposit little energy in the calorimeter, and adjusts the $\mathbb{E}_{T}$ for the $p_{T}$ of the muon. Finally, electron and $\tau_{h}$ energy corrections are applied to the appropriate calorimeter cells in the $\mathscr{E}_{T}$ calculation.

## IV. MODELING SM PREDICTIONS

## A. SM event generation

We generally estimate SM processes with MC-generated events. A model-independent search incorporates many different processes to properly model the data. We use two generators for this purpose, ALPGEN [16] for generation of all processes, except for diboson production which is generated with PYTHIA [17]. PYTHIA is also used for hadronization and showering.

ALPGEN uses exact matrix elements at leading orders for QCD and electroweak interactions. The benefit of using ALPGEN comes from its ability to calculate exact leadingorder terms for processes that include high jet multiplicities. ALPGEN produces parton-level events with information on color and flavor, and can be matched to PYTHIA for parton evolution and hadronization.

Matching of a parton from ALPGEN to PYTHIA showering has the fundamental difficulty of separation of the hard interaction from initial-state radiation and final-state radiation. To address this problem we use the MLM matching scheme [18]. In this scheme each final-state parton from the matrix element is matched in $\Delta \mathcal{R}$ to an evolved jet. We further reject events which contain an additional jet not matched to a final-state parton, except in the sample with the highest number of final-state partons.

The following processes are considered, where $j$ is a light jet ( $g, u, d$, or $s$ ), $\ell$ is a lepton, $N$ is an integer $\geq 0$ and $l p$ represents a light parton:
(1) $W+N j$,
(2) $Z / \gamma^{*}+N j$,
(3) $W+c \bar{c}+N j$,
(4) $W+b \bar{b}+N j$,
(5) $Z / \gamma^{*}+c \bar{c}+N j$,
(6) $Z / \gamma^{*}+b \bar{b}+N j$,
(7) $t \bar{t} \rightarrow(2 \ell+2 \nu+2 b)+N j$,
(8) $t \bar{t} \rightarrow(\ell \nu+2 b+2 l p)+N j$,
(9) $W W$,
(10) $W Z$,
(11) $Z Z$.

Since this analysis does not include events with identified photons, we do not consider the contributions to the
background from the $W \gamma$ and $Z \gamma$ processes. The processes involving heavy flavor (HF) quarks ( $c$ and $b$ ) are treated separately from light quark processes because they are often associated with particularly interesting final states, and we generate large number of MC events for these final states. Some of these processes are included in the lightparton simulations, so we remove the events with heavy flavor quarks from the light-parton samples so as to avoid double-counting.

For some objects, other programs provide more accurate simulations of their properties and decays. Specifically, TAUOLA [19] is used for $\tau$ decays, and EVTGEN [20] is used for the decay of $b$ hadrons. Where needed, correction factors for the cross sections, corresponding to contributions from higher-order diagrams, are determined through the normalization procedure based on the inclusive final states as discussed in Sec. V.

We assume a mass of 172.5 GeV for the top quark, consistent with recent measurements [21].

## B. Detector simulation

The events produced from the above combination of generators are processed through the D0 detector simulation and combined with random beam crossing events taken from data (Sec. IV B 1). The detector simulation is based on GEANT 3.2.1[22], to which two types of correction factors are applied. The first type of correction is event reweighting, where an overall correction is applied to the MC event, rather than to the measured kinematic properties of reconstructed objects. For example, we apply weights to account for the difference in reconstruction efficiencies between data and MC. Another type of correction modifies the objects in a MC event to account for the fact that the simulation has better resolution and a different energy scale than the detector. These corrections generally depend on properties of the objects in an event. The specific corrections used in this analysis are described below.

## 1. Instantaneous luminosity reweighting

As the instantaneous luminosity profiles of the random beam crossing events and the data are not identical, the MC is reweighted to match the instantaneous luminosity distribution in data. During the course of the data-taking period corresponding to the data used for this search the number of average collisions per beam crossing increased from two to six.

## 2. $Z_{\mathrm{PV}}$ Reweighting

Our simulated events have a narrower $z_{\mathrm{PV}}$ distribution than is observed in data. We therefore apply a weight to each event, based on the $z_{\mathrm{PV}}$ of the event, to increase the relative weight of events farther from the center of our detector to match the observed distribution.

## 3. JES

We apply JES corrections to jets in both data and MC [23]. The purpose of the JES corrections is to correct the measured jet energy to that of the particles in the jet. Jet energies initially determined from the calorimeter cell energies do not exactly correspond to the energies of final-state particles that traverse the calorimeter. As a result, a detailed calibration is applied separately in data and MC. In general, the energy of all final-state particles inside the jet cone, $E_{j}^{\mathrm{ptcl}}$, can be related to the energy measured inside the jet cone, $E_{j}$, by $E_{j}^{\mathrm{ptcl}}=\left(E_{j}-O\right) /(R S)$. Here, $O$ denotes an offset energy, primarily from additional interactions in or out of time with an event. $R$ is the average response of the calorimeter to the particles in a jet, and $S$ is the correction factor for the net energy loss from particles that scatter out of or into the jet cone. For a given cone radius, $O$ and $S$ are functions of the jet $\eta$ within the detector. $O$ is also a function of the number of reconstructed event vertices and the instantaneous luminosity; $R$ is the largest correction factor and reflects the lower response of the calorimeter to charged hadrons relative to electrons and photons. It also includes the effect of particle energy loss in front of the calorimeter. The primary response correction is derived from studies of $\gamma+$ jet events, and depends on jet energy and pseudorapidity. For all jets that contain nonisolated muons, we add the muon momenta to that of the jet. Under the assumption that these muons are from semileptonic decays of $b$ quarks, we also add an estimated average neutrino momentum assumed to be collinear with the jet direction.

## 4. Jet shifting, smearing, and removal

Additional corrections beyond the JES are needed to take into account threshold and resolution effects for jets. The jet shifting, smearing, and removal corrections are determined from $Z / \gamma \rightarrow e e+1$ jet events. The $Z / \gamma$ and the jet should be produced approximately back-to-back in $\phi$ with the same $p_{T}$. This is quantified by a $p_{T}$ imbalance variable, $\Delta S=\left(p_{T}^{j}-p_{T}^{Z / \gamma}\right) / p_{T}^{Z / \gamma}$. For jets with a $p_{T}$ well above the reconstruction threshold, the distribution of $\Delta S$ is Gaussian in both data and MC. The difference in the means of these distributions yields a shift that is applied to the MC jet energies to match the data, and a smearing is applied to MC jets based on the difference in the standard deviations of these distributions. Jets that fail the $p_{T}>$ 20 GeV requirement after shifting and smearing corrections are removed from further consideration.

## 5. Efficiencies

The efficiency of the MC simulation of our detector tends to be larger than the true efficiency of the detector. To account for this, we introduce scale factors to adjust the MC efficiency to match that observed in data. The efficiencies for electrons and muons are obtained using $Z \rightarrow$
$e e$ and $Z \rightarrow \mu \mu$ events. One of the decay products of the $Z$ boson is the tag object, which is required to pass restrictive reconstruction requirements and be matched to an object that could have fired the trigger for the event. Object efficiencies are then obtained using the second object from the $Z$ decay.

## 6. Track $P_{T}$ resolution

Electron energies are measured in the calorimeter. However, energy deposition does not depend on the charge of the electron, which is determined by the curvature of the associated track in the magnetic field. An incorrectly reconstructed track can therefore lead to an incorrect charge assignment. Bremsstrahlung from electrons can affect the curvature of the tracks. Also, a soft interaction in the inner detector can result in the process $e^{+} \rightarrow e^{+} e^{-} e^{+}$, leading to charge misidentification if the wrong sign electron track is associated with the electron. This difficulty is also present in tau decays when at least one hadron is produced.

Because the rate of charge misidentification is not properly modeled in the detector simulation, we add a scale factor to electron and tau MC events to approximate the appropriate rate of charge misidentification. We determine this scale factor by using dielectron events consistent with $Z \rightarrow e e$ decays; and we only consider events with dielectron invariant mass between 70 to 110 GeV to avoid biases against physics beyond the SM. The charge misidentification rate in data is about $1 \%$, while the MC predicts a rate of $0.5 \%$.

The disagreement in track resolution between the data and MC also affects muon $p_{T}$ measurement, which is corrected using smearing parameters determined by comparing the data and MC mass peaks for $Z \rightarrow \mu \mu$ and $J / \psi \rightarrow \mu \mu$ decays.

## 7. Electron energy smearing

In the simulation, the electron $p_{T}$ reconstructed in the calorimeter has a better resolution than in the data. We correct this using a Gaussian smearing function tuned to reproduce the shape of the $Z \rightarrow e e$ peak.

## 8. Jet taggability

The jet taggability rates (Sec. IIIF) are found to be different for MC and data. To correct for this difference, correction factors are applied as scale factors depending on $p_{T}, \eta$ and $z_{\mathrm{PV}}$ of the jet [24].

## 9. b-tagging rate

As detailed in Sec. III F, we apply a tagging algorithm to both data and MC jets to select jets originating from heavy $(b / c)$ quarks. However, the algorithm can select mistagged light jets. The tagging rates (for both heavy- and lightparton jets) depend on the $p_{T}$ and $\eta$ of the jets. The heavyquark tagging rates are measured separately in both data
and MC using dedicated samples. The performance of the $b$-tagging algorithm in MC events is better than in data. To correct the tagging rates in MC events, we first determine the flavor of the tagged jet by matching it in $\Delta \mathcal{R}$ with the initial parton. Depending on the flavor of the jet, we apply a per-jet scale factor given by $\mathrm{SF}=\epsilon^{\mathrm{data}}\left(p_{T}, \eta\right) / \epsilon^{\mathrm{MC}}\left(p_{T}, \eta\right)$, where $\epsilon^{\text {data }}\left(p_{T}, \eta\right)$ and $\epsilon^{\mathrm{MC}}\left(p_{T}, \eta\right)$ are the $b$-tagging efficiencies for a given parton flavor for data (MC) events. To maintain correct normalization, a small downward correction is applied to non- $b$-tagged jets.

## 10. Weak gauge boson $p_{T}$

The $p_{T}$ distribution of the $Z$ boson from alpgen MC is corrected to match the distribution observed in data in $Z \rightarrow e e$ decays [25]. A modified reweighting is carried over to the $W$ boson $p_{T}$ based on the theoretical ratio of the $W$ to $Z p_{T}$ spectra [26].

## 11. $\Delta \phi$

We apply a $\Delta \phi$-dependent weight derived specifically for this analysis using the inclusive distributions described in Sec. V to correct the $\Delta \phi$ between leptons in dilepton final states and the lepton and $\mathbb{E}_{T}$ in single-lepton + jets final states. This additional correction is required because the limited detector resolution at small $p_{T}$ values prevents us from obtaining a good description of the $\Delta \phi$ distribution in the region $p_{T} \approx 0$, which is dominated by SM processes, by using only the correction on the weak boson

TABLE I. Inclusive final states and their object selections, where $p_{T}^{\min }$ is the minimum allowed value of $p_{T}$ and $|\eta|^{\max }$ is the maximum allowed value of $|\eta|$.

| Final state | Object | $p_{T}^{\min }(\mathrm{GeV})$ | $\|\eta\|^{\max }$ |
| :---: | :---: | :---: | :---: |
| $e+$ jets $+X^{\mathrm{a}}$ | $e$ | 35 | 1.1 |
|  | jet | 20 | 2.5 |
|  | $\not E_{T}$ | 20 | - |
| $\mu+$ jets $+X^{\mathrm{b}}$ | $\mu$ | 25 | 1.5 |
|  | jet | 20 | 2.5 |
| $e e+X^{\mathrm{c}}$ | $\not$ T $_{T}$ | 20 | - |
| $\mu \mu+X^{\mathrm{d}}$ | $e$ | 20 | 1.1 |
| $\mu e+X^{\mathrm{e}}$ | $\mu$ | 15 | 1.5 |
|  | $\mu$ | 15 | 1.5 |
| $e \tau+X^{\mathrm{f}}$ | $e$ | 15 | 1.1 |
|  | $e$ | 15 | 1.1 |
| $\mu \tau+X^{\mathrm{g}}$ | $\tau$ | 15 | 1.1 |
|  | $\mu$ | 15 | 1.5 |

${ }^{\mathrm{a}} X \neq e, \mu, \tau, \gamma$
${ }^{\mathrm{b}} X \neq e, \mu, \tau, \gamma$
${ }^{\mathrm{c}} X \neq \mu, \tau, \gamma$
${ }^{\mathrm{d}} X \neq e, \tau, \gamma$
${ }^{\mathrm{e}} X \neq \tau, \gamma$
${ }^{\mathrm{t}} X \neq \gamma$
${ }^{\mathrm{g}} X \neq e, \gamma$
$p_{T}$ [27]. We remove events containing high $p_{T}$ objects, using the same method described in Sec. VI, from the fit to avoid introducing biases from possible new physics signals. This reweighting affects not only the $\Delta \phi$ distributions, but also other quantities that depend on the angular distribution of particles such as the $p_{T}$ of the $W$ boson.

## V. INCLUSIVE FINAL STATES

To determine the unknown scale factors from the data, we construct seven inclusive final states each dominated by a specific SM process. These seven inclusive nonoverlapping final states are specified in Table I by the relevant objects and their selection criteria. The additional objects ( $X$ in the table) are selected as shown in Table II. We reject events that include a photon in the central calorimeter with a $p_{T}>15 \mathrm{GeV}$, mainly due to difficulties in modeling. Events with real photon misidentified as electrons could contaminate the $e+$ jets, and the dilepton or trilepton final states containing at least one electrons. We have estimated the contributions from such backgrounds and consider them negligible in the region of the phase space that is relevant for the search for physics beyond the SM. The seven states $(e+$ jets, $\mu+$ jets, $e e, \mu \mu, \mu e, e \tau, \mu \tau)$ were each selected to correspond to a specific SM process.
(i) $e+$ jets

The electron + jets final states have more background from multijet events, where a jet is misidentified as an electron, than the other electron final states. Therefore the likelihood criterion used is tighter than in other final states, $\mathcal{L}_{e}>0.95$. We also require at least one jet having $E_{T}>20 \mathrm{GeV}$, $\mathbb{E}_{T}>20 \mathrm{GeV}$, and an $e p_{T}>35 \mathrm{GeV}$. This final state is dominated by $W+$ jets events with $W \rightarrow$ $e \nu$ decays. The multijet background in this final state is estimated using a sample of events with exactly one nonisolated electron with a $p_{T}>35 \mathrm{GeV}$ and the same jet and $\mathbb{E}_{T}$ criteria as in signal.
(ii) $\mu+$ jets

The $\mu+$ jets final state is dominated by $W+$ jets events with $W \rightarrow \mu \nu$ decays. To reduce the amount of multijet background, at least one jet having $E_{T}>$ 20 GeV is required, as well as $\mathscr{E}_{T}>20 \mathrm{GeV}$ and a muon with $p_{T}>25 \mathrm{GeV}$. Just as with the $e+$ jets final state, this final state is inclusive in jets with

TABLE II. Criteria required for inclusion as additional objects $(X)$ in one of the seven final states listed in Table I.

| Object | $p_{T}^{\min }(\mathrm{GeV})$ | $\|\eta\|^{\max }$ |
| :---: | :---: | :---: |
| $e$ | 15 | 1.1 |
| $\mu$ | 15 | 1.5 |
| $\tau$ | 15 | 1.1 |
| jet | 20 | 2.5 |

no other additional objects allowed. The multijet background in this final state is estimated using a sample of nonisolated muons with $p_{T}>25 \mathrm{GeV}$ and the same jet and $\mathscr{H}_{T}$ requirements as isolated muons.
(iii) $e e$

The dielectron final state requires each electron to have $p_{T}>20 \mathrm{GeV}$ and $\mathcal{L}_{e}>0.85$. The electrons are also restricted to be in the central calorimeter, $|\eta|<1.1$, and the jets have the same criteria as for the other final states. This final state is dominated by $Z / \gamma^{*} \rightarrow e e$ events. No multijet background is necessary in this channel to produce a satisfactory normalization fit.
(iv) $\mu \mu$

The dimuon final state requires at least two muons with the muon- $p_{T}$ criteria lowered to $p_{T}>15 \mathrm{GeV}$ because of the smaller contribution from multijet background. Any jet must have $p_{T}>20 \mathrm{GeV}$. This final state is inclusive in both jets and muons, but an additional $e$ or $\tau$ lepton places the event in the $\mu e$ or $\mu \tau$ final states. Analogous to the $e e$ channel, this final state is dominated by $Z / \gamma^{*} \rightarrow \mu \mu$ events. No multijet background is necessary in this channel to produce a satisfactory normalization fit.
(v) $\mu e$

The $\mu$ e final state is inclusive except for $\tau$ leptons; $e \mu \tau$ events are assigned to the $e \tau$ final state. This final state is dominated by $Z / \gamma^{*} \rightarrow \tau \tau$ events. The multijet background in this final state is estimated from a sample consisting of nonisolated electrons and isolated muons, and contains both multijet and $W+$ jet events.
(vi) e $\tau$

The $e \tau$ sample is inclusive in all objects. The electron and $\tau_{h} p_{T}$ are required to be at least 15 GeV . The electron likelihood is set to $L_{e}>$ 0.95 to reduce the large multijet background as many apparent $\tau_{h}$ correspond to misidentified jets. The parameter that separates electron from hadronic taus, $\mathrm{NN}_{e}$, is set to 0.8 to reduce the contribution from dielectron events. This final state is also dominated by $Z / \gamma^{*} \rightarrow \tau \tau$ events. The multijet background in this final state is estimated from a sample of isolated electrons and nonisolated $\tau$ leptons, and contains both multijet and $W+$ jet events.

The $\mu \tau$ state contains at least one muon and one $\tau_{h}$. It is inclusive in all objects except electrons, whose presence would move the event to the $e \tau$ final state. This final state is also dominated by $Z / \gamma^{*} \rightarrow \tau \tau$ events. The multijet background in this final state is estimated from a sample of isolated muons and nonisolated $\tau$ leptons, and contains both multijet and $W+$ jet events.

## VI. INCLUSIVE NORMALIZATION FITS

Our model does not provide proper normalization of different MC contributions because, for example, of higher-order corrections needed for the leading-order or leading-logarithm cross section calculations. To avoid uncertainties in normalization, we perform a fit, described below, for each of the inclusive final states to obtain scale factors that reproduce the distributions of the selected data using a combination of the SM MC and multijet predictions determined from data. We treat the Drell-Yan (D-Y) contributions to the $e e$ and $\mu \mu$ final states without light partons separately from those with light partons because it improves agreement between data and MC.

The fits for normalization factors are performed on kinematic distributions of different object quantities, altering the overall normalization of each input process contributing to the final state so that the $\chi^{2}$ probability for that final state is minimized for the combined fit. To avoid fitting to data at the highest values of $p_{T}$, where new physical processes can be important, we only use events that are not in the high $p_{T}$ tail, which is defined as containing $10 \%$ of the events. Distributions of basic quantities such as $\mathscr{L}_{T}, p_{T}, \eta, \Delta \phi\left(\mathrm{obj}, \mathscr{C}_{T}\right)$ of leptons and jets (here obj refers to the momentum vector of the object considered) are used in the fits while more complex variables are used to check the quality of the overall fit. The latter variables include the mass or transverse mass $M_{T}=$ $\sqrt{\left(p_{T, 1}+p_{T, 2}\right)^{2}-\left(\vec{p}_{T, 1}+\vec{p}_{T, 2}\right)^{2}}$ of two or more objects, jet multiplicities, and the $p_{T}$ of the $W$ and $Z$ bosons. If an event contains any object outside the $p_{T}$ range defined above, then none of the objects in the event are used in the fit.

The list of the seven final states, the processes that are normalized through the inclusive fits to each of the final states, and the number of events in each final state are shown in Table III. Once the fitted values are extracted, the distributions are rescaled accordingly, and the total background contribution, $B$, for a particular final state is

$$
\begin{equation*}
B=\sum_{i}^{N_{\text {bkg }}} S_{i} B_{i} \tag{1}
\end{equation*}
$$

where the scale factor $\left(S_{i}\right)$ for each background process $\left(B_{i}\right)$ is determined from the final state in which its contribution is most important and that scale factor is used in all other final states to which that background contributes. $N_{\text {bkg }}$ refers the total number of all the SM processes contributing to a particular final state.

A simplified example for the $e+$ jets $+X$ final state ( $X \neq e, \mu, \tau, \gamma$ ) is used to illustrate the procedure. The $e+$ jets $+X$ state is dominated by $W \rightarrow e \nu$ events, but there is a significant contribution from multijet and DrellYan events. We use the normalization factor for the Drell-

TABLE III. The contributions used in the inclusive fits for each of the inclusive final states and the number of selected data events in each. The dominant SM process is listed first for each final state. In the $e \tau$ and $\mu \tau$ final states, the multijet background also includes a contribution from $W+$ jets.

| State | SM process | Events |
| :---: | :---: | :---: |
| $e+$ jets $+X$ | $W+$ jets | 40 k |
|  | Multijet |  |
|  | $W / Z+\mathrm{HF}$ | 50 k |
|  | $W+$ jets $+X$ | Multijet |
|  | $W / Z+\mathrm{HF}$ |  |
|  | D-Y $+0 l p$ |  |
|  | D-Y1 $-3 l p$ | 25 k |
|  | $W / Z+\mathrm{HF}$ |  |
| $\mu \mu+X$ | $\mathrm{D}-\mathrm{Y}+0 l p$ | 24 k |
|  | $\mathrm{D}-\mathrm{Y}+1-3 l p$ |  |
|  | $W / Z+\mathrm{HF}$ |  |
| $\mu e+X$ | $Z \rightarrow \tau \tau$ | 0.34 k |
|  | Multijet | 1.3 k |
| $e \tau+X$ | $Z \rightarrow \tau \tau$ |  |
|  | Multijet |  |
|  | $Z \rightarrow e e$ | 1.0 k |
| $\mu \tau+X$ | $Z \rightarrow \tau \tau$ |  |

Yan process, determined through a separate fit to the $e e+$ $X$ final state $(X \neq \mu, \tau, \gamma)$, in the $e+$ jets fit. We also fix the scale factors to one for rare processes which have contributions that are too small to fit accurately in $e+$ jets, such as the $t \bar{t}$ contribution. We then fit for the SM $W$ boson and multijet contributions in the data. The fit optimizes agreement between the distributions in data and the SM prediction for the variables listed above. The result of the fit is two overall weights, one for $W \rightarrow e \nu$ and one for multijet $\rightarrow e+$ jets.

In the $e e$ and $\mu \mu$ final states, there are three contributions allowed to float relative to each other, $Z+0 l p, Z+$ $1-3 l p$, and the number of $W / Z+$ hf events. In the $e+$ jets and $\mu+$ jets, the $Z$ contribution is held fixed to the values found in the $e e$ and $\mu \mu$ fits, and the $W+l p$, multijet, and $W+\mathrm{hf}$ contributions are allowed to float. In the $\mu \tau$, and $\mu e$ final states, the multijet and $Z \rightarrow \tau \tau$ contributions are allowed to float, while other $Z$ contributions are fixed to values given by the fits to the $e e$ and $\mu \mu$ final states. The $e \tau$ final state is similar, but the $Z \rightarrow e e$ contribution is large enough that we also allow the normalization of this contribution to float. In all final states, the number of $t \bar{t}$ and diboson events are held fixed to the best available calculations of the cross sections (approximate next-to-next-to-leading-order for $t \bar{t}$ and next-to-leading-order for $W W$ ) [28]. The ratio of $W / Z+b \bar{b}$ to $W / Z+c \bar{c}$ are also held fixed to the expected ratio from next-to-leading-order calculations [29].

FIG. 1 (color online). $\quad e+$ jets final state (a) electron $p_{T}$ histogram and (b) transverse mass ( $e, \mathbb{E}_{T}$ ) check histogram.

The distributions of the variables for the input processes are not varied, only their relative contributions. The fit is performed using the MINUIT program [30]. For singlelepton states and hadronic $\tau$ final states, multijet events are a significant background. We assume that the contribution from other SM processes modeled by the MC samples to the multijet background is small. The scale

FIG. 2 (color online). $\quad \mu+$ jets final state (a) $\mathscr{E}_{T}$ histogram and (b) transverse mass $\left(\mu, \mathscr{E}_{T}\right)$ check histogram.

FIG. 3 (color online). ee final state (a) leading electron (with highest $\left.p_{T}\right) p_{T}$ fit histogram and (b) invariant mass $(e, e)$ check histogram.
factors of input processes for the MC events should also account for the contributions of the processes to the multijet background. The main effects of contributions from any of the MC processes to the multijet background would be to decrease the scale factor for backgrounds modeled by MC.

FIG. 4 (color online). $\quad \mu \mu$ final state (a) leading muon $p_{T}$ fit histogram and (b) invariant mass ( $\mu, \mu$ ) check histogram.

FIG. 5 (color online). $\mu e$ final state (a) electron $p_{T}$ fit histogram and (b) invariant mass ( $\mu, e$ ) check histogram.

The main purpose of the normalization process is to assure that the fundamental SM processes are wellmodeled. The results of the fit are then checked for qualitative agreement with the data. The overall scale factors are checked to compare to those from dedicated analyses. If the normalization factors are properly included in the MC , then all the scale factors should equal unity. In the $e+$ jets $+X$ and $\mu+$ jets $+X$ final states, the scale factors for the $W+$ light partons are consistent within uncertainties between the electron and muon channels. The small deviation of the scale factors from unity is caused by the presence of small contributions from $W+$ jet events in which the $W$ decays leptonically in the samples used for the estimation of the multijet backgrounds.

The scale factors needed for the $Z+$ light parton MC are consistent with 1 for the $Z+1-3 l p \mathrm{MC}$, but not for the $Z+0 l p \mathrm{MC}$. This difference is due to systematics that we do not account for in this analysis, e.g., uncertainties on the $Z p_{T}$ reweighting, jet energy scale and lepton ID. The total contribution of $Z \rightarrow e e$ to the $e \tau$ final state is within $10 \%$ of the expected value from the $e e$ fit. The ratio of the scale factors for the $W / Z+b \bar{b}(c \bar{c}) \mathrm{MC}$ relative to the $W / Z+$ $l p \mathrm{MC}$ obtained from the fits is consistent, within errors, with the next-to-leading-order predictions [29].

One histogram that is included in the overall fit and one check histogram that is not part of the fit are shown for each of the seven final states in Figs. 1-7. In the figures, the leading and second electron are the electrons with highest $p_{T}$ in the event and next highest $p_{T}$ in the event, with a similar definition for leading and second muons and jets.

FIG. 6 (color online). $e \tau$ final state (a) The $\Delta \phi\left(e, \mathscr{C}_{T}\right)$ fit histogram and (b) invariant mass $(e, \tau)$ check histogram.

The electron $p_{T}$ distribution in Fig. 1 shows a clear disagreement between data and simulation in this kinematic region arising from the need for a large multijet contribution at low $p_{T}$, and other variables that provide better agreement with a smaller multijet contribution. However, the discrepancy at low $p_{T}$ should not mask the

presence of new physics at high $p_{T}$, which is the main focus of this analysis.

## VII. EXCLUSIVE FINAL STATES

After determining the normalization scale factors, the seven inclusive subsets are merged to create an input file for the VISTA algorithm [8]. Each MC and background

FIG. 11 (color online). The $\sigma$ distribution for the 5543 vISTA comparisons before accounting for number of the trials. The curve represents a Gaussian distribution centered at zero to guide the eye. There are 116 distributions in the underflow bin with $\sigma \leq-10$. This is expected as histograms with KolmogorovSmirnov probabilities $>0.99999$ are rounded to 1 , and appear in the underflow bin.

FIG. 12 (color online). The discrepant distributions in the $\mu+$ 2 jets $+\not \mathscr{L}_{T}$ exclusive final state. (a) The transverse mass distribution of the $W$ boson plus second jet, (b) the $\Delta \mathcal{R}$ between the muon and the second jet, (c) the invariant mass distribution of the $\mu+$ second jet, and (d) $\Delta \eta$ between the highest $p_{T}$ jet and the second jet. Other contains distributions too small to list individually, $W+b \bar{b}$, diboson, $t \bar{t}$, and $\mathrm{D}-\mathrm{Y}+0 l p$.
event is given a weight calculated from the data based scale factors and any required corrections. The VISTA algorithm, developed by the CDF Collaboration, is a tool that performs a broad check of the agreement between data and the SM. We modified the CDF algorithm for our analysis strategy as described above. The resultant VISTA@D0 algorithm focuses on the D 0 high $p_{T}$ data to determine whether the data can be adequately described by the SM or if
significant discrepancies can be confirmed. VISTA mainly examines discrepancies that affect the overall distributions rather than narrow regions of phase space, addressing the numbers of expected events and MC/data agreement across full distributions of chosen variables.

The events are separated into homogeneous subsets of events according to the objects contained in each event, resulting in 117 exclusive final states. Examples of such exclusive final states include $\mu^{ \pm} \tau^{\mp}+2$ jets $+\mathbb{E}_{T}$, $e^{ \pm} \mu^{\mp}+2$ jets $+\mathbb{E}_{T}, e^{+} e^{+}+3$ jets, and $\mu+4$ jets $+\mathbb{E}_{T}$.

VISTA performs two types of checks: first, it does a normalization-only check on the number of events in each exclusive state; the goodness of the fit is calculated using Poisson probabilities. Second, it calculates a Kolmogorov-Smirnov statistic (and resulting fit probability) for the consistency of all the kinematic distributions in any final state with the predicted SM distributions. Both of these results require additional interpretation because of the large number of trials (number of final states and/or the number of distributions) involved. When observing many final states, some disagreement is expected from statistical fluctuations in the data. Thus the Poisson probability used
to determine agreement is corrected to reflect this multiple testing. A similar effect occurs when comparing kinematic distributions, and again the probabilities are first converted to standard deviations and then corrected for the number of distributions examined.

Another algorithm we use to search for new physics is called SLEUTH [5], used at D0 for the analysis of the data collected during Run I (1992-1996) of the Tevatron. SLEUTH is an attempt to systematically search for new physics as an excess at the largest values of $\sum p_{T}$. This variable corresponds to the sum of the values of the scalar $p_{T}$ of all objects in the event, including the $\mathbb{E}_{T}$. The SLEUTH algorithm is quasi-model-independent, where "quasi" refers to the assumption that the physics beyond the SM will appear as an excess of events in some final state at large $\sum p_{T}$.

For SLEUTH, the VISTA exclusive $X+0$ jet and $X+1$ jet final states are merged, as are the $X+2$ jets and $X+3$ jets final states, and light-lepton universality is assumed, combining $e X$ and $\mu X$ channels. Underlying these assumptions is the belief that any new physics will leave similar signatures in events with no radiative jets or one radiative jet,

FIG. 13 (color online). The discrepant distributions in the $\mu+1$ jet $+\mathbb{E}_{T}$ exclusive final state: (a) the $p_{T}$ of the $W$ boson, (b) the sum of the scalar values of $p_{T}$ of the $\mu$, jet, and $\mathscr{k}_{T}$, (c) the transverse mass of the $\mu$ and $\mathscr{t}_{T}$, (d) the $p_{T}$ of the $\mu$, and (e) the $\Delta \phi$ between the muon and the jet. Other contains distributions too small to list individually, $W+b \bar{b}$, diboson, $t \bar{t}$, and $\mathrm{D}-\mathrm{Y}+0 l p$.
and in electron and muon final states. Therefore combining these final states increases the statistics in each final state while reducing the trials factor needed to account for looking in multiple final states. In each final state, the $\sum p_{T}$ distribution is scanned to find the cutoff above which the significance of any excess in data relative to the SM background is maximal, with the condition that at least three events be observed above the cutoff. This defines the most interesting region for this final state. Next, pseudoexperiments are generated with pseudo data pulled from the SM background expectation for this final state, and the fraction of pseudoexperiments is determined in which the most interesting region is at least as interesting as the most interesting region found in real data. This gives the probability that the most significant excess observed in the considered final state arise from a background fluctuation. Finally, a corrected probability is estimated from the fraction of hypothetical experiments that would produce a region in any final state at least as interesting as the most interesting region observed among all final states in real data. We define a significant output from SLeuth as one with a corrected probability of $<0.001$ (that is over 3 Gaussian standard deviations from the SM prediction using a one-sided confidence interval).

## VIII. SENSITIVITY TEST

To check the sensitivity of a search with SLEUTH, we examine whether a top quark (produced in $t \bar{t}$ pairs) which contributes objects with high $p_{T}$ would have been discovered in the current data sample. For this test, we used all the background samples, except for the $t \bar{t} \mathrm{MC}$. The main concern is whether other final states would compensate for the missing $t \bar{t}$ events, and thus SLEUTH would not be sensitive to $t \bar{t}$ production in data.

We examine the $\ell j j b \bar{b} \mathscr{C}_{T}$ final state, which we expect to be dominated by $t \bar{t}$ events. Figure 8 shows that presence or absence of a $t \bar{t}$ signal has a great impact. With a threshold of 0.001 , the SLEUTH test, including the $t \bar{t} \mathrm{MC}$, yields a statistical probability of compatibility of 0.98 after correcting for the number of trials. However, without the $t \bar{t}$ contribution this probability is $<1.1 \times 10^{-5}$. In Fig. 8 and other SLEUTH plots, the insets show the results for data and MC that pass the $\sum p_{T}$ cut maximizing the significance of excess in data.

## IX. RESULTS

## A. Numerical discrepancy using the VISTA analysis

In VISTA, the separation of the input data into final states completely defined by the objects in an event, yields a total of 117 unique exclusive final states. The probability $(\tilde{\mathcal{P}})$ that the yield observed in data results from a statistical fluctuation of the SM sample in channel $f_{s}$ is determined from

$$
\begin{equation*}
\tilde{\mathcal{P}}=1-\left(1-p_{f s}\right)^{N_{f s}} \stackrel{p_{f s} \ll 1}{\approx} N_{f s} \times p_{f s} \tag{2}
\end{equation*}
$$

where $N_{f s}$ is the number of trials and $p_{f s}$ is the probability that the number of events predicted for the channel $f_{s}$ in the SM would fluctuate to what is observed in data, before applying the correction for the number of trials. The number of trials is $N_{f s}=117$, corresponding to the number of final states, and

$$
\begin{equation*}
p_{f s}=\int_{0}^{\infty} \exp \left[-\frac{\left(N-N_{B}\right)^{2}}{2 \sigma_{B}^{2}}\right] d N \sum_{N_{\text {data }}}^{\infty} \frac{N^{i}}{i!} e^{-N} \tag{3}
\end{equation*}
$$

where $N_{B}$ and $\sigma_{B}$ are the expected SM event yield from background and its uncertainty, respectively, and $N_{\text {data }}$ is the number of events observed in any channel. The Gaussian significance is the value of $\sigma$ that satisfies the equation

$$
\begin{equation*}
\int_{\sigma}^{\infty} \frac{1}{\sqrt{2 \pi}} e^{-\left(x^{2}\right) /(2)} d x=\tilde{\mathcal{P}} \tag{4}
\end{equation*}
$$

The final-state probabilities converted into standard deviations, before the correction factor for the number of trials, are shown in Fig. 9. This distribution shows most final states near $\sigma=0$, with some excess for $\sigma>3$. Of the 117 final states, two show significant discrepancy after correction for the number of trials. These are the final states $\mu+$

2 jets $+\mathbb{E}_{T}$, with a probability corresponding to a $4.5 \sigma$ discrepancy, and $\mu^{+} \mu^{-}+\mathbb{Z}_{T}$ with a discrepancy of $6.7 \sigma$ (also shown in Fig. 9).

The discrepancy for the $\mu+2$ jets $+\mathbb{E}_{T}$ final state shows the greatest difference from the SM prediction in the modeling of jet distributions. There is a significant excess in the number of jets at high $|\eta|$, which points to likely problems with modeling initial-state-radiation/final-state-radiation jets in the forward region, as can be seen in Fig. 10(a). This difference is observed in dedicated analyses [31], and the discrepancy becomes less severe when using SHERPA [32] MC events.

The $\mu^{+} \mu^{-}+\not \mathbb{E}_{T}$ discrepancy can be attributed to difficulties modeling the muon momentum distribution for high $p_{T}$ muons. As noted in Sec. IV B 6, the muon smearing modeling is based on muons from $Z$ and $J / \psi$ decays, dominated by muons below 60 GeV , and is not as reliable at high $p_{T}$. The prime signature of poorly simulated high $p_{T}$ muons is an excess of $\not \mathscr{L}_{T}$ because of the mismodeling of the resolution of the mismeasured track. The $\Delta \phi$ between

the positive muon and $\mathscr{E}_{T}$ in the $\mu^{+} \mu^{-}+\mathbb{E}_{T}$ final state is shown in Fig. 10(b), where the excess tends to be for events where the $\mathscr{Z}_{T}$ is collinear with a muon.

## B. VISTA Shape analysis of discrepancies in distributions

The 117 final states contribute a total of 5543 individual one-dimensional distributions in various variables, and comparison between simulation and data is performed for each. The trials-factor adjusted probability is determined from $\tilde{\mathcal{P}}=1-\left(1-p_{\text {shp }}\right)^{5543}$, where $p_{\text {shp }}$ is the Kolmogorov-Smirnov probability to observe a discrepancy for any individual distribution (before applying the correction for 5543 trials). As with the probability for a final-state normalization discrepancy in any final state, the probability for a discrepancy in a spectrum is converted into units of standard deviation. Any deviation $>3 \sigma$ is considered discrepant. The distribution of deviations before correction for the number of trials is shown in Fig. 11.

Sixteen distributions are found to be discrepant at the $3 \sigma$ level after correcting for the trials. The majority of these are related to spatial distributions involving jets. All these discrepancies are related to known simplifications in our modeling assumptions, e.g., no systematic uncertainties taken into account, aside from the adjustments made by the normalization factors. These discrepancies would not

FIG. 18 (color online). Check of most discrepant CDF plots from [9], $\ell^{ \pm} \ell^{\mp} \ell^{\prime}+\mathscr{E}_{T}$. The inset shows the distribution above the $\Sigma p_{T}$ cut.

FIG. 19 (color online). Since there are no data events in the $\mu^{ \pm} e^{ \pm}+2$ jets $+\mathscr{E}_{T}$ final state, the distribution for $\mu^{ \pm} e^{\mp}+$ 2 jets $+\mathscr{E}_{T}$ is shown. The inset shows the distribution above the $\Sigma p_{T}$ cut. Other contains the $Z \rightarrow \mu \mu$ and $W / Z+b \bar{b}$ distributions.
be expected to severely affect the SLEUTH search for new physics at high $p_{T}$ tails. All 16 discrepant distributions are shown in Figs. 12-15 and are listed in Table IV. In the figures, the second jet refers to the lower $p_{T}$ jet in the two jet final states.

## C. SLEUTH

All VISTA final states are used as input to Sledth, and the 117 inclusive final states are folded into 31 final states after applying global charge conjugation invariance, rebinning in the number of jets, and assuming light lepton universality. The two VISTA final states that show broad numerical excesses are found again with the SLEUTH algorithm, as expected. No additional final states have a significant SLEUTH output, as defined in Sec. VII.

In the SLEUTH runs performed at CDF, using a slightly different analysis strategy, the four most interesting observed final states were $\mu^{ \pm} e^{ \pm}, \mu^{ \pm} e^{ \pm}+2$ jets $+\mathbb{E}_{T}$, $\mu^{ \pm} e^{ \pm}+\mathbb{E}_{T}$, and $\ell^{ \pm} \ell^{\mp} \ell^{\prime}+\mathscr{E}_{T}$ in $2.0 \mathrm{fb}^{-1}$ [9] of integrated luminosity. These states were also among the most

TABLE V. The sLeuth states with $\tilde{\mathcal{P}}<0.99$. The value of $\mathcal{P}$ represents the corresponding probability without taking into account the trial factor.

| Final state | $\mathcal{P}$ | $\tilde{\mathcal{P}}^{\mathrm{a}}$ |
| :---: | :---: | :---: |
| $\ell^{+} \ell^{-}+\not \mathbb{Z}_{T}$ | $<10^{-5}$ | $<0.001$ |

| $e^{ \pm} \mu^{\mp}+\not \mathbb{Z}_{T}$ | 0.0081 | 0.31 |
| $\ell^{ \pm} \tau^{ \pm}$ | 0.057 | 0.91 |
| $\ell^{ \pm}+2 b+2 j+\not \mathbb{Z}_{T}$ | 0.099 | 0.98 |

${ }^{a}$ The value of $\tilde{\mathcal{P}}$ is not necessarily accurate below 0.001 . The important check is whether the value drops below the threshold. Further discussion can be found in [8].

FIG. 20 (color online). Distribution of final state SLEUTH probabilities converted into units of $\sigma$ before inclusion of the finalstate trials factor.
discrepant observed by CDF in $0.9 \mathrm{fb}^{-1}$ [8] of integrated luminosity. Our results for these states are shown in Figs. $16-18$, except for $\mu^{ \pm} e^{ \pm}+2$ jets $+\boldsymbol{E}_{T}$, for which we find no events with 0.16 events expected. Figure 19 shows a related final state, where the muon and electron are of opposite sign rather than of the same sign where CDF sees a discrepancy. None of these states are significantly discrepant in our analysis.

The SLEUTH final states with $\tilde{\mathcal{P}} \leq 0.99$ are shown in Table V. A plot including all of the final-state probabilities converted to units of $\sigma$ can be seen in Fig. 20. The final state $\ell^{ \pm}+\tau^{\mp}+\mathbb{E}_{T}$, which was not identified as having a significant discrepancy between data and the SM in VISTA, falls close to our SLEUTH threshold. Figure 21 shows the $\sum p_{T}$ distribution for this final state.

## X. CONCLUSIONS

We have performed a global study of D 0 high $p_{T}$ data to search for significant deviations from the standard model. This broad search for beyond standard model physics is based on $1.1 \mathrm{fb}^{-1}$ of integrated luminosity collected in Run II of the Fermilab Tevatron Collider in the D0 experiment. Using the VISTA algorithm, a total of 117 exclusive final states and 5543 kinematic distributions were compared to the SM background predictions. Only two out of 117 exclusive final states, $\mu^{ \pm}+2$ jets $+\mathscr{E}_{T}$ and $\mu^{+} \mu^{-}+$

FIG. 21 (color online). SLEUTH plot for $\ell^{ \pm}+\tau^{\mp}+\not \mathscr{L}_{T}$. The inset shows the distribution above the $\Sigma p_{T}$ cut. Other includes D-Y ee + jet events, $\mathrm{D}-\mathrm{Y} \mu \mu+$ jet events, diboson events, and $t \bar{t}$ events.
$\boldsymbol{E}_{T}$, show a statistically significant discrepancy. Given the known modeling difficulties in both final states together with our neglect in this study of systematical uncertainties, we cannot attribute the observed discrepancies to sources of physics beyond the standard model. A quasi-modelindependent search for new physics was also performed using the algorithm SLEUTH by looking for statistically significant excess at high $\sum p_{T}$ in a wide array of exclusive final states. No additional final states cross the discovery threshold in SLEUTH beyond the excesses noted by VISTA.

## 4. $\mathrm{NO} \nu \mathrm{A}$

### 4.1 Introduction

The NuMI Off-axis $\nu_{e}$ Appearance ( $\mathrm{NO} \nu \mathrm{A}$ ) experiment is a long baseline neutrino oscillation experiment instantiated in a two-detector configuration designed to use the NuMI beamline at Fermilab to measure $\nu_{\mu} \rightarrow \nu_{e}, \bar{\nu}_{\mu} \rightarrow \bar{\nu}_{e}, \nu_{\mu} \rightarrow \nu_{\mu}$ and $\bar{\nu}_{\mu} \rightarrow \bar{\nu}_{\mu}$ transitions for neutrino energies and detector separations in the so-called "atmospheric regime." NO $\nu$ A has a particularly rich physics scope. Interaction ("appearance") rates of of $\nu_{e}$ and $\bar{\nu}_{e}$ permit a determination of the neutrino "mass hierarchy," i.e., whether the third Standard Model neutrino mass eigenstate $\nu_{3}$ is more or less massive than the other two; measure the amount of $C P$ violation in the neutrino sector by measuring the $C P$ phase angle $\delta$; measure the size of the PMNS mixing matrix angle $\theta_{13}$; and determine if the mass eigenstate $\nu_{3}$ couples more strongly to $\nu_{\mu}$ or to $\nu_{\tau}$ by measuring if the PMNS mixing matrix angle $\theta_{23}$ exceeds or is less than $\frac{\pi}{4}$, respectively. Recent $\bar{\nu}_{e}$ reactor results showing that the measured value of $\theta_{13}$ is relatively large, $\theta_{13} \simeq 9^{\circ}$, implies substantial appearance rates for $\mathrm{NO} \nu \mathrm{A}$. Additionally, measurements of $\bar{\nu}_{\mu}$ and $\nu_{\mu}$ interaction rates ("disappearance rates") permit improved precision in the measurements of the atmospheric oscillation parameters $\theta_{23}$ and $\left|\Delta m_{\mathrm{atm}}\right|$.

### 4.2 Detector Alignment

Measurements of $\mathrm{NO} \nu \mathrm{A}$ of higher level physics quantities like the $\nu_{\mu} \rightarrow \nu_{e}$ oscillation probability clearly depend on algorithms for pattern recognition, shower shape reconstruction, event selection, etc. These algorithms, in turn, rely on a knowledge of the 3 -space position of "hit" cells where energy is deposited. Incorrect hit cell positions will introduce systematic errors to things like event selection efficiency and electromagnetic shower shape reconstruction that will, in turn, propagate to the final systematic error in the higher level physics quantity of interest. Knowledge of the 3 -space position of the 350 k channels of $\mathrm{NO} \nu \mathrm{A}$ 's far detector is essential and SMU was at the core of the effort to measure these positions.

The lead worker for alignment studies at SMU was postdoc Vladimir Kravtsov who joined SMU in mid-November 2011 and is stationed full-time at Fermilab. Kravtsov focused on developing algorithms for in-situ measurements of the curvature and relative alignment of the 15 m long cells within a plane as a far detector block is built. The raw data is created using a cw "phase-based" 3-dimensional laser scanner (Leica HDS6100) that emits amplitude modulated $\sim 670 \mathrm{~nm}$ laser light in fixed spherical coordinate steps $\Delta \phi$ and $\Delta \theta$. The laser light strikes the horizontal modules, reflects back toward the scanner and the phase difference between the transmitted and reflected light is a measure of the distance between the scanner and module surface. Since the laser light is emitted uniformly in solid angle while the non-planar module surface is at varying distances from the scanner, the resulting "point cloud" of measured points on a module surface is somewhat complicated. The gist of Kravtsov's algorithm is to convert the point cloud into a non-uniform mesh
of elevation versus position in a reference plane and search for local maxima that correspond to the flat horizontal portions of a module's top surface. The centers of these portions are directly above the corresponding cell centers, the geometrical quantity of interest. Fig. 1 shows the cross section of a 32 -channel module and Fig. 2 shows several modules on the assembly table being assembled into a plane. The laser scanner is well above the assembly table, out of view.

## 

Figure 1: Cross-sectional view of a 32-cell module showing the non-planar top and bottom surfaces between cells. The relatively narrow top flat surfaces of a module are searched for to locate the cell centers beneath them.

Figure 2: A partial plane of modules on the assembly table at the Ash River site. The laser scanner used to measure the surface features of the modules is attached to the ceiling, out of view.

Figure 3: Measured cell curvature for 3 neighboring cells in a module. Note the consistent shape for each cell and appropriate pitch between cells, consistent with the manufacturing technique at the extrusion factory.

Kravtsov's algorithm is efficient at measuring the in-plane curvature of a module. Averaging over 50 cm contiguous sections of each 15 m long cell allows cell curvature to be measured with good statistical precision. Since cells are constrained to be physically connected to their neighbors within a module, a simple quadratic fit for in-plane curvature is sufficient. Fig 3 show results for 3 neighboring cells in a particular module. A clear banana shape is seen for each cell and the curvature
has the same sense. The distance between curves is completely consistent with the $\sim 4 \mathrm{~cm}$ cell-to-cell separation measured at the extrusion factory.

After the in-plane and out-of-plane curvatures are measured for a cell, it will be possible to describe the trajectory of a cell's center along its length by an appropriate curve. The parameters of this curve will be stored in a database for later reading during event reconstruction to better estimate the true location of hits cells. The current algorithm, developed with prototype detectors, is now automated and an automated system for transferring raw laser scan data to Fermilab for those cells in blocks under construction at Ash River is now established.

### 4.3 Monte Carlo Production Site

T. Coan, with the assistance of postdoc V. Kravtsov and FNAL computing professionals, made signficiant progress in establishing SMU as a Monte Carlo (MC) production site that would be the first such university site within $\mathrm{NO} \nu \mathrm{A}$ and so serve as a computing model for other $\mathrm{NO} \nu \mathrm{A}$ university sites. SMU has a non-trivial amount of computing resources, $\sim 1800$ cores with the Intel chipset Xeon E5540 and 6 GB of RAM/core plus an associated Lustre file system of 340 TB capacity, that is available for opportunistic use. (The SMU ATLAS group is also a user of these resources.) Equally important, its computing facility is a member of Open Science Grid and runs the 64-bit Linux operating system, making interaction with it relatively straightforward for $\mathrm{NO} \nu \mathrm{A}$. Additionally, the facility has administrative support fully paid for by SMU , so there is no burden to NO $\nu \mathrm{A}$. Our goal was to be able to submit batch MC generation jobs via the grid using standard $\mathrm{NO} \nu \mathrm{A}$ job submission procedures, have them run at SMU, and then either transfer the data back to FNAL or store them locally at SMU, whichever is more sensible for the particular job. Coan has negotiated a processing allotment of $\sim 2 \mathrm{M}$-cpu hours annually for $\mathrm{NO} \nu \mathrm{A}$, corresponding to approximately 280 cores running continuously. This level corresponds to the current (late 2012) NO $\nu \mathrm{A}$ activity on Fermigrid.

In late 2012, effort was focused on the installation of the CERN Virtual Machine File System (CVMFS) for $\mathrm{NO} \nu \mathrm{A}$ software on the SMU cluster. This was perhaps the last major step before getting SMU Monte Carlo production operational. This scheme allows the running of NO $\nu \mathrm{A}$ software on local machines from a central server without having to actually install the software locally, thereby reducing software maintenance overhead enormously. SMU hired a second systems administrator for its research computing cluster, at no cost to $\mathrm{NO} \nu \mathrm{A}$ or the SMU physics department, in mid-October 2012. This helps to ensure purely technical issues (e.g., hardware disruptions, firewall issues, kernel upgrades on local machines, etc.) are resolved efficiently. Finally, Coan purchased 96 TB of disk space to be integrated into the SMU cluster to support generation of Monte Carlo events for $\mathrm{NO} \nu \mathrm{A}$-wide use.

### 4.4 Outfitting at Ash River

T. Coan, at the request of $\mathrm{NO} \nu \mathrm{A}$ project management, was asked to be one of the physicists responsible for overseeing the outfitting of the far detector hall at Ash River and was on-site from mid-May through the end of July 2012. In conjunction with the NO $\nu$ A deputy project manager, this task involved coordinating and overseeing myriad jobs relating to such tasks as the installation of the APD cooling system, cabling for the various readout racks (high voltage, low voltage and network), module optical connector measurements and laser scanner data transmission. Although this effort is not tied directly to the development of specific data analysis code, it provides a useful, detailed overview of detector construction that may prove essential for later uncovering sources of systematic errors once data taking begins.

### 4.5 Management of the Calibration and Alignment Group

T. Coan is one of the co-convenors for the calibration and alignment group. This is a leadership position responsible for developing and managing a coherent effort to align the cells of $\mathrm{NO} \nu \mathrm{A}$ 's near and far detectors, calibrate the energy response of all cells, and monitor and correct for time dependent variations of detector response at various levels of granularity. Multiple university and national lab groups have workers in this group involved in efforts to user laser scan and cosmic ray data for detector cell alignment, to use stopping muons and muon $\mathrm{dE} / \mathrm{dx}$ to provide an energy calibration for cells, to use cosmic muons for normalizing cell-to-cell response, efforts to measure APD response linearity and threshold effects, algorithm development for $\pi^{0}$ mass peak and width measurements as a tool to check for time variations in the higher level detector response, etc. Work on developing special calibration triggers was also started. Although the group made considerable, development of the full suite of software necessary to calibrate and align the first data was still ongoing in late 2012 and early 2013.

## 5) SMU Theory: DoE Research Report:

## Fredrick Olness:

Olness works in the general area of Parton Distribution Functions (PDFs) and heavy quarks. He currently serves as co-spokesperson of the CTEQ collaboration, is a member of the International Advisory Committee for the Deep Inelastic Scattering (DIS) Workshop series, and is on the Steering Committee of the LHC-Theory Initiative. Olness also served on the organizing committee for the CTEQ/LPC Workshop (Fermilab, November 2011) and the Fall 2011 Texas-APS Meeting (Texas-A\&M, Commerce, October 2011). Within CTEQ, he has organized and/or lectured at the past six CTEQ Summer Schools, including presenting the four introductory lectures at the 2010 CTEQ-MCnet Summer school. He also was the "Theorist of the Week" (DESY, March 2010), was invited to present at the "Atlas Workshop of the Americas" (UT-Arlington, August 2010). Locally, Olness is active with the SMU Physics QuarkNet program, and serves as the Co-Director of the Dallas Regional Science Fair.

- PDFs and Nuclear Target Corrections: Refs. [1, 2, 3, 4, 5, 6, 7, 8, 9]

The Parton Distribution Functions (PDFs) are the essential ingredient which allow us to predict and interpret hadronic processes at fixed-target experiments, HERA, RHIC, Tevatron, and the LHC. In our first series of studies, we fit the charged and neutral current DIS processes separately, and extracted the nuclear correction factor for each data set. Specifically, we found that the nuclear corrections dictated by the separate charged and neutral data were quite different.[2, 3] The result of this global analysis yields the PDFs for the proton and for all nuclear A values. We have released the full set of nCTEQ PDFs used in the above studies, and these are available on-line at the HepForge repository. We have produced 19 separate PDF sets, each with 19 different nuclear A values for a total of 361 PDF sets.

- W/Z Production at the LHC and the Strange PDF: Refs. [10, 5]

At the LHC, $W$ and $Z$ boson production are used as "benchmark" processes to calibrate the decay modes of the newly discovered Higgs boson, and to search for "new physics" signatures. Motivated by questions from members of the ATLAS Standard Model group, we examined the influence of the strange quark PDF on these processes. At the LHC, the strange contribution to the $W / Z$ production processes can be as large as $30 \%$; hence a large uncertainty in the strange quark can degrade the precision these benchmark measurements. Additionally, we observed that because the $u, d$-valence quarks yield a different rapidity distribution from the $s$-quarks, an accurate measurement of the $W / Z$ could constrain the relative mix of valence and sea PDFs. Our study was published in Refs. [10, 5], and some of this work was also presented at the 2010 Atlas Workshop of the Americas held at UT-Arlington.

- Extending to Higher Order Calculations: Refs. [11, 12, 13, 14, 15, 16]

The H1 and Zeus collaborations have joined forces to produce the HERA-PDF series of proton structure fits with improved precision and reduced systematic errors.

For the massive DIS calculation, we have the complete results out to NLO, and we have used approximation methods to extend to $\mathrm{N}^{3} \mathrm{LO}$ using appropriate rescaling factors to estimate the higher order contributions. The results of this analysis were presented in Ref. [15].

- Heavy Ion Collisions at RHiC and LHC:

Ref. [17]
The LHC also has the capability to run in heavy ion mode. For example, the LHC ran with lead beams in Fall 2010, and another heavy ion run is scheduled for early 2013. In Ref. [17] we present a detailed phenomenological study of direct photon production in association with a heavy-quark jet for RHIC and LHC at NLO in QCD. This observable can provide strong constraints, over a broad $x$-range on the poorly determined nuclear parton distribution functions which are extremely important for the interpretation of results in heavy-ion collisions.

## - Model Independent Constraints on "New Physics:" <br> Refs. [18, 19]

Hadroproduction data from HERA, Tevatron, and LHC spans a broad range of energies, and these measurements can be sensitive to contributions from strongly-interacting new physics. We completed an updated QCD+SUSY global analysis on strongly interacting super-partners using the latest, most complete collider data from HERA and Tevatron to impose limits on masses of light super-partners (gluinos) as a function of $\alpha_{s}$. We find improved constraints compared to our previous (2005) study, and these limits are competitive with the best (model-independent) limits available from LEP. These limits are cited in the pdfLive (Particle Data Group) database.

- Correlated Theoretical Errors:

Ref. [20]
While at CERN, Olness and Dave Soper (U. Oregon) initiated a project to formulate the theoretical systematic uncertainties in a manner that could be numerically implemented into the global fitting analysis. The general formulation of theoretical correlated errors appears in Ref.[20].

## - Dimensional Regularization meets Freshman E\&M:

Ref. [21]
As an extension of CTEQ Summer School lectures by Olness, we developed a pedagogical example that provides an introduction to regularization, renormalization, and dimensional transmutation. This work simply elucidates renormalization scheme dependence, and the role of symmetries in a setting (a Freshman E\&M example) which is more accessible.[21].

## - Future Heavy Ion Colliders:

We proposed a new measurement at a future Electron-Ion Collider (EIC) that could clarify existence of the hypothetical "intrinsic" mechanism for charm quark production. This measurement relies on observation of charmed mesons in neutral-current DIS at large Bjorken $x$ and momentum transfer $Q$ comparable to charm mass. Intrinsic production may enhance the rate of charm meson production by up to an order of magnitude. Thus, an EIC may be uniquely suited for verifying the intrinsic charm mechanism, in contrast to other envisioned experiments. We presented some preliminary calculations on techniques to distinguish intrinsic heavy flavor production, and investigate the unique perspective provided by such a future Electron-Ion facility.[22]

- Future facilities

Refs. [23, 24, 25]

As we plan for future experiments, many scenarios include various high-intensity neutrino experiments.[24] Ref. [23] describes the potential EW "new physics" signals, and Ref. [25] outlines the QCD issues that can be addressed at a future high-intensity neutrino experiment. Olness presented this work at a Fermilab"Wine \& Cheese" talk in October 2009.

## 1 DOE Final Report - Hornbostel

### 1.1 Research Overview

Most of the work described in this proposal was done as part of the High Precision Quantum Chromodynamics (HPQCD) Collaboration, with members P. Lepage (Cornell), C. Davies (Glasgow), J. Shigemitsu (Ohio State), H. Trottier (Simon Fraser), R. Horgan (Cambridge), E. Follana (Zaragoza), and M. Wingate (Cambridge), along with students and postdocs. HPQCD focuses on developing and employing a variety of new tools in lattice QCD with the aim of producing a range of phenomenologically relevant calculations with accuracies to within a couple per cent. These tools include improved Lagrangians, mostly with staggered quarks, more efficient lattice perturbation theory, effective actions for nonrelativistic systems, and better fitting methods. The collaboration has and continues to determine values for fundamental quantities such as the strong coupling constant $\alpha_{s}$, spectra, quark masses, and decay constants that are among the world's most precise. A particular focus is on providing precise measurements of the strongly-interacting component of the matrix elements needed to measure and overconstrain CKM matrix elements, in order to determine this more precisely, and especially in the hope that a discrepancy will point to new phenomena.

My specific contributions have been in the early development of improved lattice actions for nonrelativistic systems, and their application to charmonium and $\Upsilon$ spectra, $\alpha_{s}$ and heavy-quark mass determinations, scale setting for $\alpha_{s}$, simulation methods for highlyimproved dynamical quarks, and the use of current correlators to extract masses and current renormalizations. Research completed under this grant includes improved calculations of masses and decay constants for charm mesons using a relativistic highly-improved action and the extension to heavier masses up to the $b$ mass, current renormalization factors used to determine $D$ and $B$-meson decay constants, and improvements in fitting methods.

### 1.2 Improved Actions and Highly-Improved Staggered Quarks (HISQ)

From the early 1990s, new tools in lattice QCD such as tadpole improvement and renormalized perturbation theory revived the use of improved actions, introduced by Symanzik. These allowed the removal of lattice spacing errors using effective interactions which are perturbatively calculable, and led to more accurate simulations at greatly reduced computational cost. Our recent implementations of improved actions for QCD use the staggeredquark formulation, which retains chiral symmetry. When combined with Symanzik improvement, this is the most accurate action available and very efficient for simulations. The most recent incarnation (HISQ) is also particularly well-suited for relativistic $c$ quarks and (almost) $b$ quarks.

In the following, I describe projects which used the HISQ action and MILC configurations to measure fundamental parameters of the Standard Model, mainly in systems with $c$ or $b$ quarks.

### 1.3 Charm Systems

We just completed an updated calculation of the mass of the $J / \psi$, its leptonic width, and radiative decay [1]. New results agree with experiment, and include $M_{J / \psi}-M_{\eta_{c}}=116.5(3.2)$, $\Gamma\left(J / \psi \rightarrow e^{+} e^{-}\right)=5.48(16) \mathrm{keV}$, and $\Gamma\left(J / \psi \rightarrow \gamma \eta_{c}\right)=2.49(19) \mathrm{keV}$. The leptonic width in particular provides a successful $2 \%$ test of QCD. New ingredients in these decay calculations are the inclusion of all three light sea quarks using MILC ASQTAD configurations for the first time, and two methods to nonperturbatively renormalize the nonconserved vector current. The first is a variation of current-current correlator method discussed elsewhere; the second is by the normalization of the vector form factor between HISQ-NRQCD mesons.

### 1.4 Current Correlators, $m_{c}$ and $m_{b}$

In Ref. [2], we used the HISQ action to update sum rule method for determining the charm quark mass by comparing high-order perturbative $\overline{\mathrm{MS}}$ current-current correlators to lattice simulations rather than experimental cross sections. We were able to extract a precise value of the $c$-quark mass $m_{c}$, as well as a competitive value for $\alpha_{s}$. In Ref. [3], we extended our correlator method to include a broad range of heavy-quark masses, from below $m_{c}$ almost to $m_{b}$. We extracted a fit for the heavy MS mass as a function of $m_{\eta_{h}}$, giving both $m_{c}^{(4)}(3 \mathrm{GeV})=0.986(6) \mathrm{GeV}$ and $m_{b}^{(5)}(10 \mathrm{GeV})=3.617(25) \mathrm{GeV}$, among the most precise values available. Simultaneously we found $\alpha_{s}^{(5)}\left(M_{Z}\right)=0.1183(7)$, consistent with our determination using plaquettes, with competitive uncertainty. This approach was successful because of the fineness of the lattice configurations from MILC, with spacings from 0.15 fm to 0.045 fm , allowing us to simulate using a relativistic action with mass close enough to $m_{b}$ to allow accurate extrapolation, as well extrapolations to the continuum. We are applying extrapolations to the $b$ in several other calculations.

## $1.5 \quad s, u$ and $d$ Masses

One of the main goals of the HPQCD collaboration is to use lattice calculations to improve the precision of the fundamental parameters of the Standard Model. Among the least well known are the light-quark masses, due to confinement. The Particle Data Group quotes errors of roughly $30 \%$. We were able recently to leverage our $1 \%$-accurate $m_{c}$, along with comparably accurate results for the ratio $m_{s} / m_{c}$ of bare masses, to improve the uncertainty for the $\overline{\mathrm{MS}}$ ratio by nearly an order-of-magnitude [4] as compared to the PDG value. In particular, $m_{c} / m_{s}=11.85(16)$, giving the $\overline{\mathrm{MS}}$ mass $m_{s}^{(3)}(2 \mathrm{GeV})=92.4(1.5) \mathrm{MeV}$. We have similar reductions in errors in a new $s$ to light-quark ratio, resulting in an averaged lightquark mass of $3.40(7) \mathrm{MeV}$. Combined with the MILC $u$ and $d$ ratio, this gives MS masses $m_{u}=2.01(14) \mathrm{MeV}$ and $m_{d}=4.79(16) \mathrm{MeV}$.

### 1.6 Light Quark Condensates

Both to improve the precision of our current correlator fits involving light quarks, and because of their intrinsic interest, we directly calculated the condensates we use for $u$ and $d$,
and separately for $s$ quarks, published in Ref. [5]. Lattice QCD provides the only method to do this from first principles, allowing us to replace phenomenological estimates with well-defined values. Using $u, d, s, c$ HISQ sea quarks, with gauge configurations provided by the MILC collaboration, we computed the first direct determination of the strange quark condensate, and converted it to a nonperturbative $\overline{\mathrm{MS}}$ condensate suitable for use in the operator product expansion, finding $-(290(15) \mathrm{MeV})^{3}$. We also obtained a new value for the corresponding light-quark condensate of $-(283(2) \mathrm{MeV})^{3}$. We will employ values for the strange- and light-quark condensates directly in our fits to correlators made from heavylight quarks in order to extract quantities such as the current renormalization needed for $D$ and $B$ meson decays.

### 1.7 Relativistic $b$ Quarks using HISQ

In previous work, we were able to extend the correlator method for extracting the charm mass and $\alpha_{s}$ using the HISQ action to heavier masses $m_{h}$, as finer lattices became available from MILC and $\left(a m_{h}\right)$ errors were reduced. By fitting moments to a function of $m_{h}$, we were able to successfully extrapolate to $m_{b}$. Using a fully relativistic action with chiral symmetry provides significant advantages in that it avoids the largest NRQCD errors from relativistic corrections and current renormalization. The cost is in spacing errors of the form $\left(a m_{h}\right)$. The newest lattices from MILC, with spacing of 0.045 fm , now allow us to work just below $m_{b}$, with minimal extrapolation errors.

We extended this technique to other $b$-quark systems. In particular, we studied systems with identical heavy quarks, with $m_{h}$ ranging from below $c$ to $b$, as well as pseudoscalar mesons which combine a variable $m_{h}$ with a mass fixed $s$ or $c$. We computed masses and decay constants as a function of $m_{h}$ for both cases. This then includes new and accurate measurements of $M_{B_{c}}=6.285(10)$, and decay constants $f_{B_{c}}=0.427(6)$ and $f_{\eta_{b}}=$ $0.667(6)$ [6]. We have applied the same method to pseudoscalar meson decay constants as a function of the heavy quark mass [7]. In particular, we have improved by a factor of three the calculation of the leptonic decay constant $f_{B_{s}}$, with an error of $2 \%$. In the same study we found agreement with experiment of $m_{B_{s}}-m_{\eta_{b}} / 2$ at the same precision, and confirmed the heavy-quark mass dependence of $f_{B_{s}}$ predicted by HQET.

### 1.8 Improved Fitting Methods

To extract continuum physical quantities such as masses and decay constants, we must fit lattice monte carlo simulation data to appropriate continuum quantities such as propagators. Significant advances in the precision of lattice simulations have required similar advances in fitting technology. Toward this end, we have invested considerable effort in developing constrained Bayesian techniques [8] and code to allow for accurate fits and efficient use of high-statistics data. For example, fits to current correlators used to obtain precise values for $\alpha_{s}, m_{b}$ and $m_{c}$ simultaneously fit nearly 90 simulation results with well over 100 fit parameters, extracting these quantities while accounting for systematic errors due to discretization, higher orders in $\alpha_{s}$, finite volume, light-quark masses, experimental input data, nonperturbative contributions and others [3]. Because such extensive fits can
be computationally time consuming, we have developed methods to accelerate and simplify them by moving parameters out of fits and into data [9].

# Nuclear Corrections in $\boldsymbol{v} A$ DIS and Their Compatibility with Global NPDF Analyses 

Received: 19 September 2011 / Accepted: 8 December 2011 / Published online: 13 January 2012
© Springer-Verlag 2012

#### Abstract

We perform a global $\chi^{2}$-analysis of nuclear parton distribution functions using data from charged current neutrino-nucleus ( $\nu A$ ) deep inelastic scattering (DIS), charged-lepton-nucleus ( $\ell^{ \pm} A$ ) DIS, and the Drell-Yan (DY) process. We show that the nuclear corrections in $v A$ DIS are not compatible with the predictions derived from $\ell^{ \pm} A$ DIS and DY data. We quantify this result using a hypothesis-testing criterion based on the $\chi^{2}$ distribution which we apply to the total $\chi^{2}$ as well as to the $\chi^{2}$ of the individual data sets. We find that it is not possible to accommodate the data from $v A$ and $\ell^{ \pm} A$ DIS by an acceptable combined fit. This implies that either the twist-2 parton distribution functions in nuclei are not universal, or that higher-twist terms play a more important role in the nuclear environment and have to be taken into account.

## 1 PDFs and Nuclear Corrections

High statistics neutrino deep-inelastic scattering (DIS) experiments have generated significant interest in the literature as they provide crucial information for global fits of parton distribution functions (PDFs). The neutrino DIS data provide the most stringent constraints on the strange quark distribution in the proton, and allow for flavor decomposition of the PDFs which is essential for precise predictions of the benchmark gauge boson

Presented by Fredrick Olness at LIGHTCONE 2011, 23-27 May, 2011, Dallas.

[^79]production processes at the LHC. Moreover, the neutrino experiments have been used to make precision tests of the standard model (SM) in the neutrino sector. A prominent example is the extraction of the weak mixing angle $\theta_{W}$ in a Paschos-Wolfenstein type analysis [22]. A good knowledge of the neutrino DIS cross sections is also very important for long baseline experiments of the next generation which aim at measuring small parameters of the NMS mixing matrix such as the mixing angle $\theta_{13}$ and eventually the CP violating phase $\delta$.

Due to the weak nature of neutrino interactions the use of heavy nuclear targets is unavoidable, and this complicates the analysis of the precision physics discussed above since model-dependent nuclear corrections must be applied to the data. Our present understanding of the nuclear corrections is mainly based on charged lepton-nucleus ( $\ell A$ ) DIS data. In the early 1980s the European Muon Collaboration (EMC) [2] found that the nucleon structure functions $F_{2}$ for iron and deuterium differ. This discovery triggered a vast experimental program to investigate the nuclear modifications of the ratio $R\left[F_{2}^{\ell A}\right]=F_{2}^{\ell A} /\left(A F_{2}^{\ell N}\right)$ for a wide range of nuclear targets with atomic number $A$, see Table 1. By now, such modifications have been established in a kinematic range from relatively small Bjorken $x\left(x \sim 10^{-2}\right)$ to large $x(x \sim 0.8)$ in the deep inelastic region with squared momentum transfer $Q^{2}>1 \mathrm{GeV}^{2}$. The behavior of the ratio $R\left[F_{2}^{\ell A}\right]$ can be divided into four regions: (1) $R>1$ for $x \gtrsim 0.8$ (Fermi motion region), (2) $R<1$ for $0.25 \lesssim x \lesssim 0.8$ (EMC region), (3) $R>1$ for $0.1 \lesssim x \lesssim 0.25$ (anti-shadowing region), and (4) $R<1$ for $x \lesssim 0.1$ (shadowing region), with different physics mechanisms explaining the nuclear modifications. The shadowing suppression at small $x$ occurs due to coherent multiple scattering inside the nucleus of a $q \bar{q}$ pair coming from the virtual photon [1] with destructive interference of the amplitudes [7]. The anti-shadowing region is theoretically less well understood but might be explained by the same mechanism with constructive interference of the multiple scattering amplitudes [7] or by the application of momentum, charge, and/or baryon number sum rules. Conversely, the modifications at medium and large $x$ are usually explained by nuclear binding and medium effects and the Fermi motion of the nucleons [10].

Instead of trying to address the origin of the nuclear effects, the data on nuclear structure functions can be analyzed in terms of nuclear PDFs (NPDFs) which are modified as compared to the free nucleon PDFs. Relying on factorization theorems in the same spirit as in the free nucleon case, the advantage of this approach is that the universal NPDFs can be used to make predictions for a large variety of processes in $\ell A, v A, p A$, and $A A$ collisions. In addition, the nuclear correction factors required for the interpretation of the neutrino experiments can be calculated in a flexible way, taking into account the precise observable, the nuclear $A$, and the scale $Q^{2}$. The factorization assumption in the nuclear environment is therefore a question of considerable theoretical and practical importance and global analyses of NPDFs based on $\ell A$ DIS and fixed target Drell-Yan (DY) data confirm its validity in the presently explored kinematic range.

However, in a recent analysis [17] of $\nu \mathrm{Fe}$ DIS data from the NuTeV collaboration we found that the nuclear correction factors are surprisingly different from the predictions based on the $\ell^{ \pm} F e$ charged-lepton results with important implications for global analyses of proton PDFs. This finding is not completely unexpected since the structure functions in charged current (CC) neutrino DIS and neutral current (NC) electron/muon DIS are distinct observables with different parton model expressions. From this perspective it is clear that the nuclear correction factors will not be exactly the same even for a universal set of NPDFs. Note also that some models in the literature predict differences between reactions in CC and NC DIS [6]. What is, however, unexpected is the degree to which the $R$ factors differ between the structure functions $F_{2}^{\nu F e}$ and $F_{2}^{\ell F e}$. In particular the lack of evidence for shadowing in neutrino scattering down to $x \sim 0.02$ is quite surprising.

The study in Ref. [17] left open the question, whether the neutrino DIS data could be reconciled with the charged-lepton DIS data by a better flavor separation of the NPDFs. In this letter, we address this question in the $A$-dependent framework of Ref. [16] by performing a global $\chi^{2}$-analysis of the combined data from $v A$ DIS, $\ell$ A DIS and the DY process listed in Table 1.

When combining neutrino and charged-lepton+DY data into a compromise fit, we introduce a weight parameter $w$ into the $\chi^{2}$ via:

$$
\begin{equation*}
\chi^{2}=\sum_{l^{ \pm} A \text { data }} \chi_{i}^{2}+\sum_{\nu A \text { data }} w \chi_{i}^{2} . \tag{1}
\end{equation*}
$$

The $w$ factor allows us to adjust for the different number of points in the separate data sets, and provides a parameter that interpolates between the $\nu A$ and the $\ell^{ \pm} A+\mathrm{DY}$ data. We should stress that the $\chi^{2}$ cited in Table 2 and also in the text is the standard $\chi^{2}$; Eq. (1) is only used internally in the fitting procedure. We construct a set of compromise fits with weights $w=\left\{0, \frac{1}{7}, \frac{1}{2}, 1, \infty\right\}$ and study the dependence of the result on this weight. The fit to only neutrino data, denoted $w=\infty$ in Table 2, is compatible with the results in [17]. Similarly, the fit to only charged-lepton+DY data, denoted $w=0$, agrees well with the analysis in [16].

Table 1 The DIS $F_{2}^{A} / F_{2}^{A^{\prime}}$ data sets together with DY $\sigma_{D Y}^{p A} / \sigma_{D Y}^{p A^{\prime}}$ and with neutrino DIS $d \sigma^{\nu A} / d x d y$ data sets used in the fit. The table details the specific nuclear targets, and the number of data points with kinematical cuts. References for the data sets are cited in Refs. [16,17]

Fig. 1 Predictions from the compromise fits for the nuclear correction factors $R\left[F_{2}^{\ell F e}\right] \simeq F_{2}^{\ell F e} / F_{2}^{\ell N}$ (left) and $R\left[F_{2}^{\nu F e}\right] \simeq$ $F_{2}^{\nu F e} / F_{2}^{\nu N}$ (right) as a function of $x$ for $Q^{2}=5 \mathrm{GeV}^{2}$. The data points displayed in figure a) are from BCDMS and SLAC experiments [3-5,8,11] and those displayed in figure b) come from the NuTeV experiment [20,21]

We first examine the nuclear correction factors $R\left[F_{2}^{F e}\right] \simeq F_{2}^{F e} / F_{2}^{N}$ needed to correct the nuclear data to the free nucleon level. ${ }^{1}$ We compute these quantities in the QCD parton model at next-to-leading order employing the NPDF fits in Table 2. The $x$-dependence of $R\left[F_{2}^{F e}\right]$ is shown in Fig. 1; similar results hold at $Q^{2}=20 \mathrm{GeV}^{2}$ which we do not present here. The $w=0$ fit uses only the $\ell A$ DIS+DY data, and this agrees well with the SLAC and BCDMS points [3-5,8,11] displayed in Fig. 1a). However, as we mix in the $v A$ data, Table 2 shows the $\chi^{2}$ of the $\ell A$ data rise from 638 for $w=0$ to 736 for $w=1$. Correspondingly, the $w=\infty$ fit uses only the $\nu A$ data, and this agrees well with the data from the NuTeV experiment $[20,21]$ displayed in Fig. 1b). Now as we mix in the $\ell A$ DIS+DY data, we see the $\chi^{2}$ of the $v A$ data rise from 4192 for $w=\infty$ to 4710 for $w=1 / 7$. Finally, comparing the results obtained with the $w=0$ and the $w=\infty$ fits one can see that they predict considerably different $x$-shapes.

The fits with weights $w=\left\{\frac{1}{7}, \frac{1}{2}, 1\right\}$ interpolate between these two incompatible solutions. As can be seen in Fig. 1a, b, with increasing weight the description of the $\ell F e$ data is worsened in favor of a better agreement with the $\nu \mathrm{Fe}$ points. This trend clearly demonstrates that the $\ell F e$ and the $\nu \mathrm{Fe}$ data pull in opposite directions. We identify the fits with $w=1 / 2$ or $w=1$ as the best candidates for a possible compromise.

To be able to decisively accept or reject the compromise fits, we apply a statistical goodness-of-fit criterion $[9,13,19]$ based on the probability distribution for the $\chi^{2}$ given that the fit has $N$ degrees of freedom:

$$
\begin{equation*}
P\left(\chi^{2}, N\right)=\frac{\left(\chi^{2}\right)^{N / 2-1} e^{-\chi^{2} / 2}}{2^{N / 2} \Gamma(N / 2)} \tag{2}
\end{equation*}
$$

This allows us to define the percentiles $\xi_{p}$ via $\int_{0}^{\xi_{p}} P\left(\chi^{2}, N\right) d \chi^{2}=p \%$ where $p=\{50,90,99\}$. Here, $\xi_{50}$ serves as an estimate of the mean of the $\chi^{2}$ distribution and $\xi_{90}$, for example, gives us the value where there is only a $10 \%$ probability that a fit with $\chi^{2}>\xi_{90}$ genuinely describes the given set of data. In a global PDF fit, the best fit $\chi^{2}$ value often deviates from the mean value because the data come from different possibly incompatible experiments having unidentified, unknown errors which are not accounted for in the experimental

[^80]systematic errors. For this reason we rescale the $\xi_{90}$ and $\xi_{99}$ percentiles relative to the best fit $\chi_{0}^{2}$ [19] to define $C_{90}=\chi_{0}^{2}\left(\xi_{90} / \xi_{50}\right)$ and $C_{99}=\chi_{0}^{2}\left(\xi_{99} / \xi_{50}\right)$. This defines our criterion: a fit with a given $\chi^{2}$ is compatible with the best fit with $\chi_{0}^{2}$ at $90 \%(99 \%)$ confidence if $\chi^{2}<C_{90}\left(\chi^{2}<C_{99}\right)$. We apply it to both the total $\chi^{2}$ and the $\chi^{2}$ of the individual data sets.

For the $\ell A$ DIS+DY data we use the fit with $w=0$ as benchmark with $\chi_{0}^{2}=638$ and $N=677$ degrees of freedom (for 708 data points and 31 free parameters). The upper limits on the $\chi^{2}$ at $90 \%$ and $99 \%$ confidence level (C.L.) are then $C_{90}^{l^{ \pm} A}=683.6$ and $C_{99}^{l^{ \pm} A}=722.2$. The benchmark fit for the $\nu A$ DIS data $(w=\infty)$ uses 3,134 data points with 33 free parameters resulting in $N=3,101$ and one finds $C_{90}^{\nu A}=4,330$ and $C_{99}^{\nu A}=4,445$. We see that none of the compromise fits satisfies both limits at the $90 \%$ C.L. which is usually used in global analyses of PDFs to define the uncertainty bands. At the $99 \%$ C.L., there are two fits ( $w=1 / 2, w=1$ ) which are below the $C_{99}^{\nu A}$ limit. However, only the $w=1 / 2$ fit satisfies the corresponding constraint from the charged-lepton benchmark fit.

We now apply our criterion also to the individual data sets with IDs between 1 and 40 in Table 1 . For the $\ell A$ DIS + DY data (ID $=[1,31]$ ) we determine the $31 C_{90}\left(C_{99}\right)$ limits by using the individual $\chi_{i}^{2}$ of the $w=0$ fit as $\chi_{0, i}^{2}$. For the $\nu A$ DIS data (ID $=[32,40]$ ) we proceed in a similar manner using the individual $\chi_{i}^{2}$ of the $w=\infty$ fit. The results of this detailed analysis are depicted in Fig. 2, where we show the quantity

$$
\begin{equation*}
\frac{\Delta \chi^{2}}{\Delta C_{90}}=\frac{\chi_{i}^{2}-\chi_{0, i}^{2}}{C_{90, i}-\chi_{0, i}^{2}} \quad(i=1, \ldots, 40) \tag{3}
\end{equation*}
$$

where $\chi_{i}^{2}$ represents the $\chi^{2}$-value of the $i$ 'th data set. In cases where $\chi_{i}^{2}>C_{90, i}$ the fit is not compatible with the best fit at the $90 \%$ level and $\Delta \chi^{2} / \Delta C_{90}>1$. The exact $90 \%$ C.L. limit is shown as a constant solid line and the dotted line represents the $99 \%$ confidence limit. The local application of the $\chi^{2}$ hypothesis-testing criterion reveals that even the compromise fit with weight $w=\frac{1}{2}$ which was considered acceptable at the $99 \%$ C.L. when looking at the nuclear correction factors and at the global change in $\chi^{2}$, cannot be accepted as a compromise solution as both the charged-lepton and neutrino DIS data on iron exceed the $99 \%$ limit.

In conclusion, the tension between the $\ell^{ \pm} F e$ and $\nu F e$ data sets leaves us with no possible compromise fit when investigating the results in detail, not even when using the $99 \%$ percentile as the limit as opposed to the more restrictive $90 \%$ limit which is usually used to construct the error PDFs. This detailed analysis confirms the preliminary conclusions of Refs. [16,17] that there is no possible compromise fit which adequately describes the neutrino DIS data along with the charged-lepton DIS and DY data.

At face value, this conclusion differs from some results in the literature which argue the $v A$ and $\ell^{ \pm} A$ data are in accord. [15] Here, we believe an essential element in our analysis is the use of the correlated systematic errors of the $\nu A$ data. To highlight this point, we now repeat our analysis, but we combine the statistical and all systematic errors in quadrature (thereby neglecting the information contained in the correlation matrix) for $v A$ data for the $w=1$ fit with $Q^{2}>4 \mathrm{GeV}^{2}$ (as before); we denote this the "Ucor4" fit, and we obtain $\chi^{2} / p t$ of 1.14 for $\ell^{ \pm} A$ and 1.00 for $v A$. We also use a $Q^{2}>5 \mathrm{GeV}^{2}$ fit (denoted "Ucor5") to mimic the cuts of Ref. [15]; here we obtain $\chi^{2} / p t$ of $721 / 633=1.14$ for $\ell^{ \pm} A$ and $2,828 / 2,947=0.96$ for $v A$.

If we examine the total $\chi^{2}$ values, we find the $\chi^{2} / \operatorname{dof} \sim 1$, and might be tempted to conclude we are able to fit both the $v A$ and $\ell^{ \pm} A$ data simultaneously. However, if we look at individual data sets and apply

Fig. $2 \Delta \chi^{2} / \Delta C_{90}$ as defined in Eq. (3) for the 40 individual data sets. Results are shown for the $w=\frac{1}{2}$-fit (left) and the fit 'Ucor5' (right) with $w=1$. The solid and dashed lines indicate the $90 \%$ and $99 \%$ confidence limits. The highlighted data sets correspond to the DIS NuTeV $\ell^{ \pm} F e(\mathrm{ID}=8), v F e(\mathrm{ID}=35)$, and $\bar{v} F e(\mathrm{ID}=36)$
our hypothesis testing criteria, the picture is quite different. Fig. 2b displays the results for the Ucor5 fit. The higher $Q^{2}$ cut of the Ucor5 fit removes some of the very precise NuTeV data at small-x, thus resulting in an improved $\chi^{2}$ compared to Ucor4. Nevertheless, many of the $\ell^{ \pm} F e$ data sets (ID $=3,4,5,6,8$ ) still lie outside the $99 \%$ CL percentile. ${ }^{2}$ Thus, we still conclude that there is no compromise fit for the $\nu A$ and $\ell^{ \pm} A$ data even if we relax the constraints by using uncorrelated errors.

Consequently, the nuclear correction factor for the neutrino DIS data are indeed incompatible with that of the charged lepton DIS and DY data, and this result depends crucially on the use of the precision correlated errors of the neutrino data. This result has important implications for both nuclear and proton PDFs. If we do not know the appropriate nuclear correction to relate different targets of nuclear $A$, our ability to extract PDFs is limited. For example, the CTEQ6.6 analysis [14] sidesteps this issue by removing most of the $\nu A$ data from the fit; however, they retain the NuTeV dimuon data since this data is critical to constraining the strange quark PDF. This underscores the importance of the $v A$ data for flavor differentiation.

Although the NuTeV data provides the tightest constraints due to their statistics, we note that this issue cannot be tied to a single data set. For example, we find that NuTeV is generally compatible with CCFR and CDHSW. ${ }^{3}$ The CHORUS $v P b$ and $\bar{\nu} P b$ data have larger uncertainties, so they can be compatible with both the $\ell^{ \pm} A$ data and the NuTeV $\nu F e$ data because the $\Delta \chi^{2} / \Delta C_{90}<1$ for all weights. Compared to the theory predictions, NuTeV agrees well in the central $x$ region, but exhibits differences both for low $x$ at low $Q^{2}$, and also for very high $x(x \sim 0.65)$.

## 2 Conclusions

We have demonstrated that the $v A$ and $\ell^{ \pm} A$ data prefer different nuclear correction factors, and that there is no single "compromise" result that will simultaneously satisfy both data sets. While we have focused on the phenomenological aspects for the present study, this result has strong implications for the extraction of both nuclear and proton PDFs using combined neutrino and charged-lepton data sets. Possibilities include unexpectedly large higher-twist effects, or even non-universal nuclear effects; we leave such questions for a future study.

## 3 nCTEQ PDF Sets Available On-line

The nCTEQ PDF sets are available on-line at the HepForge repository (http://projects.hepforge.org/ncteq/). This repository contains the 19 families of PDFs used in Refs. [12, 16, 18], and each family contains PDF grids for a range of nuclei specified by the number of nucleons $(\mathrm{A})$ and the number of protons $(\mathrm{Z})$; in total there are 361 separate nuclear PDF grids. A sample Fortan program is included to demonstrate the use of these nuclear PDF sets.

Acknowledgments We thank Tim Bolton, Michiel Botje, Janet Conrad, Sasha Glazov, Andrei Kataev, Sergey Kulagin, Shunzo Kumano, Dave Mason, W. Melnitchouk, Donna Naples, Roberto Petti, Voica A. Radescu, Mary Hall Reno, and Martin Tzanov for valuable discussions. F.I.O., I.S., and J.Y.Y. acknowledge the hospitality of Argonne, BNL, CERN, Fermilab, and Les Houches where a portion of this work was performed. This work was partially supported by the U.S. Department of Energy under grant DE-FG02-04ER41299, contract DE-FG02-97IR41022, contract DE-AC05-06OR23177 (under which Jefferson Science Associates LLC operates the Thomas Jefferson National Accelerator Facility), the National Science Foundation grant 0400332, and the Lightner-Sams Foundation. We study nuclear effects of charged current deep inelastic neutrino-iron scattering in the framework of a $\chi^{2}$ analysis of parton distribution functions (PDFs). A set of iron PDFs are extracted and used to compute $x_{B j}$ dependent and $Q^{2}$-dependent nuclear correction factors which are required in global analyses of free nucleon PDFs. We compare our results with nuclear correction factors from neutrino-nucleus scattering models and correction factors for $\ell^{ \pm}$-iron scattering. Except for very high $x_{B j}$, our correction factors differ in both shape and magnitude from the correction factors of the models and charged-lepton scattering.

## 1. Impact of Nuclear Corrections on PDFs

The high statistics measurements of neutrino deeply inelastic scattering (DIS) on heavy nuclear targets has generated significant interest in the literature since these measurements provide valuable information for global fits of parton distribution functions (PDFs). It is necessary to use both Charged Current (CC) $W^{ \pm}$probes and Neutral Current (NC) $\{\gamma, Z\}$ probes to disentangle the separate PDF flavor components. Toward this goal, the use of nuclear targets is unavoidable due to the weak nature of the $\left\{W^{ \pm}, Z\right\}$ interactions, and this complicates the extraction of free nucleon PDFs because model-dependent corrections must be applied to the data.

In early PDF analyses, the nuclear corrections were static correction factors without any (significant) dependence on the energy scale $Q$, the atomic number $A$, or the specific observable. The increasing precision of both the experimental data and the extracted PDFs demand that the applied nuclear correction factors be equally precise as
these contributions play a crucial role in determining the PDFs.
In this study we reexamine the source and size of the nuclear corrections that enter the PDF global analysis, and quantify the associated uncertainty. Additionally, we provide the foundation for including the nuclear correction factors as a dynamic component of the global analysis so that the full correlations between the heavy and light target data can be exploited.

A recent study [1] analyzed the impact of new data sets from the NuTeV, Chorus; and E-866 Collaborations on the PDFs. This study found that the NuTeV data set (together with the model used for the nuclear corrections) pulled against several of the other data sets, notably the E-866, BCDMS and NMC sets. Reducing the nuclear corrections at large values of $x$ reduced the severity of this pull and resulted in improved $\chi^{2}$ values. These results suggest on a purely phenomenological level that the appropriate nuclear corrections for $\nu$-DIS may well be smaller than assumed.

[^82]
## 2. Global Analysis Framework

To investigate this question further, we use the high-statistics $\nu$-DIS experiments to perform a dedicated PDF fit to neutrino-iron data [2]. Since we first will study iron alone and will not (initially) combine the data with measurements on different target materials, we need not make any assumptions about the nuclear corrections; this side-steps a number of difficulties $[3,1,4]$. While this approach has the advantage that we do not need to model the $A$-dependence, it has the drawback that the data from just one experiment will not be sufficient to constrain all the parton distributions; therefore, other assumptions must enter the analysis. The theoretical framework will roughly follow the CTEQ6 analysis of free proton PDFs [5]. We outline the key features of our analysis below, and focus on the issues specific to our study of NuTeV neutrino-iron data in terms of nuclear parton distribution functions.

### 2.1. Basic formalism

For our PDF analysis, we will use the general features of the QCD-improved parton model and the $\chi^{2}$ analyses as outlined in Ref. [5]. We adopt the framework of the recent CTEQ6 analysis of proton PDFs where the input distributions at the scale $Q_{0}=1.3 \mathrm{GeV}$ are parameterized as
$x f_{i}\left(x, Q_{0}\right)=A_{0} x^{A_{1}}(1-x)^{A_{2}} e^{A_{3} x}\left(1+e^{A_{4}} x\right)^{A_{5}}$
for $i=\left\{u_{v}, d_{v}, g, \bar{u}+\bar{d}, s, \bar{s}\right\}$, and
$x f_{i}\left(x, Q_{0}\right)=A_{0} x^{A_{1}}(1-x)^{A_{2}}+\left(1+A_{3} x\right)(1-x)^{A_{4}}$
for $i=\{\bar{d} / \bar{u}\}$ where $u_{v}$ and $d_{v}$ are the up- and down-quark valence distributions, $\bar{u}, \bar{d}, s, \bar{s}$ are the up, down, strange and anti-strange sea distributions, and $g$ is the gluon. Furthermore, the $f_{i}=f_{i}^{p / A}$ denote parton distributions of bound protons in the nucleus $A$, and the variable $0 \leq x \leq A$ is defined as $x:=A x_{A}$ where $x_{A}=Q^{2} / 2 p_{A} \cdot q$ is the usual Bjorken variable formed out of the four-momenta of the nucleus and the exchanged boson. This parameterization is designed for $0 \leq x \leq 1$ and we here neglect ${ }^{2}$ the

[^83]distributions at $x>1$. Note that the condition $f_{i}(x>1, Q)=0$ is preserved by the DGLAP evolution and has the effect that the evolution equations and sum rules for the $f_{i}^{p / A}$ are the same as in the free proton case.

The PDFs for a nucleus $(A, Z)$ are constructed as
$f_{i}^{A}(x, Q)=\frac{Z}{A} f_{i}^{p / A}(x, Q)+\frac{(A-Z)}{A} f_{i}^{n / A}(x, Q)$
where we relate the distributions inside a bound neutron, $f_{i}^{n / A}(x, Q)$, to the ones in a proton by assuming isospin symmetry. The nuclear structure functions are given by parallel relations such that they can be computed in next-to-leading order as convolutions of the nuclear PDFs with the conventional Wilson coefficients, i.e., generically $F_{i}^{A}(x, Q)=\sum_{k} C_{i k} \otimes f_{k}^{A}$.

In order to take into account heavy quark mass effects we calculate the relevant structure functions in the ACOT scheme [11, 12] in NLO QCD [13]. Finally, the differential cross section for charged current (anti-)neutrino-nucleus scattering is given in terms of three structure functions:

$$
\begin{aligned}
& \frac{d^{2} \sigma}{d x d y} \stackrel{(-)}{\nu} A=\frac{G_{F}^{2} M E}{\pi}\left[\left(1-y-\frac{M x y}{2 E}\right) F_{2}^{(-)} A\right. \\
&+\frac{y^{2}}{2} 2 x F_{1}^{(-)} A \\
& \nu
\end{aligned}
$$

where the '+' ('-') sign refers to neutrino (antineutrino) scattering and where $G_{F}$ is the Fermi constant, $M$ the nucleon mass; and $E$ the energy of the incoming lepton (in the laboratory frame).

### 2.2. Methodology

The basic formalism described in the previous sections is implemented in a global PDF fitting package, but with the difference that no nuclear corrections are applied to the analyzed data; hence, the resulting PDFs are for a bound proton in an iron nucleus. The parameterization provides enough flexibility to describe current data sets entering a global analysis of free nucleon PDFs; given that the nuclear modifications of the $x$-shape appearing in this analysis are modest, this parameterization will also accommodate the iron PDFs.

Because the neutrino data alone do not have the power to constrain all of the PDF components, we will need to impose some minimal set of external constraints. For example, our results are rather insensitive to the details of the gluon distribution with respect to both the overall $\chi^{2}$ and also the effect on the quark distributions. The nuclear gluon distribution is very weakly constrained by present data, and a gluon PDF with small nuclear modifications has been found in the NLO analysis of Ref. [14]. We have therefore fixed the gluon input parameters to their free nucleon values. For the same reasons the gluon is not sensitive to this analysis, fixing the gluon will have minimal effect on our results. Furthermore, we have set the $\bar{d} / \bar{u}$ ratio to the free nucleon result assuming that the nuclear modifications to the down and up sea are similar such that they cancel in the ratio. This assumption is supported by Fig. 6 in Ref. [14].

## 3. Analysis of iron data

### 3.1. Iron Data Sets

We determine iron PDFs using the recent NuTeV differential neutrino and anti-neutrino DIS cross section data [15]. In addition, we include NuTeV/CCFR dimuon data [16] which are sensitive to the strange quark content of the nucleon. There are other measurements of neutrino-iron DIS available in the literature from the CCFR [17, 18, 19, 20]; CDHS [21] and CDHSW [22] collaborations; see, e.g., Ref. [23] for a review. There is also a wealth of charged lepton-iron DIS data including SLAC [24] and EMC $[25,26] .{ }^{3}$ For the initial study we limit our analysis to the NuTeV experiment alone; we will compare and contrast different experiments in a subsequent study.

### 3.1.1. PDF Reference Sets

For the purposes of this study, we use two different reference sets of free-proton PDFs which we denote 'Base-1' and 'Base-2'.

Since we focus on iron PDFs and the associated nuclear corrections, we need a base set of PDFs

[^84]which are essentially free of any nuclear effects; this is the purpose of the Base-1 reference set [1]. Therefore, to extract the Base-1 PDFs we omit the CCFR and NuTeV data from our fit so that our base PDFs do not contain any large residual nuclear corrections. ${ }^{4}$ The absence of such nuclear effects will be important when we extract the nuclear corrections factors.
The Base-2 PDFs are essentially the CTEQ6.1M PDFs with a modified strange PDF introduced to accommodate the NuTeV dimuon data. ${ }^{5}$ In the manner of the CTEQ6.1M PDF's, the Base-2 fit does not apply any deuteron corrections to the data; this is in contrast to the Base-1 PDFs. Also, the Base-2 fit does include the CCFR data that has been corrected to a free nucleon using charged-lepton correction factors [20].
By comparing the free-proton PDF 'Base-1' and 'Base-2' sets with the iron PDF sets, we can gauge the size of the nuclear effects. Furthermore, differences between observables using the 'Base-1' respectively the 'Base-2' reference sets will indicate the uncertainty due to the choice of the freeproton PDF.

### 3.1.2. Comparison of the Fits with Data

Specifically, we determine iron PDFs using the recent NuTeV differential neutrino ( 1371 data points) and anti-neutrino (1146 data points) DIS cross section data [15]. and we include NuTeV/CCFR dimuon data (174 points) which are sensitive to the strange quark content of the nucleon. Using the ACOT scheme, we impose kinematic cuts of $Q>2 \mathrm{GeV}$ and $W>3.5 \mathrm{GeV}$, and obtain a good fit with a $\chi^{2}$ of 1.35 per data point; we identify this fit as 'A2.'[2]

[^85]
### 3.2. Iron PDFs

We now examine the nuclear (iron) parton distributions $f_{i}^{A}\left(x, Q^{2}\right)$ in Figure 1 which shows the PDFs from fit 'A2' at our input scale $Q_{0}=m_{c}=$ 1.3 GeV versus $x$. For an almost isoscalar nucleus like iron the $u$ and $d$ distributions are very similar. Therefore, we only show the $u_{v}$ and $\bar{u}$ partons, together with the strange sea. ${ }^{6}$ As explained above, the gluon distribution is very similar to the familiar CTEQ6M gluon at the input scale such that we don't show it here. In order to indicate the constraining power of the NuTeV data, the band of reasonable fits is depicted. The fits in this band were obtained (as outlined above) by varying the initial conditions and the number of free parameters to fully explore the solution space. All the fits shown in the band have $\chi^{2} / D O F$ within 0.02 , which roughly corresponds to a range of $\Delta \chi^{2} \sim 50$ for the 2691 data points.

As can be seen in Figure 1, the $u_{v}$ distribution has a very narrow band across the entire $x$ range. The up- and strange-sea distributions are less precisely determined. At values of $x$ down to, say, $x \simeq 0.07$ the bands are still reasonably well confined; however, they open up widely in the small- $x$ region. Cases where the strange quark sea lies above the up-quark sea are unrealistic, but are present in some of the fits since this region ( $x \lesssim 0.02$ ) is not constrained by data. We have included the curves for our free-proton Base-1 PDFs (dashed), as well as the HKN04 [7] (dotted), the NLO HKN07 [8] (dotted-dashed), and DS [14] (dot-dashed) nuclear PDFs. ${ }^{7}$

The comparison with the Base-1 PDFs is straightforward since the same theoretical framework (input scale, functional form, NLO evolution) has been utilized for their determination. Therefore, the differences between the solid band

[^86]

Figure 1. Parton distributions for iron. The central PDF from fit 'A2' is shown by the solid line. The dashed lines depict parton distributions constructed according to Eq. 1 with $A=56$ and $Z=26$ using the Base- 1 free-proton PDFs. Additional results are shown from HKNO4 [7]; (NLO) HKN07 [8], and (DS) [14]. The vertical line marks the lower limit of the data in the $x$ variable.
('A2') and the dashed line (Base-1) exhibit the nuclear effects, keeping in mind that the freeproton PDFs themselves have uncertainties.

For the comparison with the HKN04 distributions, it should be noted that a $\mathrm{SU}(3)$-flavor symmetric sea has been used; therefore, the HKN04 strange quark distribution is larger, and the light quark sea smaller, than their Base-1 PDF counterparts over a wide range in $x$. Furthermore, the HKN04 PDFs are evolved at leading order.

In a recent analysis, the HKN group has published a new set of NPDFs (HKN07) including uncertainties [8]. They provide both LO and NLO sets of PDFs, and we display the NLO set. These PDFs also use a more general set of sea distributions such that $\bar{u}(x) \neq \bar{d}(x) \neq \bar{s}(x)$ in general.

The DS PDFs are linked to the GRV98 PDFs [27] with a rather small radiatively generated strange sea distribution. Consequently, the light quark sea is enhanced compared to the other sets. Additionally, the DS sets are evolved in a 3-fixedflavor scheme in which no charm parton is included in the evolution. However, at the scale $Q=m_{c}$ of Fig. 1 this is of no importance.

## 4. Nuclear Correction Factors

In the previous section we analyzed charged current $\nu-\mathrm{Fe}$ data with the goal of extracting the iron nuclear parton distribution functions. In this section, we now compare our iron PDFs with the free-proton PDFs (appropriately scaled) to infer the proper heavy target correction which should be applied to relate these quantities.

Within the parton model, a nuclear correction factor $R[\mathcal{O}]$ for an observable $\mathcal{O}$ can be defined as follows:
$R[\mathcal{O}]=\frac{\mathcal{O}[\mathrm{NPDF}]}{\mathcal{O}[\text { free }]}$
where $\mathcal{O}[\mathrm{NPDF}]$ represents the observable computed with nuclear PDFs, and $\mathcal{O}$ [free] is the same observable constructed out of the free nucleon PDFs. Clearly, $R$ can depend on the observable under consideration simply because different observables may be sensitive to different combinations of PDFs.

This means that the nuclear correction factor $R$ for $F_{2}^{A}$ and $F_{3}^{A}$ will, in general, be different. Additionally, the nuclear correction factor for $F_{2}^{A}$ will yield different results for the charged current
$\nu-F e$ process ( $W^{ \pm}$exchange) as compared with the neutral current $\ell^{ \pm}-F e$ process ( $\gamma$ exchange). Schematically, we can write the nuclear correction for the DIS structure function $F_{2}$ in a charged current (CC) $\nu-A$ process as: ${ }^{8}$
$R_{C C}^{\nu}\left(F_{2} ; x, Q^{2}\right) \simeq \frac{d^{A}+\bar{u}^{A}+\ldots}{d^{\emptyset}+\bar{u}^{\emptyset}+\ldots}$
and contrast this with the neutral current (NC) $\ell^{ \pm}-A$ process:

$$
\begin{aligned}
& \quad R_{N C}^{e, \mu}\left(F_{2} ; x, Q^{2}\right) \simeq \\
& \frac{\left(-\frac{1}{3}\right)^{2}\left[d^{A}+\bar{d}^{A}+\ldots\right]+\left(+\frac{2}{3}\right)^{2}\left[u^{A}+\bar{u}^{A}+\ldots\right]}{\left(-\frac{1}{3}\right)^{2}\left[d^{\emptyset}+\bar{d}^{\emptyset}+\ldots\right]+\left(+\frac{2}{3}\right)^{2}\left[u^{\emptyset}+\bar{u}^{\emptyset}+\ldots\right]},
\end{aligned}
$$

where the superscript " 0 " denotes the "free nucleon" PDF which is constructed via the relation:
$f_{i}^{\emptyset}(x, Q)=\frac{Z}{A} f_{i}^{p}(x, Q)+\frac{(A-Z)}{A} f_{i}^{n}(x, Q)$
Clearly, the $R$-factors depend on both the kinematic variables and the factorization scale. Finally, we note that Eq. 2 is subject to uncertainties of both the numerator and the denominator.
We will now evaluate the nuclear correction factors for our extracted PDFs, and compare these with selected results from the literature [28, 29]. ${ }^{9}$ Because we have extracted the iron PDFs from only iron data, we do not assume any particular form for the nuclear $A$-dependence; hence the extracted $R[\mathcal{O}]$ ratio is essentially model independent.

## 4.1. $F_{2}^{F e} / F_{2}^{D} \mathrm{NC}$ charged lepton scattering

We will also find it instructive to compare our results with the $F_{2}^{\mathrm{Fe}} / F_{2}^{\mathrm{D}}$ as extracted in neutral current charged-lepton scattering; $\ell^{ \pm}-F e$. In Fig. 2 we compare the experimental results for the structure function ratio $F_{2}^{\mathrm{Fe}} / F_{2}^{\mathrm{D}}$ for the following experiments: BCDMS-85 [30], BCDMS-87 [31], SLAC-E049 [32], SLAC-E139 [3], SLAC-140 [24]. The curve (labeled SLAC/NMC parameterization) is a fit to this data. While there is

[^87]

Figure 2. Parameterization for the neutral current charged lepton structure function $F_{2}^{F e} / F_{2}^{D}$. For comparison we show experimental results from the BCDMS collaboration (BCDMS-85 [30]; BCDMS-87 [31]) and from experiments at SLAC (SLAC-E049 [32], SLAC-E139 [3], and SLACE140 [24]). Normalization uncertainties of the data have not been included.
a spread in the individual data points, the parameterization describes the bulk of the data at the level of a few percent or better. It is important to note that this parameterization is independent of atomic number $A$ and the energy scale $Q^{2}$ [33]; this is in contrast to the results we will derive using the PDFs extracted from the nuclear data. ${ }^{10}$ Additionally, we note that while this parameterization has been extracted using ratios of $F_{2}$ structure functions, it is often applied to other observables such as $F_{1,3, L}$ or $d \sigma$. We can use this parameterization as a guide to judge the approximate correspondence between this neutral current (NC) charged lepton DIS data and our charged current (CC) neutrino DIS data.

### 4.2. R Factors for $d^{2} \sigma / d x d Q^{2}$

We begin by computing the nuclear correction factor $R$ according to Eq. (2) for the neutrino differential cross section as this represents the bulk

[^88]

Figure 3. Nuclear correction factor $R$ for the differential cross section $d^{2} \sigma / d x d Q^{2}$ in charged current neutrino-Fe scattering at $Q^{2}=5 \mathrm{GeV}^{2}$. Results are shown for the charged current neutrino (solid lines) and anti-neutrino (dashed lines) scattering from iron. The upper (lower) pair of curves shows the result of our analysis with the Base-2 (Base-1) free-proton PDFs.
of the NuTeV data included in our fit. More precisely, we show $R$-factors for the charged current cross sections $d^{2} \sigma / d x d Q^{2}$ at fixed $Q^{2}$. Our results are displayed in Fig. 3 for $Q^{2}=5 \mathrm{GeV}^{2}$ and a neutrino energy $E_{\nu}=150 \mathrm{GeV}$ which implies, due to the relation $Q^{2}=2 M E_{\nu} x y$, a minimal $x$ value of $x_{\text {min }}=0.018$. The solid (dashed) lines correspond to neutrino (anti-neutrino) scattering using the iron PDFs from the 'A2' fit.

We have computed $R$ using both the Base-1 and Base-2 PDFs for the denominator of Eq. (2); recall that Base-1 includes a deuteron correction while Base-2 uses the CCFR data and does not include a deuteron correction. The difference between the Base-1 and Base-2 curves is approximately $2 \%$ at small $x$ and grows to $5 \%$ at larger $x$, with Base-2 above the Base- 1 results. The difference of these curves, in part, reflects the uncertainty introduced by the proton PDF [2]. As this behavior is typical, in the following plots (Figs. 4) we will only show the Base-1 results. We also observe that the neutrino (anti-neutrino) results coincide in the region of large $x$ where the valence

Figure 4. Nuclear correction factor $R$ for the structure function $F_{2}$ in neutrino and anti-neutrino scattering from Fe for $Q^{2}=\{5,20\} \mathrm{GeV}^{2}$. The solid curve shows the result of our analysis of NuTeV data; the uncertainty from the fit is represented by the shaded (yellow) band. For comparison we show the correction factor from the Kulagin-Petti model (dashed-dot line) [28], HKN07 (dashed-dotted line) [8], and the SLAC/NMC parametrization (dashed line).

PDFs are dominant, but differ by a few percent at small $x$ due to the differing strange and charm distributions.
4.3. $\mathbf{R}$ Factors for $F_{2}^{\nu}\left(x, Q^{2}\right)$ and $F_{2}^{\bar{\nu}}\left(x, Q^{2}\right)$

We now compute the nuclear correction factors for charged current neutrino-iron scattering. The results for $\nu-F e$ and those of $\bar{\nu}-F e$ are shown in Fig. 4. The numerator in Eq. 2 has been computed using the nuclear PDF from fit ' A 2 ', and for the denominator we have used the Base-1 PDFs. For comparison we also show the correction factor from the Kulagin-Petti model [28, 29] (dashed-dotted), and the SLAC/NMC curve (dashed) which has been obtained from an
$A$ and $Q^{2}$-independent parameterization of calcium and iron charged-lepton DIS data.

Due to the neutron excess in iron, both our curves and the KP curves differ when comparing scattering for neutrinos and anti-neutrinos; the SLAC/NMC parameterization is the same in both figures. For our results (solid lines), the difference between the neutrino and anti-neutrino results is relatively small, of order $3 \%$ at $x=0.6$. Conversely, for the KP model (dashed-dotted lines) the $\nu-\bar{\nu}$ difference reaches $10 \%$ at $x \sim 0.7$, and remains sizable at lower values of $x$.

To demonstrate the dependence of the $R$ factor on the kinematic variables, in Fig. 4 we have plotted the nuclear correction factor for two sep-
arate values of $Q^{2}$. Again, our curves and the KP model yield different results for different $Q^{2}$ values, in contrast to the SLAC/NMC parameterization.
Comparing the nuclear correction factors for the $F_{2}$ structure function with those obtained for the differential cross section (Fig. 3), we see these are quite different, particularly at small $x$. Again, this is because the cross section $d^{2} \sigma$ is comprised of a different combination of PDFs than the $F_{2}$ structure function. In general, our $R$-values for $F_{2}$ lie below those of the corresponding $R$-values for the cross section $d \sigma$ at small $x$. Since $d \sigma$ is a linear combination of $F_{2}$ and $F_{3}$, the $R$-values for $F_{3}$ (not shown) therefore lie above those of $F_{2}$ and $d \sigma$. Again, we emphasize that it is important to use an appropriate nuclear correction factor which is matched to the particular observable.

As we observed in the previous section, our results have general features in common with the KP model and the SLAC/NMC parameterization, but the magnitude of the effects and the $x$-region where they apply are quite different. Our results are noticeably flatter than the KP and SLAC/NMC curves, especially at moderate$x$ where the differences are significant. The general trend we see when examining these nuclear correction factors is that the anti-shadowing region is shifted to smaller $x$ values and any turnover at low $x$ is minimal given the PDF uncertainties. In general, these plots suggest that the size of the nuclear corrections extracted from the NuTeV data are smaller than those obtained from charged lepton scattering (SLAC/NMC) or from the set of data used in the KP model. We will investigate this difference further in the following section.

## 4.4. $F_{2}^{F e} / F_{2}^{D}$ from Iron PDFs

Since the SLAC/NMC parameterization was fit to $F_{2}^{F e} / F_{2}^{D}$ for charged-lepton DIS data, we can perform a more balanced comparison by using our iron PDFs to compute this same quantity. The results are shown in Fig. 5 where we have used our iron PDFs to compute $F_{2}^{F e}$, and the Base-1 and Base-2 PDFs to compute $F_{2}^{D}$.

As with the nuclear correction factor results

Figure 5. Predictions (solid and dashed line) for the structure function ratio $F_{2}^{F e} / F_{2}^{D}$ using the iron PDFs extracted from fits to NuTeV neutrino and anti-neutrino data. The SLAC/NMC parameterization is shown with the dot-dashed line. The structure function $F_{2}^{D}$ in the denominator has been computed using either the Base-2 (solid line) or the Base-1 (dashed line) PDFs.
of the previous section, we find our results have some gross features in common while on a more refined level the magnitude of the nuclear corrections extracted from the CC iron data differs from the charged lepton data. In particular, we note that the so-called "anti-shadowing" enhancement at $x \sim[0.06-0.3]$ is not reproduced by the charged current (anti-)neutrino data. Examining our results among all the various $R[\mathcal{O}]$ calculations, we generally find that any nuclear enhancement in the small $x$ region is reduced and shifted to a lower $x$ range as compared with the SLAC/NMC parameterization. Furthermore, in the limit of large $x$ ( $x \gtrsim 0.6$ ) our results are slightly higher than the data, including the very precise SLAC-E139 points; however, the large theoretical uncertainties on $F_{2}^{D}$ in this $x$-region make it difficult to extract firm conclusions.
This discussion raises the more general question as to whether the charged current ( $\nu-F e$ ) and neutral current ( $\ell^{ \pm}-F e$ ) correction factors are entirely compatible $[15,34,35,36,37,38]$. There is a priori no requirement that these be equal; in fact, given that the $\nu-F e$ process in-
volves the exchange of a $W$ and the $\ell^{ \pm}-F e$ process involves the exchange of a $\gamma$ we necessarily expect this will lead to differences at some level. ${ }^{11}$

### 4.5. Future Studies

It is important to resolve whether the differences we observe in Fig. 5 arise from the uncertainty of the nuclear corrections, or if they are genuinely a consequence of $\mathrm{NC} / \mathrm{CC}$ effects. A combined analysis of CC neutrino and NC charged-lepton data sets will shed more light on these issues. To best address these questions, we need to include the nuclear dimension (parameterized by the nuclear A value) as a dynamic component of the global fit; this will allow us to fit both the CC $W^{ \pm}$-exchange processes at large A, as well as the the NC $\gamma$-exchange processes at small A in a coherent framework. Figure 6 presents an an illustrative example of how the PDFs can be extended to incorporate the necessary A dependence to implement such a program. This extended analysis with additional data sets is in progress, and should help clarify these questions.

Figure 6. Illustration of the gluon $\operatorname{PDF} x f_{g}^{A}(x, \mu)$ vs. $x$ as a function of the nuclear $A$. At small $x$ the lower curves correspond to larger A values.

[^89]
## 5. CONCLUSIONS

While the nuclear corrections extracted from charged current $\nu-F e$ scattering have similar characteristics as the neutral current $l^{ \pm}-F e$ charged-lepton results, the detailed $x$ and $Q^{2}$ behavior is quite different. This observation raises the deeper question as to whether the charged current and neutral current nuclear correction factors may be substantially different. This present study of the iron PDFs provides a foundation for a general investigation (involving a variable A parameter) that can definitively address this topic. Resolving these questions is essential if we are to reliably use the plethora of nuclear data to obtaining free-proton PDFs which form the basis of the LHC analyses.

(Received 23 July 2009; published 5 November 2009)

#### Abstract

We perform a $\chi^{2}$ analysis of nuclear parton distribution functions (NPDFs) using neutral current charged-lepton ( $\ell^{ \pm} A$ ) deeply inelastic scattering (DIS), and Drell-Yan data for several nuclear targets. The nuclear $A$ dependence of the NPDFs is extracted in a next-to-leading order fit. We compare the nuclear corrections factors $\left(F_{2}^{F e} / F_{2}^{D}\right)$ for this charged-lepton data with other results from the literature. In particular, we compare and contrast fits based upon the charged-lepton DIS data with those using neutrino-nucleon DIS data.

DOI: 10.1103/PhysRevD.80.094004

## I. INTRODUCTION

## A. PDFs and nuclear corrections

Parton distribution functions (PDFs) are of supreme importance in contemporary high-energy physics as they are needed for the computation of reactions involving hadrons based on QCD factorization theorems [1-3]. For this reason various groups present global analyses of PDFs for protons [4-14] and nuclei [15-20] which are regularly updated in order to meet the increasing demand for precision. The PDFs are nonperturbative objects which must be determined by experimental input. To fully constrain the $x$ dependence and flavor dependence of the PDFs requires large data sets from different processes which typically include deeply inelastic scattering (DIS), Drell-Yan (DY), and jet production.

While some of this data is extracted from free protons, much is taken from a variety of nuclear targets. Because the neutrino cross section is so small, to obtain sufficient statistics for the neutrino-nuclear DIS processes it is necessary to use massive targets (e.g., iron, lead, etc.). Therefore, nuclear corrections are required if we are to include the heavy-target data into the global analysis of proton PDFs.

The heavy-target neutrino DIS data plays an important role in extracting the separate flavor components of the PDFs. In particular, this data set gives the most precise

[^90]PACS numbers: $12.38 .-\mathrm{t}$, 13.15.+g, 13.60. $-\mathrm{r}, 24.85 .+\mathrm{p}$
information on the strange quark PDF. As the strange quark uncertainty may limit the precision of particular Large Hadron Collider (LHC) $W$ and $Z$ measurements, the nuclear corrections and their uncertainties will have a broad impact on a comprehensive understanding of current and future data sets.

## B. Nuclear corrections in the literature

In previous PDF analyses [21,22], a fixed nuclear correction was applied to "convert" the data from a heavy target to a proton. As such, these nuclear correction factors were frozen at a fixed value. They did not adjust for the $Q^{2}$ scale or the physical observable $\left(F_{2}, F_{3}, \frac{d \sigma}{d x d y}\right)$, and they did not enter the PDF uncertainty analysis.

While this approach may have been acceptable in the past given the large uncertainties, improvements in both

FIG. 1. Nuclear correction ratio, $F_{2}^{F e} / F_{2}^{D}$, as a function of $x$. The parametrized curve is compared to SLAC and BCDMS data [23-29].
data and theory precision demand comparable improvements in the treatment of the nuclear corrections.

Figure 1 displays the $F_{2}^{F e} / F_{2}^{D}$ structure function ratio as measured by the SLAC and BCDMS collaborations. The SLAC/NMC curve is the result of an $A$-independent parametrization fit to calcium and iron charged-lepton DIS data [23-30]. This parametrization was used to convert heavy-target data to proton data, which then would be input into the global proton PDF fit. ${ }^{1}$ The SLAC/NMC parametrization was then applied to both charged-leptonnucleus and neutrino-nucleus data, and this correction was taken to be independent of the scale $Q$ and the specific observable $\left\{F_{2}, F_{3}, \ldots\right\}$. Recent work demonstrates that the parametrized approximation of Fig. 1 is not sufficient and it is necessary to account for these details [31-33].

## C. Outline

In this paper, we present a new framework for a global analysis of nuclear PDFs (NPDFs) at next-to-leading order (NLO). An important and appealing feature of this framework is that it naturally extends the proton analysis by endowing the free fit parameters with a dependence on the atomic number $A$. This will allow us to study proton and nuclear PDFs simultaneously such that nuclear correction factors needed for the proton analysis can be computed dynamically.

In Sec. II, we outline our method for the analysis, specify the DIS and DY data sets, and present the $\chi^{2}$ of our fit. In Sec. III, we compute the nuclear correction factors $\left(F_{2}^{F e} / F_{2}^{D}\right)$ for the fit to the $\ell^{ \pm} A$ and DY data. In Sec. IV, we compare these results to the nuclear correction factors $\left(F_{2}^{F e} / F_{2}^{D}\right)$ from the $\nu A$ fit of Ref. [33]. Finally, we summarize our results in Sec. V.

## II. NPDF GLOBAL ANALYSIS FRAMEWORK

## A. PDF analysis framework

In this section, we present the global analysis of NPDFs using charged-lepton DIS ( $l^{ \pm} A$ ) and Drell-Yan data to extend the analysis of Ref. [30] for a variety of nuclear targets. This analysis is performed in close analogy with what is done for the $A=1$ free proton case [34]. We will use the general features of the QCD-improved parton model and the $\chi^{2}$ analyses as outlined in Ref. [33]. The input distributions are parametrized as

$$
\begin{aligned}
x f_{k}\left(x, Q_{0}\right) & =c_{0} x^{c_{1}}(1-x)^{c_{2}} e^{c_{3} x}\left(1+e^{c_{4}} x\right)^{c_{5}} \\
k & =u_{v}, d_{v}, g, \bar{u}+\bar{d}, s, \bar{s}
\end{aligned}
$$

$\bar{d}\left(x, Q_{0}\right) / \bar{u}\left(x, Q_{0}\right)=c_{0} x^{c_{1}}(1-x)^{c_{2}}+\left(1+c_{3} x\right)(1-x)^{c_{4}}$,

[^91]at the scale $Q_{0}=1.3 \mathrm{GeV}$. Here, the $u_{v}$ and $d_{v}$ are the upand down-quark valence distributions, $\bar{u}, \bar{d}, s, \bar{s}$ are the antiup, antidown, strange, and antistrange sea distributions, and $g$ is the gluon.

We note that there is a new series of PDFs in the literature from the NNPDF Collaboration [4,5,12-14] which are generated using a neural network. This approach has the advantage that no initial $x$-dependent parametrization is required. In comparison to the ansatz of Eq. (1), the neural network approach generally yields wider error bands, particularly in the small- $x$ region. This reflects, in part, the fact that the small- $x$ region is dominantly controlled by the $c_{1}$ parameter of Eq. (1), and this parameter is constrained by data at moderate to small values of $x$. With sufficiently precise data the errors given, for example, by the Hessian technique, may well be small, leading to relatively small errors for the extrapolation of the PDFs outside the region where the fits were constrained by data. In such cases, the parametrization-independent NNPDF estimates may well be more realistic, as they express the larger uncertainties in regions not directly constrained by data.

In order to accommodate different nuclear target materials, we introduce a nuclear $A$ dependence in the $c_{k}$ coefficients:
$c_{k} \rightarrow c_{k}(A) \equiv c_{k, 0}+c_{k, 1}\left(1-A^{-c_{k, 2}}\right), \quad k=\{1, \ldots, 5\}$.

This ansatz has the advantage that in the limit $A \rightarrow 1$ we have $c_{k}(A) \rightarrow c_{k, 0}$; hence, $c_{k, 0}$ is simply the corresponding coefficient of the free proton. Thus, we can relate the $c_{k, 0}$ parameters to the analogous quantities from proton PDF studies.

It is noteworthy that the $x$ dependence of our input distributions $f_{k}^{p / A}\left(x, Q_{0}\right)$ is the same for all nuclei $A$; hence, this approach treats the NPDFs and the proton PDFs on the same footing. ${ }^{2}$ Additionally, this method facilitates the interpretation of the fit at the parameter level by allowing us to study the $c_{k}(A)$ coefficients as functions of the nuclear A parameter.

With the $A$-generalized set of initial PDFs, we can apply the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) evolution equations to obtain the PDFs for a bound proton inside a nucleus $A, f_{i}^{p / A}(x, Q)$. We can then construct the PDFs for a general $(A, Z)$ nucleus:

$$
\begin{equation*}
f_{i}^{(A, Z)}(x, Q)=\frac{Z}{A} f_{i}^{p / A}(x, Q)+\frac{(A-Z)}{A} f_{i}^{n / A}(x, Q) \tag{3}
\end{equation*}
$$

where we relate the distributions of a bound neutron, $f_{i}^{n / A}(x, Q)$, to those of a proton by isospin symmetry.

[^92]Similarly, the nuclear structure functions are given by

$$
\begin{equation*}
F_{i}^{(A, Z)}(x, Q)=\frac{Z}{A} F_{i}^{p / A}(x, Q)+\frac{(A-Z)}{A} F_{i}^{n / A}(x, Q) . \tag{4}
\end{equation*}
$$

These structure functions can be computed at next-toleading order as convolutions of the nuclear PDFs with the conventional Wilson coefficients, i.e., generically

$$
\begin{equation*}
F_{i}^{(A, Z)}(x, Q)=\sum_{k} C_{i k} \otimes f_{k}^{(A, Z)} . \tag{5}
\end{equation*}
$$

To account for heavy quark mass effects, we calculate the relevant structure functions in the Aivazis-Collins-OlnessTung (ACOT) scheme [35,36] at NLO QCD [37].

## B. Inputs to the global NPDF fit

Using the above framework, we can then construct a global fit to charged-lepton-nucleus ( $l^{ \pm} A$ ) DIS data and Drell-Yan data. To guide our constraints on the $c_{k, 0}$ coefficients, we use the global fit of the proton PDFs based upon Ref. [30]. This fit has the advantage that the extracted proton PDFs have minimal influence from nuclear targets. To provide the $A$-dependent nuclear information, we use a variety of $l^{ \pm} A$ DIS data and Drell-Yan data. The complete list of nuclear targets and processes is listed in Tables I, II, and III; there are 1233 data points before kinematical cuts are applied.

The structure of the fit is analogous to that of Ref. [33]. For the quark masses we take $m_{c}=1.3 \mathrm{GeV}$ and $m_{b}=$ 4.5 GeV . To limit effects of higher-twist we choose standard kinematic cuts of $Q_{\text {cut }}=2.0 \mathrm{GeV}$, and $W_{\text {cut }}=$ 3.5 GeV as they are employed in the CTEQ proton analyses. ${ }^{3}$ There are 708 data points which satisfy these cuts.

[^93]

FIG. 2 (color online). We display the $A$-dependent coefficients $c_{k}(A), k=\{1,5\}$, for the up-valence (top) and down-valence PDF (bottom) as a function of the nuclear $A$. The dependence of the coefficients $c_{k}(A)$ is shown by the following lines: $c_{1}$ solid (red) line, $c_{2}$ long-dashed (blue) line, $c_{3}$ dashed (green) line, $c_{4}$ dash-dotted (magenta) line, and $c_{5}$ dotted (brown) line.

FIG. 3 (color online). We display the (a) $x u(x)$ and (b) $x d(x)$ PDFs for a selection of nuclear $A$ values ranging from $A=\{1,207\}$. We choose $Q_{0}=1.3 \mathrm{GeV}$. The different curves depict the PDFs of nuclei with the following atomic numbers (from top to bottom at $x=0.01) A=1,2,4,8,20,54$, and 207.

FIG. 4 (color online). The computed nuclear correction ratio, $F_{2}^{F e} / F_{2}^{D}$, as a function of $x$ for $Q^{2}=5 \mathrm{GeV}^{2}$. (a) shows the fit (fit B) using charged-lepton-nucleus ( $\ell^{ \pm} A$ ) and DY data whereas (b) shows the fit using neutrino-nucleus ( $\nu A$ ) data (fit A2 from Ref. [33]). Both fits are compared with the SLAC/NMC parametrization, as well as fits from Kulagin-Petti (KP) (Ref. [31,32]) and Hirai et al. (HKN07), (Ref. [15]). The data points displayed in (a) are the same as in Fig. 1 and those displayed in (b) come from the NuTeV experiment [53,54].

## A. Charged-lepton $\left(\ell^{ \pm} A\right)$ data

The present nuclear PDF global analysis provides us with a complete set of NPDFs $f_{i}^{A}(x, Q)$ with full functional dependence on $\{x, Q, A\}$. Consequently, the traditional nuclear correction $F_{2}^{F e} / F_{2}^{D}$ does not have to be applied as a "frozen" external factor, but can now become a dynamic part of the fit which can be adjusted to accommodate the various data sets.

Having performed the fit outlined in Sec. II, we can then use the $f_{i}^{A}(x, Q)$ to construct the corresponding quantity $F_{2}^{F e} / F_{2}^{D}$ to find the form that is preferred by the data. In order to construct the ratio, we use the expression given by Eq. (4) for iron and deuterium. This result is displayed in Fig. 4(a) for a scale of $Q^{2}=5 \mathrm{GeV}^{2}$, and in Fig. 5(a) for a scale of $Q^{2}=20 \mathrm{GeV}^{2}$. Comparing these figures, we immediately note that our ratio $F_{2}^{\mathrm{Fe}} / F_{2}^{D}$ has nontrivial $Q$ dependence-as it should.

Figures 4(a) and 5(a) also compare our extracted $F_{2}^{F e} / F_{2}^{D}$ ratio with the ( $Q$-independent) SLAC/NMC parametrization of Fig. 1 and with the fits from Kulagin-Petti (KP) $[31,32]$. We observe that in the intermediate range ( $x \in \sim[0.07,0.7]$ ) where the bulk of the SLAC/NMC data constrains the parametrization, our computed $F_{2}^{F e} / F_{2}^{D}$ ratio compares favorably. When comparing the different curves, one has to bear in mind the following two points. First, all curves in principle have an uncertainty band which is not shown. Second, the data points used to extract the SLAC/NMC curve are measured at different $Q^{2}$ whereas our curve is always at a fixed $Q^{2}=5 \mathrm{GeV}^{2}$ or $Q^{2}=20 \mathrm{GeV}^{2}$. In light of these facts, we conclude that our fit agrees very well with other models and parametrizations as well as with the measured data points.

It should be noted that the kinematic cuts we employed to avoid higher twist effects effectively exclude all data

FIG. 5 (color online). Same as Fig. 4 for $Q^{2}=20 \mathrm{GeV}^{2}$.
points in the high- $x$ region above $x \gtrsim 0.7$. This is reflected by the fact that our curves in Figs. 4(a) and 5(a) stop at $x=$ 0.7 . The high- $x$ region is beyond the scope of this paper and will be the subject of a future analysis.

Thus, we find that data sets used in this fit $\left(F_{2}^{A} / F_{2}^{D}\right.$, $F_{2}^{A} / F_{2}^{A^{\prime}}$, and $\sigma_{D Y}^{p A} / \sigma_{D Y}^{p A^{\prime}}$ ) are compatible with the SLAC, BCDMS, and NMC data. Additionally, we can go further and use our complete set of NPDFs $f_{i}^{A}(x, Q)$ to compute the appropriate nuclear correction not only for $F_{2}^{F e} / F_{2}^{D}$, but for any nuclear target $(A)$ for any $Q$ value, and for any observable. We make use of this property in the following section where we compute the corresponding quantity for a different nuclear process.

## IV. $\ell^{ \pm} \boldsymbol{A}$ AND $\boldsymbol{\nu} \boldsymbol{A}$ NUCLEAR CORRECTIONS

## A. Nuclear corrections in $\boldsymbol{\nu} \boldsymbol{A}$ DIS

In a previous analysis [33], we examined the charged current (CC) neutrino-nucleus DIS process $\nu A \rightarrow \mu X$, and extracted the $F_{2}^{F e} / F_{2}^{D}$ ratio. ${ }^{4}$

These results are displayed in Figs. 4(b) and 5(b). The solid line is the result of the global fit (fit A2), and this is compared with the previous SLAC/NMC parametrization, as well as fits KP and HKN07. The data points displayed come from the NuTeV experiment [53,54]. The (yellow) band is an approximation of the uncertainty of the fits.

As observed above, the SLAC/NMC parametrization is generally consistent with the results of KP and HKN as well as our B fit to $\ell^{ \pm} A$ and DY data. However, the A2 fit of Figs. 4(b) and 5(b) does not agree with any of these three results. We now examine this in detail.

## B. $\ell^{ \pm} A$ and $\nu \boldsymbol{A}$ comparison

The contrast between the charged-lepton $\left(\ell^{ \pm} A\right)$ case and the neutrino $(\nu A)$ case is striking; while the charged-lepton results generally align with the SLAC/NMC, KP, and HKN determinations, the neutrino results clearly yield different behavior in the intermediate $x$ region. We emphasize that both the charged-lepton and neutrino results are not a model-they come directly from global fits to the data. To emphasize this point, we have superimposed illustrative data points in Figs. 4(b) and 5(b); these are simply the $\nu A$ DIS data $[53,54]$ scaled by the appropriate structure function, calculated with the proton PDF of Ref. [33].

The mismatch between the results in charged-lepton and neutrino DIS is particularly interesting given that there has been a long-standing "tension" between the light-target charged-lepton data and the heavy-target neutrino data in the historical fits $[55,56]$. This study demonstrates that the tension is not only between charged-lepton light-target

[^94]data and neutrino heavy-target data, but we now observe this phenomenon in comparisons between neutrino and charged-lepton heavy-target data.

There are two possible interpretations of this result.
(1) There is, in fact, a single "compromise" solution for the $F_{2}^{F e} / F_{2}^{D}$ nuclear correction factor which yields a good fit for both the $\nu A$ and $\ell^{ \pm} A$ data.
(2) The nuclear corrections for the $\ell^{ \pm} A$ and $\nu A$ processes are different.

Considering possibility 1 , the "apparent" discrepancy observed in Figs. 4 and 5 could simply reflect uncertainties in the extracted nuclear PDFs. The global fit framework introduced in this work paves the way for a unified analysis of the $\ell^{ \pm} A$, DY, and $\nu A$ data which will ultimately answer this question. Having established the nuclear correction factors for neutrino and charged-lepton processes separately, we can combine these data sets (accounting for appropriate systematic and statistical errors) to obtain a compromise solution. ${ }^{5}$

If it can be established that a compromise solution does not exist, then the remaining option is that the nuclear corrections in neutrino and charged-lepton DIS are different. This idea has previously been discussed in the literature [31,32,57]. We note that the charged-lepton processes occur (dominantly) via $\gamma$ exchange, while the neutrinonucleon processes occur via $W^{ \pm}$exchange. Thus, the different nuclear corrections could simply be a consequence of the differing propagation of the intermediate bosons (photon, $W$ ) through dense nuclear matter. Regardless of whether this dilemma is resolved via option 1 or 2, understanding this puzzle will provide important insights about processes involving nuclear targets. Furthermore, a deeper understanding could be obtained by a future high-statistics, high-energy neutrino experiment using several nuclear target materials [58-60].

## V. CONCLUSIONS

We presented a new framework to carry out a global analysis of NPDFs at next-to-leading order QCD, treating proton and nuclear targets on equal footing. Within this approach, we have performed a $\chi^{2}$ analysis of nuclear PDFs by extending the proton PDF fit of Ref. [30] to DIS $l^{ \pm} A$ and Drell-Yan data. The result of the fit is a set of nuclear PDFs which incorporate not only the $\{x, Q\}$ dependence, but also the nuclear- $A$ degree of freedom; thus we can accommodate the full range of nuclear targets from light $(A=1)$ to heavy $(A=207)$. We find a good fit to the

[^95]combined data set with a total $\chi^{2} /$ DOF of 0.946 demonstrating the viability of the framework.

We have used our results to compute the nuclear corrections factors, and to compare these with the results from the literature. We find good agreement for those fits based on a charged-lepton data set.

Separately, we have compared our nuclear corrections (derived with a charged-lepton data set) with those computed using neutrino DIS $(\nu A \rightarrow \mu X)$ data sets. Here, we observe substantive differences.

This fit is novel in several respects.
(i) Since we constructed the nuclear PDF fits analogous to the proton PDF fits, this framework allows a meaningful comparison between these two distributions.
(ii) The above unified framework integrates the nuclear correction factors as a dynamic component of the fit. These factors are essential if we want to use the heavy-target DIS data to constrain the strange quark distribution of the proton, for example.
(iii) This unified analysis of proton and nuclear PDFs provides the foundation necessary to simultaneously analyze $\ell^{ \pm} A$, DY, and $\nu A$ data. This will ultimately help in determining whether (1) a compromise solution exists, or (2) the nuclear corrections depend on the exchanged boson (e.g., $\gamma / Z$ or $\left.W^{ \pm}\right)$.
ing and important question. The resolution of this issue is essential for a complete understanding of both the proton and nuclear PDFs.

#### Abstract

We perform a global $\chi^{2}$ analysis of nuclear parton distribution functions using data from charged current neutrino-nucleus ( $\nu A$ ) deep-inelastic scattering (DIS), charged-lepton-nucleus ( $\ell^{ \pm} A$ ) DIS, and the Drell-Yan (DY) process. We show that the nuclear corrections in $\nu A$ DIS are not compatible with the predictions derived from $\ell^{ \pm} A$ DIS and DY data. We quantify this result using a hypothesis-testing criterion based on the $\chi^{2}$ distribution which we apply to the total $\chi^{2}$ as well as to the $\chi^{2}$ of the individual data sets. We find that it is not possible to accommodate the data from $\nu A$ and $\ell^{ \pm} A$ DIS by an acceptable combined fit. Our result has strong implications for the extraction of both nuclear and proton parton distribution functions using combined neutrino and charged-lepton data sets.

High statistics neutrino deep-inelastic scattering (DIS) experiments have generated significant interest in the literature as they provide crucial information for global fits of parton distribution functions (PDFs). The neutrino DIS data provide the most stringent constraints on the strange quark distribution in the proton, and allow for flavor decomposition of the PDFs which is essential for precise predictions of the benchmark gauge boson production processes at the LHC. Moreover, the neutrino experiments have been used to make precision tests of the standard model (SM). A prominent example is the extraction of the weak mixing angle $\theta_{W}$ in a Paschos-Wolfenstein type analysis [1]. A good knowledge of the neutrino DIS cross sections is also very important for long baseline experiments of the next generation which aim at measuring small parameters of the mixing matrix such as the mixing angle $\theta_{13}$ and eventually the $C P$ violating phase $\delta$.

Because of the weak nature of neutrino interactions the use of heavy nuclear targets is unavoidable, and this complicates the analysis of the precision physics discussed above since model-dependent nuclear corrections must be applied to the data. Our present understanding of the nuclear corrections is mainly based on charged-leptonnucleus ( $\ell A$ ) DIS data. In the early 80s the European Muon Collaboration (EMC) [2] found that the nucleon structure functions $F_{2}$ for iron and deuterium differ. This discovery triggered a vast experimental program to investigate the nuclear modifications of the ratio $R\left[F_{2}^{\ell A}\right]=$ $F_{2}^{\ell A} /\left(A F_{2}^{\ell N}\right)$ for a wide range of nuclear targets with atomic number $A$, see Table I. By now, such modifications have been established in a kinematic range from relatively small

Bjorken $x\left(x \sim 10^{-2}\right)$ to large $x(x \sim 0.8)$ in the deepinelastic region with squared momentum transfer $Q^{2}>$ $1 \mathrm{GeV}^{2}$. The behavior of the ratio $R\left[F_{2}^{\ell A}\right]$ can be divided into four regions: (i) $R>1$ for $x \gtrsim 0.8$ (Fermi motion region), (ii) $R<1$ for $0.25 \leqq x \leqq 0.8$ (EMC region), (iii) $R>1$ for $0.1 \leqq x \leqq 0.25$ (antishadowing region), and (iv) $R<1$ for $x \leqq 0.1$ (shadowing region), with different physics mechanisms explaining the nuclear modifications. The shadowing suppression at small $x$ occurs due to coherent multiple scattering inside the nucleus of a $q \bar{q}$ pair coming from the virtual photon [5] with destructive interference of the amplitudes [6]. The antishadowing region is theoretically less well understood but might be explained by the same mechanism with constructive interference of the multiple scattering amplitudes [6] or by the application of momentum, charge, and/or baryon number sum rules. Conversely, the modifications at medium and large $x$ are usually explained by nuclear binding and medium effects and the Fermi motion of the nucleons [7].

Instead of trying to address the origin of the nuclear effects, the data on nuclear structure functions can be analyzed in terms of nuclear PDFs (NPDFs) which are modified as compared to the free nucleon PDFs. Relying on factorization theorems in the same spirit as in the free nucleon case, the advantage of this approach is that the universal NPDFs can be used to make predictions for a large variety of processes in $\ell A, \nu A, p A$, and $A A$ collisions. In addition, the nuclear correction factors required for the interpretation of the neutrino experiments can be calculated in a flexible way, taking into account the precise observable, the nuclear $A$, and the scale $Q^{2}$. The factorization assumption in the
nuclear environment is therefore a question of considerable theoretical and practical importance and global analyses of NPDFs based on $\ell A$ DIS and fixed target Drell-Yan (DY) data confirm its validity in the presently explored kinematic range.

However, in a recent analysis [3] of $\nu \mathrm{Fe}$ DIS data from the NuTeV collaboration we found that the nuclear correction factors are surprisingly different from the predictions based on the $\ell^{ \pm} \mathrm{Fe}$ charged-lepton results with important implications for global analyses of proton PDFs. This is not

TABLE I. The charged-lepton DIS data sets together with DY and with neutrino DIS data sets used in the fit. The table details the specific nuclear targets, and the number of data points with kinematical cuts ( $Q^{2}>4 \mathrm{GeV}^{2}, W>3.5 \mathrm{GeV}$ ). References for the data sets are cited in Refs. [3,4].

completely unexpected since the structure functions in charged current (CC) neutrino DIS and neutral current (NC) electron or muon DIS are distinct observables with different parton model expressions. From this perspective it is clear that the nuclear correction factors will not be exactly the same even for a universal set of NPDFs. Note also that some models in the literature predict differences between reactions in CC and NC DIS [8]. What is, however, unexpected is the degree to which the $R$ factors differ between the structure functions $F_{2}^{\nu \mathrm{Fe}}$ and $F_{2}^{\ell \mathrm{Fe}}$. In particular the lack of evidence for shadowing in neutrino scattering down to $x \sim 0.02$ is quite surprising.

The study in Ref. [3] left open the question, whether the neutrino DIS data could be reconciled with the chargedlepton DIS data by a better flavor separation of the NPDFs. In this letter, we address this question in the $A$-dependent framework of Ref. [4] by performing a global $\chi^{2}$ analysis of the combined data from $\nu A$ DIS, $\ell A$ DIS and the DY process listed in Table I.

When combining neutrino and charged-lepton + DY data into a compromise fit, we introduce a weight parameter $w$ into the $\chi^{2}$ via

$$
\begin{equation*}
\chi^{2}=\sum_{l^{ \pm} A \text { data }} \chi_{i}^{2}+\sum_{\nu A \text { data }} w \chi_{i}^{2} \tag{1}
\end{equation*}
$$

The $w$ factor allows us to adjust for the different number of points in the separate data sets, and provides a parameter that interpolates between the $\nu A$ and the $\ell^{ \pm} A+\mathrm{DY}$ data. We should stress that the $\chi^{2}$ cited in Table II and also in the text is the standard $\chi^{2}$; Eq. (1) is only used internally in the fitting procedure. We construct a set of compromise fits with weights $w=\left\{0, \frac{1}{7}, \frac{1}{2}, 1, \infty\right\}$ and study the dependence of the result on this weight. The fit to only neutrino data, denoted $w=\infty$ in Table II, is compatible with the results in [3]. Similarly, the fit to only charged-lepton + DY data, denoted $w=0$, agrees well with the analysis in [4].

We first compute the nuclear correction factors $R\left[F_{2}^{\ell \mathrm{Fe}}\right] \simeq F_{2}^{\ell \mathrm{Fe}} / F_{2}^{\ell N}$ and $R\left[F_{2}^{\nu \mathrm{Fe}}\right] \simeq F_{2}^{\nu \mathrm{Fe}} / F_{2}^{\nu N}$ in the QCD parton model at next-to-leading order employing the NPDF fits in Table II for the numerator and free nucleon PDFs for the denominator [9]. The $x$ dependence of $R\left[F_{2}^{\ell \mathrm{Fe}}\right]$ and $R\left[F_{2}^{\nu \mathrm{Fe}}\right]$ is shown in Figs. 1(a) and 1(b), respectively, at $Q^{2}=5 \mathrm{GeV}^{2}$. Similar results hold at $Q^{2}=20 \mathrm{GeV}^{2}$ which we do not present here. We observe that the fit to only $\ell A$ DIS + DY data $(w=0)$ well describes the SLAC and BCDMS points in Fig. 1(a). The same is true for the fit to only $\nu A$ DIS data $(w=\infty)$ which is compatible with the results from the NuTeV experiment

TABLE II. Summary table of a family of compromise fits.

| $w$ | $l^{ \pm} A$ | $\chi^{2}(/ \mathrm{pt})$ | $\nu A$ | $\chi^{2}(/ \mathrm{pt})$ | total $\chi^{2}(/ \mathrm{pt})$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| 0 | 708 | $638(0.90)$ | $\cdots$ | $\cdots$ | $638(0.90)$ |
| $1 / 7$ | 708 | $645(0.91)$ | 3134 | $4710(1.50)$ | $5355(1.39)$ |
| $1 / 2$ | 708 | $680(0.96)$ | 3134 | $4405(1.40)$ | $5085(1.32)$ |
| 1 | 708 | $736(1.04)$ | 3134 | $4277(1.36)$ | $5014(1.30)$ |

[10] exemplified in Fig. 1(b). However, comparing the results obtained with the $w=0$ and the $w=\infty$ fits one can see that they predict considerably different $x$ shapes.

The fits with weights $w=\left\{\frac{1}{7}, \frac{1}{2}, 1\right\}$ interpolate between these two incompatible solutions. As can be seen in Figs. 1(a) and 1(b), with increasing weight the description of the $\ell \mathrm{Fe}$ data is worsened in favor of a better agreement with the $\nu \mathrm{Fe}$ points. This trend clearly demonstrates that the $\ell \mathrm{Fe}$ and the $\nu \mathrm{Fe}$ data pull in opposite directions. We identify the fits with $w=1 / 2$ or $w=1$ as the best candidates for a possible compromise.

To be able to decisively accept or reject the compromise fits, we apply a statistical goodness-of-fit criterion [11-13] based on the probability distribution for the $\chi^{2}$ given that the fit has $N$ degrees of freedom:

$$
\begin{equation*}
P\left(\chi^{2}, N\right)=\frac{\left(\chi^{2}\right)^{N / 2-1} e^{-\chi^{2} / 2}}{2^{N / 2} \Gamma(N / 2)} \tag{2}
\end{equation*}
$$

This allows us to define the percentiles $\xi_{p}$ via $\int_{0}^{\xi_{p}} P\left(\chi^{2}, N\right) d \chi^{2}=p \% \quad$ where $\quad p=\{50,90,99\}$. Here, $\xi_{50}$ serves as an estimate of the mean of the $\chi^{2}$ distribution and $\xi_{90}$, for example, gives us the value where there is only a $10 \%$ probability that a fit with $\chi^{2}>\xi_{90}$ genuinely describes the given set of data. In a global PDF fit, the best fit $\chi^{2}$ value often deviates from the mean value because the data come from different possibly incompatible experiments having unidentified, unknown errors which are not accounted for in the experimental systematic errors. For this reason we rescale the $\xi_{90}$ and $\xi_{99}$ percen-

FIG. 1 (color online). Predictions from the compromise fits for the nuclear correction factors $R\left[F_{2}^{\ell \mathrm{Fe}}\right] \simeq F_{2}^{\ell \mathrm{Fe}} / F_{2}^{\ell N}$ (a) and $R\left[F_{2}^{\nu \mathrm{Fe}}\right] \simeq F_{2}^{\nu \mathrm{Fe}} / F_{2}^{\nu N}$ (b) as a function of $x$ for $Q^{2}=5 \mathrm{GeV}^{2}$. The data points displayed in (a) are from BCDMS and SLAC experiments (for references see [4]) and those displayed in (b) come from the NuTeV experiment [10].
tiles relative to the best fit $\chi_{0}^{2}$ [11] to define $C_{90}=$ $\chi_{0}^{2}\left(\xi_{90} / \xi_{50}\right)$ and $C_{99}=\chi_{0}^{2}\left(\xi_{99} / \xi_{50}\right)$. This defines our criterion: a fit with a given $\chi^{2}$ is compatible with the best fit with $\chi_{0}^{2}$ at $90 \%$ (99\%) confidence if $\chi^{2}<C_{90}$ ( $\chi^{2}<C_{99}$ ). We apply it to both the total $\chi^{2}$ and the $\chi^{2}$ of the individual data sets.

For the $\ell A$ DIS + DY data we use the fit with $w=0$ as benchmark with $\chi_{0}^{2}=638$ and $N=677$ degrees of freedom (for 708 data points and 31 free parameters). The upper limits on the $\chi^{2}$ at $90 \%$ and $99 \%$ confidence level (C.L.) are then $C_{90}^{I^{ \pm} A}=684$ and $C_{99}^{l^{ \pm} A}=722$. The benchmark fit for the $\nu A$ DIS data $(w=\infty)$ uses 3134 data points with 33 free parameters resulting in $N=3101$ and one finds $C_{90}^{\nu A}=4330$ and $C_{99}^{\nu A}=4445$. We see that none of the compromise fits satisfies both limits at the $90 \%$ C.L. which is usually used in global analyses of PDFs to define the uncertainty bands. At the $99 \%$ C.L., there are two fits $(w=1 / 2, w=1)$ which are below the $C_{99}^{\nu A}$ limit. However, only the $w=1 / 2$ fit satisfies the corresponding constraint from the charged-lepton benchmark fit.

We now apply our criterion also to the individual data sets with IDs between 1 and 40 in Table I. For the $\ell A$ DIS + DY data $(\mathrm{ID}=[1,31])$ we determine the $31 C_{90}$ ( $C_{99}$ ) limits by using the individual $\chi_{i}^{2}$ of the $w=0$ fit as $\chi_{0, i}^{2}$. For the $\nu A$ DIS data (ID $=[33,40]$ ) we proceed in a similar manner using the individual $\chi_{i}^{2}$ of the $w=\infty$ fit. The results of this detailed analysis are depicted in Fig. 2, where we show the quantity

$$
\begin{equation*}
\frac{\Delta \chi^{2}}{\Delta C_{90}}=\frac{\chi_{i}^{2}-\chi_{0, i}^{2}}{C_{90, i}-\chi_{0, i}^{2}} \quad(i=1, \ldots, 40), \tag{3}
\end{equation*}
$$

where $\chi_{i}^{2}$ represents the $\chi^{2}$-value of the $i$ th data set. In cases where $\chi_{i}^{2}>C_{90, i}$ the fit is not compatible with the best fit at the $90 \%$ level and $\Delta \chi^{2} / \Delta C_{90}>1$. The exact

FIG. 2 (color online). $\Delta \chi^{2} / \Delta C_{90}$ as defined in Eq. (3) for the 40 individual data sets. Results are shown for the $w=\frac{1}{2}$-fit (a) and the fit "Ucor5" (b) with $w=1$. The solid and dashed lines indicate the $90 \%$ and $99 \%$ confidence limits. The highlighted data sets correspond to DIS $\ell^{ \pm} \mathrm{Fe}(\mathrm{ID}=8), \nu \mathrm{Fe}(\mathrm{ID}=35)$, and $\bar{\nu} \mathrm{Fe}(\mathrm{ID}=36)$.
$90 \%$ C.L. limit is shown as a constant solid line and the dotted line represents the $99 \%$ confidence limit. The local application of the $\chi^{2}$ hypothesis-testing criterion reveals that even the compromise fit with weight $w=\frac{1}{2}$ which was considered acceptable at the $99 \%$ C.L. when looking at the nuclear correction factors and at the global change in $\chi^{2}$, cannot be accepted as a compromise solution as both the charged-lepton and neutrino DIS data on iron exceed the $99 \%$ limit.

In conclusion, the tension between the $\ell^{ \pm} \mathrm{Fe}$ and $\nu \mathrm{Fe}$ data sets leaves us with no possible compromise fit when investigating the results in detail, not even when using the $99 \%$ percentile as the limit as opposed to the more restrictive $90 \%$ limit which is usually used to construct the error PDFs. This detailed analysis confirms the preliminary conclusions of Refs. [3,4] that there is no possible compromise fit which adequately describes the neutrino DIS data along with the charged-lepton data.

At face value, this conclusion differs from some results in the literature which argue the $\nu A$ and $\ell^{ \pm} A$ data are in accord [14]. Here, we believe an essential element in our analysis is the use of the correlated systematic errors of the $\nu A$ data. To highlight this point, we now repeat our analysis, but we combine the statistical and all systematic errors in quadrature (thereby neglecting the information contained in the correlation matrix) for $\nu A$ data for the $w=1$ fit with $Q^{2}>4 \mathrm{GeV}$ (as before); we denote this the "Ucor4" fit, and we obtain $\chi^{2} / p t$ of 1.14 for $\ell^{ \pm} A$ and 1.00 for $\nu A$. We also use a $Q^{2}>5 \mathrm{GeV}$ fit (denoted "Ucor5") to mimic the cuts of Ref. [14]; here we obtain $\chi^{2} / p t$ of 1.14 for $\ell^{ \pm} A$ and 0.96 for $\nu A$.

If we examine the total $\chi^{2}$ values, we find the $\chi^{2} / \operatorname{dof} \sim 1$, and might be tempted to conclude we are able to fit both the $\nu A$ and $\ell^{ \pm} A$ data simultaneously. However, if we look at individual data sets and apply our hypothesis-testing criteria, the picture is quite different. Figure 2(b) displays the results for the Ucor5 fit. The higher $Q^{2}$ cut of the Ucor5 fit removes some of the very precise NuTeV data at small- $x$, thus resulting in an improved $\chi^{2}$ compared to Ucor4. Nevertheless, many of the $\ell^{ \pm} A$ data sets (ID $=3,4,5$, $6,8)$ still lie outside the $99 \%$ C.L. percentile. Thus, we still conclude that there is no compromise fit for the $\nu A$ and $\ell^{ \pm} A$ data even if we relax the constraints by using uncorrelated errors.

Consequently, the nuclear correction factor for the neutrino DIS data are indeed incompatible with that of the charged-lepton DIS and DY data, and this result depends crucially on the use of the precision correlated errors of the neutrino data. This result has important implications for both nuclear and proton PDFs. If we do not know the appropriate nuclear correction to relate different nuclear targets, our ability to extract PDFs is limited. For example, the CTEQ6.6 analysis [15] sidesteps these issues by removing most of the $\nu$ A data from the fit; however, they
retain the NuTeV dimuon data since this data is critical to constraining the strange quark PDF. This underscores the importance of the $\nu A$ data for flavor differentiation.

Although the NuTeV data provide the tightest constraints due to their statistics, we note that this issue cannot be tied to a single data set. For example, we find that NuTeV is generally compatible with CCFR and CDHSW [16]. The CHORUS $\nu P b$ and $\bar{\nu} P b$ data have larger uncertainties, so they can be compatible with both the $\ell^{ \pm} A$ data and the $\mathrm{NuTeV} \nu \mathrm{Fe}$ data because the $\Delta \chi^{2} / \Delta C_{90}<1$ for all weights. Compared to the theory predictions, NuTeV agrees well in the central $x$ region, but exhibits differences both for low $x$ at low $Q^{2}$, and also for very high $x(x \sim 0.65)$.

We have demonstrated that the $\nu A$ and $\ell^{ \pm} A$ data prefer different nuclear correction factors, and that there is no single "compromise" result that will simultaneously satisfy both data sets. While we have focused on the phenomenological aspects for the present study, this result has strong implications for the extraction of both nuclear and proton PDFs using combined neutrino and chargedlepton data sets. Possibilities include unexpectedly large higher-twist effects, or even nonuniversal nuclear effects; we leave such questions for a future study.

#### Abstract

We survey some of the recent developments in the extraction and application of heavy quark Parton Distribution Functions (PDFs). We also highlight some of the key HERA measurements which have contributed to these advances.

Keywords: Quantum Chromodynamics, Parton Distribution Functions, Heavy Quarks, Deeply Inelastic Scattering.

## Two Decades of HERA physics

The HERA electron-proton collider ring began its physics program in 1992 and completed accelerator operations in 2007. The data collected by the HERA facility allowed for physics studies over a tremendously expanded kinematic region compared to the previous fixed-target experiments. This point is illustrated in Figure 1 where we display the $e^{+} p$ Neutral Current (NC) cross section vs. $Q^{2}$ for the HERA data (runs I and II) together with the fixed-target data. We observe that the HERA data allows us to extend our reach in $Q^{2}$ by more than two decades for large to intermediate $x$ values, and also extends the small $x$ region down to $\sim 10^{-5}$.

Additionally, the large statistics and reduced systematics of the experimental data demand that the theoretical predictions keep pace. Over the lifetime of HERA we have seen many of the theoretical calculations advanced from Leading-Order (LO), to Next-to-Leading-Order (NLO), and some even to Next-to-Next-to-Leading-Order (NNLO).

As the required theoretical precision has increased, it has been necessary to revisit the many inputs and assumptions which are used in the calculations. We will

Figure 1: $e^{+} p$ NC cross section for the combined HERA data as compared with the HERAPDF1.5 fit as a function of $Q^{2}$ for different values of $x$. (Figure from H1prelim-10-142 \& ZEUS-prel-10-018.)

[^96]

Figure 2: The computed nuclear correction ratio, $F_{2}^{F e} / F_{2}^{N}$, as a function of $x$ for $Q^{2}=5 \mathrm{GeV}^{2}$. Figure-a) shows the fit (fit B from Ref. [16]) using charged-lepton-nucleus $\left(\ell^{ \pm} A\right)$ and DY data whereas Figure-b) shows the fit using neutrino-nucleus ( $v A$ ) data (fit A2 from Ref. [2]). Both fits are compared with the SLAC/NMC parameterization [16], as well as fits from Kulagin-Petti (KP) (Ref. [3, 4]) and Hirai et al. (HKN07), (Ref. [5]). The data points displayed in Figure-a) come from a selection of SLAC and BCDMS data. [6, 7, 8, 9, 10, 11, 12].
examine the role that the heavy quarks-and their associated masses-play in these calculations, both for the evolution of the parton distribution functions (PDFs) and also the hard-scattering cross sections.

## Determining the Heavy Quark PDFs

HERA's reach to larger $Q^{2}$ and smaller $x$ values takes us to a new kinematic region where the heavy quarks $(s, c, b)$ play a more important role. For example, the strange and charm quark contributions to $F_{2}$ at small $x$ values can be $30 \%$ or more of the total inclusive result. To make high-precision predictions for the structure functions we must therefore be capable of reducing the uncertainty of these heavy quark contributions; this requires, in part, precise knowledge of the PDFs which enter the calculation.

The determination of the PDFs requires a variety of data sets which constrain different linear combinations of the PDF flavors. For example, Neutral Current (NC) charged-lepton Deeply Inelastic Scattering (DIS) (at low $Q^{2}$ ) probes a charge weighted combination $\sim 4 u+d+s+4 c$. In contrast, charged current (CC) neutrino DIS can probe different flavor combinations via $W^{ \pm}$-boson exchange; additionally the neutrino measurements can probe the parity-violating $x F_{3}$ structure function.

## Nuclear Correction Factors

The most precise determination of the strange quark PDF component comes from neutrino-nucleon ( $\nu-\mathrm{N}$ ) di-muon DIS ( $v N \rightarrow \mu^{-} \mu^{+} X$ ) process. This (dominantly) takes place via the Cabibbo favored partonic
process $v s \rightarrow \mu^{-} c$ followed by a semi-leptonic charm decay. As the neutrino cross section is small, this measurement is typically made using heavy nuclear targets ( $\mathrm{Fe}, \mathrm{Pb}$ ), so nuclear corrections must be applied to relate the results to a proton or isoscalar nuclei.

However, recent analyses indicate that the nuclear corrections for the $v$-N and $\ell^{ \pm}-\mathrm{N}$ DIS processes are different [1]; hence, this introduces an uncertainty into the strange quark PDF extraction which was not realized previously. Figure 2 displays the nuclear correction factors obtained for the a) $\ell^{ \pm}-\mathrm{N}$ and b$) ~ v-\mathrm{N}$ processes. Here, we plot the ratio of $F_{2}^{F e}$ to an isoscalar $F_{2}^{N}$ as a function of $x$ for the $Q^{2}$ value indicated.

The contrast between the charged-lepton $\left(\ell^{ \pm} A\right)$ case and the neutrino ( $v A$ ) case in Figure 2 is striking; while the charged-lepton results generally align with the SLAC/NMC [2], KP [3, 4] and HKN [5] determinations, the neutrino results clearly yield different behavior in the intermediate $x$-region. We emphasize that both the charged-lepton and neutrino results are not a model-they come directly from global fits to the data. To emphasize this point, we have superimposed illustrative data points in the figures; these are simply a) the SLAC and BCDMS data $[6,7,8,9,10,11,12]$ or b) the $v A$ DIS data [13] scaled by the appropriate structure function, calculated with the proton PDF of Ref. [2].

The mis-match between the results in charged-lepton and neutrino DIS is particularly interesting given that there has been a long-standing "tension" between the light-target charged-lepton data and the heavy-target neutrino data in the historical fits [14, 15]. This study demonstrates that the tension is not only between charged-lepton light-target data and neutrino heavy-target data, but we now observe this phenomenon

Figure 3: The a) gluon $x g\left(x, Q_{0}\right)$ and b) strange quark $x s\left(x, Q_{0}\right)$ nuclear PDFs as a function of $x$ for a selection of nuclear A values $\{1,2,4,9,12,27,56,108,207\}$ (from top to bottom at $x=0.01$ ). We choose $Q_{0}=1.3 \mathrm{GeV}$.
in comparisons between neutrino and charged-lepton heavy-target data.

## The nCTEQ PDFs

The above example underscores the importance of a comprehensive treatment of the nuclear corrections to achieve the precision demanded by the current precision data. To move toward this goal, the nCTEQ project was developed to extend the global analysis framework of the traditional CTEQ proton PDFs to incorporate a broader set of nuclear data thereby extracting the PDFs of a nuclear target. In essence, a nuclear PDF not only depends on the momentum fraction $x$ and energy scale $Q$, but also on the nuclear " A " value: $f(x, Q, A)$. The structure of the nCTEQ analysis is closely modeled on that of the proton global analysis; in fact, the nuclear parameterizations are designed efficiently to make use of the proton limit $(\mathrm{A}=1)$ as a "boundary condition" to help constrain the fit.

In Figure 3 we display the gluon and strange nuclear PDFs as a function of $x$ for a selection of nuclear A values. We observe that for $x \simeq 0.01$ the nuclear modifications for the strange quark can be $\sim 25 \%$, and for the gluon can be even larger. The details of the nuclear PDF analysis is discussed in Refs. [1, 16, 2] ${ }^{2}$

The nCTEQ web-page contains 19 families of nPDF grid files which may be used to explore the variation due to the different data sets and kinematic cuts. In particular, there is a collections of nPDFs which interpolate between that of Figure 2-a) which uses the charged-lepton-nucleus ( $\ell^{ \pm} A$ ) data and of Figure 2-b) which uses the neutrino-nucleus $(v A)$ data.

[^97]

Figure 4: $\kappa(x)$ vs. $x$ for $Q=1.5 \mathrm{GeV}$ for a selection of PDFs, where we define $\kappa(x)=2 s(x) /(\bar{u}(x)+\bar{d}(x))$

## The Strange Quark PDF

We now compare a selection of $s(x)$ distributions to gain a better understanding of the uncertainties arising from the nuclear correction factors used to analyze the $v \mathrm{~N}$ DIS. One measure of the strange quark content of the proton is to compare $s(x)$ with the average up-quark and down-quark sea PDFs: $(\bar{u}(x)+\bar{d}(x)) / 2$. Thus, we define the ratio $\kappa(x)=2 s(x) /(\bar{u}(x)+\bar{d}(x))$. If we had exact $S U(3)$ flavor symmetry, we would expect $\kappa=1$; the extent to which $\kappa$ is below one measures the suppression of the strange quark as compared to the up and down sea. In Figure 4 we display $\kappa(x)$ for some recent CTEQ PDFs and note that $\kappa(x)$ has a large variation, especially at small $x$ values. This reflects, in part, the fact that the strange quark is poorly constrained for $x \lesssim 0.1$. For the CTEQ6, 6HQ, 6.1, and 6.5 PDF sets, the strange quark was arbitrarily set to $\sim 1 / 2$ the average of the up and down sea-quarks. For the CTEQ6.6 PDF set, the strange quark was allowed additional freedom; this is reflected in Figure 5 which compares the relative uncertainty of the strange quark in the 6.1 and 6.6 PDF sets.

Figure 5: Relative uncertainty of the strange quark PDF as a function of $x$ for $Q=2 \mathrm{GeV}$. The inner band is for the CTEQ6.1 PDF set, and the outer band is for the CTEQ6.6 PDF set. The band is computed as $s_{i}(x) / s_{0}(x)$ where $s_{0}(x)$ is the central PDF for each set; for CTEQ6.1, $i=[1,40]$, and for CTEQ6.6, $i=[1,44]$.

Figure 6: The differential cross section $(d \sigma / d y)$ for $W^{+}$production at the LHC $(\sqrt{s}=14 \mathrm{TeV})$ as a function of rapidity $y$. The partonic contributions are also displayed. At $y=0$, the contributions (from top to bottom) are $\{$ total, $u \bar{d}, c \bar{s}, u \bar{s}, c \bar{d}\}$

## $W / Z$ at the LHC

The above reexamination of the nuclear corrections introduces additional uncertainties into the data sets, which manifests itself in increased uncertainties on the strange quark PDF. To see how these uncertainties might affect other processes, we consider, as an example, $W / Z$ production at the LHC. As we go to higher energies, the heavy quarks will play an increasingly important role because we can probe the PDFs at smaller $x$ and larger $Q$; this means that the heavy quark PDF uncertainties can have an increased influence on LHC observables compared to Tevatron observables.

In Figure 6 we display the LO differential cross section for $W$ production at the LHC as a function of rapidity $y$, as well as the individual partonic contributions. We note that in the central rapidity region the contribution from the heavy quarks can be $30 \%$ or more of the total cross section; this is in sharp contrast to the sit-
uation at the Tevatron where the heavy quark contributions are minimal. Thus, a large uncertainty in the heavy quark PDFs can influence such "benchmark" processes as $\mathrm{W} / \mathrm{Z}$ production at the LHC. Of course, given the high statistics from the LHC (the 2011 proton-proton run exceeded $5 \mathrm{fb}^{-1}$ ), it may be possible to turn the question around and ask to what extent the LHC data may constrain the heavy quark PDFs.

## Zero Mass (ZM) and General Mass (GM) Schemes

We now turn to charm production and the measurement of the charm PDF. HERA extracted precise measurements of $F_{2}^{c}$ and $F_{2}^{b}$, and recently these analyses have been updated ${ }^{3}$ to include the low $Q^{2}$ data to cover the kinematic range of $Q^{2}=[2,1000] \mathrm{GeV}^{2}$ and $x$ down to $10^{-5}[17,18]$.

A global fit of HERA I data $[19,20]$ for $F_{2}^{c}$ was performed using both the General Mass Variable Flavor Scheme (GM-VFS), and also the Zero Mass Variable Flavor Scheme (ZM-VFS). [21] While the GM-VFN result yielded an improved $\chi^{2}$, the ZM-VFN results-when implemented consistently-yielded an acceptable fit to the data. Given the expanded kinematic coverage of the recent HERA data, it would be of interest to repeat this comparison. Presumably the new data sets would allow for increased differentiation between the ZM-VFN and GM-VFN scheme results.

## Choice of Theoretical Schemes

Having illustrated the impact of different theoretical schemes on the data analysis, we take a moment to compare and contrast some of the different schemes that are currently being used for various PDF analysis efforts. While many of the global analyses use a Variable Flavor Number (VFN) scheme to include the heavy quark as a parton, the detailed implementation of this scheme can lead to notable differences. At the 2009 Les Houches workshop, a comparison was performed among a number of the different programs to quantify these differences. All programs used the same PDFs and $\alpha_{S}$ values so that the differences would only reflect the particular scheme. The complete details can be found in Ref. [22], and Figures 7 and 8 display sample comparisons.

Figure 7 compares the S-ACOT scheme which is used for the CTEQ series of global analyses, [23, 24] and the FONLL which is used by the Neural Network PDF (NNPDF) collaboration. [25] In the figure, these two

[^98]

Figure 7: Comparison of $F_{2}^{c}$ for the Fixed-Order-Next-to-LeadingLog (FONLL) with the Simplified-ACOT (S-ACOT) scheme. There are four curves displayed, two for the ordinary $\chi$-rescaling, and two for an alternate $\chi$-rescaling (labeled " v 2 "). The FONLL and S-ACOT results are identical throughout the $x$ range. (Figure from Ref. [22].)

Figure 8: Comparison of $F_{2}^{c}$ for the Fixed-Order-Next-to-LeadingLog (FONLL) and the MSTW08 NLO results. The FONLL results are shown for both the " A " and " B " variations. The FONLL results differ from the MSTW08 results for low $Q$ and $x$; for larger values of $Q$ and $x$ they are more comparable. (Figure from Ref. [22].)
implementations (S-ACOT and FONLL-A) are numerically equivalent.

Figure 8 compares two variations of the FONLL scheme ("A" and "B") with the MSTW08 results which is used in the MSTW series of PDF global analyses. [26, 27] Here these differences reflect the different organization and truncation of the perturbation expansion; it does not indicate that one choice is right or wrong. We expect such differences to be proportional to $\sim \alpha_{S}^{N} \times O\left(m^{2} / Q^{2}\right)$. Thus, as we increase the order of perturbation theory or the energy scale the differences should decrease; we have explicitly verified the difference is reduced as $Q^{2}$ increases, as it should. When we are able to carry these calculations out to higher orders, the scheme differences should be further reduced; this work is in progress.

## Charm Mass Dependence and $\boldsymbol{F}_{\mathbf{2}}^{\boldsymbol{c}}$

The experimental extraction of the "inclusive" $F_{2}^{c}$ requires a differential NLO calculation of DIS charm production to be extrapolated over the unobserved kinematic regions. These analyses generally make use of the HVQDIS program [28] which computes $F_{2}^{c}$ in a Fixed-Flavor-Number (FFN) scheme at NLO. In this calculation, the charm is produced only via a gluon splitting, $g \rightarrow c \bar{c}$, and there is no charm PDF. Thus, the charm mass $\left(m_{c}\right)$ enters only the partonic cross section $\hat{\sigma}\left(m_{c}\right)$ and the final state phase space; there is no PDF charm threshold.

Although we would also like to perform the extraction of $F_{2}^{c}$ using a Variable-Flavor-Number (VFN) scheme, the challenge is that no NLO differential program exists for this process. In lieu of a VFN extraction, another avenue is to study the influence of different theoretical schemes and $m_{c}$ parameters in the analysis of the $F_{2}^{c}$ data. We describe such a study below.

In many analyses, the value of the charm mass is taken as an external fixed parameter. A recent investigation has taken a closer look at the role of the charm mass parameter $m_{c}$ and examined the combined effects of $m_{c}$ and the theoretical scheme used; preliminary results of this study are displayed in Figure 9. For each of the schemes listed in the legend, fits were generated for fixed $m_{c}$ values in the range $[1.2,1.8] \mathrm{GeV}$. Thus, the minimum of the $\chi^{2}$ curve represents the "optimal" choice of the charm mass parameter $m_{c}$ for that specific scheme.

We observe that the various schemes prefer $m_{c}$ values ranging from 1.2 to 1.7 GeV , The largest $m_{c}$ value $(1.68 \mathrm{GeV})$ comes from the Zero Mass VFN Scheme (ZM VFNS) which only uses $m_{c}$ for the PDF charm

Figure 9: Comparison of $\chi^{2}$ for HERAPDF1.0 $+F_{2}^{c \bar{c}}$ fits using different heavy flavor schemes as a function of the charm quark mass parameter $m_{c}^{\text {model }}$. (Figure from Hlprelim-10-143 \& ZEUS-prel-10019)
threshold; it is absent in the phase space for the zeromass case. In contrast, for the S-ACOT- $\chi$ scheme the " $\chi$ " notation ${ }^{4}$ indicates there are effectively two factors of $m_{c}$ in the final phase space, and this yields the smallest value of $m_{c}(1.26 \mathrm{GeV})$.

The ACOT scheme and the Roberts-Thorne (RT) scheme yield $m_{c}$ values in the intermediate region. The ACOT scheme uses the full kinematic mass relations in the partonic relations, and the scaling variable is intermediate ( $m_{c}=1.58 \mathrm{GeV}$ ) between the ZM VFN scheme and the S-ACOT- $\chi$ scheme. The S-ACOT scheme (not shown) is virtually identical to the full ACOT scheme, and also yields a $m_{c}$ value in the intermediate region. Therefore, comparing the S-ACOT$\chi$ and S-ACOT schemes, we find that the $\chi$-rescaling variable is dominantly responsible for the shift of the optimal $m_{c}$ value from $\sim 1.26$ to $\sim 1.58$. This observation suggests that it is the rescaling of the $x$ variable which enters the PDFs that generates the dominant effect. While this study is continuing, it does indicate the sensitivity of the charm mass and scheme choice in these precision analyses.

Figure 10: Measurement of $\gamma+c$ and $\gamma+b$ vs. $P_{T}^{\gamma}$ as measured by D-Zero. (Figure from Ref. [32].)

Figure 11: The integrated momentum fraction (in percent) of the "extrinsic" charm and bottom quarks generated by gluon splitting as a function of the scale $Q$. Reference lines are indicated at $1 \%$ and $2 \%$.

## Extrinsic \& Intrinsic Charm PDFs

The charm quark and bottom quark PDFs can be probed directly at the Tevatron by studying photonheavy quark final states which occur via the sub-process $g Q \rightarrow \gamma Q$ at LO. This process has been measured at the Tevatron for both charm and bottom final states, and we display the results in Figure 10 as a function of $P_{T}^{\gamma}$ for two rapidity configurations. This measurement is particularly interesting as the dominant process involves a heavy quark PDF; this is in contrast to DIS charm or bottom production, for example, where over much of the kinematic range the process is dominated by the gluon-initiated process (e.g., $\gamma g \rightarrow Q \bar{Q}$ ) rather than the heavy quark initiated process $(\gamma Q \rightarrow Q)$.

[^99]

Figure 12: $d \sigma / d p_{T \gamma}(\mathrm{pb} / \mathrm{GeV})$ at the Tevatron for the CTEQ6.6 PDFs, and two intrinsic charm (IC) models. (Figure from Ref. [30].)

Figure 13: Ratio of $d \sigma / d p_{T \gamma}(\mathrm{pb} / \mathrm{GeV})$ at the LHC $(\sqrt{s}=7 T e V)$ for the BPHS IC model to the CTEQ6.6 PDF for a selection of rapidity bins. (Figure from Ref. [30].)

Examining Figure 10 we observe that the bottom quark production measurements compare favorably with the theoretical predictions throughout the $P_{T}^{\gamma}$ range, but the charm results rise above the theory predictions for large $P_{T}^{\gamma}$. Although there may be a number of explanations for the excess charm cross section at large $P_{T}^{\gamma}$, one possibility is the presence of intrinsic charm (IC) in the proton. In the usual DGLAP evolution of the proton PDFs, we begin the evolution at a low energy scale $Q_{0}<m_{c}$ and evolve up to higher scales. The charm and bottom PDFs are defined to be zero for $Q<m_{c, b}$, and above the mass scale the heavy quark PDFs are generated by gluon splitting, $g \rightarrow Q \bar{Q}$; we refer to this as the "extrinsic" contribution to the heavy quark PDFs. In Figure 11 we display the integrated mo-

Figure 14: Measurement of $F_{L}$ using the combined HERA data set from H1 and ZEUS. The data are compared with a selection of theoretical predictions. (Figure H1prelim-10-044 EG ZEUS-prel-10-008).
mentum fractions for the charm and bottom quarks as a function of the scale $Q$; these are zero for $Q<m_{c, b}$, and then begin to grow via the $g \rightarrow Q \bar{Q}$ process.

It has been suggested that there may also be an "intrinsic contribution to the heavy quark PDFs which is present even at low scales $Q<m_{c, b}$. While it is difficult to constrain the detailed functional shape of any intrinsic heavy quark distribution, the total momentum fraction of any intrinsic contribution must be less than approximately $1 \%$ if it is to be compatible with the global analyses.

In Figure 12 we illustrate the effect of including an additional intrinsic charm component in the proton. The BHPS IC model concentrates the momentum fraction at large $x$ values, and the Sea-like IC model distributes the charm more uniformly. ${ }^{5}$ It is intriguing that the IC modification of the proton PDF can increase the theoretical prediction in the large $P_{T}^{\gamma}$ region, but this observation alone is not sufficient to claim the presence of IC; this would require independent verification. In Figure 13 we display the cross section ratio for $\gamma+c$ at the LHC for the BHPS IC model for a selection of rapidity bins. Thus the LHC can validate or refute this possibility with a high-statistics measurement of $\gamma+c$, especially if they can observe this in the forward rapidity region.

## The Longitudinal Structure Function $\boldsymbol{F}_{\boldsymbol{L}}$

Most of the previous discussion has addressed the determination of the quark PDFs. Constraining the gluon PDF is a challenge, and the longitudinal structure function $F_{L}$ is particularly interesting as it involves both the

[^100]

Figure 15: Fractional flavor decomposition of $F_{L}^{i} / F_{L}$ vs. $Q$ in GeV for a) $x=10^{-1}$ and b) $x=10^{-5}$. Reading from the bottom, we plot the cumulative contributions for $\{u, d, s, c, b\}$.
heavy quark and the gluon distributions. Using the combined data from H1 and ZEUS, HERA has extracted $F_{L}$ in an extended kinematic regime, and Figure 14 displays the result of the combined data as compared with various theoretical predictions.

The measurement of $F_{L}$ is special for a number of reasons, and we write this schematically as:

$$
\begin{equation*}
F_{L} \simeq \frac{m^{2}}{Q^{2}} q(x)+\alpha_{S}\left\{C_{g} \otimes g(x)+C_{q} \otimes q(x)\right\} \tag{1}
\end{equation*}
$$

Note that the LO term is zero in the limit of massless quarks as the $\left(m^{2} / Q^{2}\right)$ factor in Eq. (1) suppresses the helicity violating contributions; this is a consequence of the Callan-Gross relation. Therefore, for light quarks the dominant contributions come from the NLO gluon term; hence, $F_{L}$ can provide useful information about the gluon PDF.

For the heavy quarks the picture is less obvious. While the NLO heavy quark contributions will clearly be small compared to the dominant gluon terms, the heavy quarks can contribute at LO if they can overcome the $\left(m^{2} / Q^{2}\right)$ suppression. This is why the prediction of $F_{L}$ into the low $Q^{2}$ region as measured in Figure 14 is such a theoretical challenge. This raises a number of questions: What is the flavor composition of $F_{L}$ ? Where are the heavy quark contributions important?

In Figure 15 we display the fractional contributions to the structure functions $F_{L}^{i} / F_{L}$ vs. $Q$. We observe that for large $x$ and low $Q$ the heavy flavor contributions are minimal. For example, in Figure 15-a) at $Q \sim 5 \mathrm{GeV}$ we see the $u$-quark structure function $F_{L}^{u}$ comprises $\sim 80 \%$ of the total, $F_{L}^{d}$ is about $10 \%$, and the $s, c$ and $b$ quarks divide the remaining fraction.

At smaller $x$ values the picture changes and the heavy quarks are more prominent. In Figure 15-b) for $Q \sim$ 2 GeV we see the $u$-quark structure function $F_{L}^{u}$ comprises $\sim 55 \%, F_{L}^{d}$ and $F_{L}^{s}$ are both about $20 \%$, and the $c$ and $b$ quarks make up the small remaining fraction.

However, $F_{L}^{c}$ increases quickly as $Q$ increases and is comparable to $F_{L}^{u}(\sim 40 \%)$ for $Q \sim 20 \mathrm{GeV}$. Additionally, for large $Q \sim 100 \mathrm{GeV}$ we see the contributions of the $u$-quark and $c$-quark are comparable, the $d$-quark and $s$-quark are comparable, and the relative sizes of the $u, c$ to $d, s$ terms are proportional to their couplings: $4 / 9$ to $1 / 9$. Thus, for low $x$ and intermediate to large $Q$ values we see that the quark masses (aside from the top) no longer play a prominent role and we approach the limit of "flavor democracy."

## Concluding Remarks

We reviewed a number of recent developments regarding the extraction and application of heavy quark Parton Distribution Functions (PDFs). The high precision HERA measurements were essential in developing and refining the theoretical treatment of the heavy quarks. Even though the accelerator facility stopped operation four years ago, the analysis of the data continues. The results of these analyses will provide the foundation upon which future PDF analyses will be built, and the advances of the experimental analysis and theoretical tools developed at HERA will continue to influence future hadronic studies including those now beginning at the LHC.

The neutrino deep inelastic scattering (DIS) data is very interesting for global analyses of proton and nuclear parton distribution functions (PDFs) since they provide crucial information on the strange quark distribution in the proton and allow for a better flavor decompositon of the PDFs. In order to use neutrino DIS data in a global analysis of proton PDFs nuclear effects need to be understood. We study these effects with the help of nuclear PDFs extracted from global analyses of charged-lepton DIS, Drell-Yan and neutrino DIS data at next-to-leading order in QCD.

## 1. Introduction

Parton distribution functions are of great importance in contemporary high energy physics. Because they encode fundamental information on the structure of hadrons, PDFs are needed for the computation of any high energy reaction (at HERA, RHIC, Tevatron, LHC, . . . ) involving hadrons in the initial state.

Many groups perform and regularly update global analyses of PDFs for protons [1], , , , 母 ] and nuclei [5, 6, 7]. Although not often emphasized, nuclear effects are present also in the analyses of proton PDFs since a number of experimental data is taken on nuclear targets. Most of the nuclear targets used in the proton analysis are made of light nuclei in which nuclear effects are expected to be small. However, the neutrino DIS data is taken on heavy nuclei such as iron and lead and is sensitive to the strange quark content of the proton. It should be noted that a good knowledge of the strange quark PDF has a significant influence on the $W$ - and $Z$ boson benchmark processes at LHC. Moreover, the neutrino experiments have been used to make precision tests of the Standard Model $(\mathrm{SM})$ in the neutrino sector. A prominent example is the extraction of the weak mixing angle $\sin \theta_{W}$ in a Paschos-Wolfenstein type analysis.

Historically, nuclear corrections based on information from the charged-lepton-nucleus ( $\ell A$ ) DIS data have been applied to the neutrino-nucleus ( $v A$ ) DIS data. Furthermore, the same correction factors have been applied to several different observables in $v A$-DIS ( $F_{2}, F_{3}$, cross section and dimuon production) and at different scales $Q^{2}$. Conversely, it is much more flexible to compute nuclear corrections in the Parton Model (PM) using nuclear PDFs taking different observables and scales into account. For this reason, we perform global analyses of nuclear PDFs at next-to-leading order (NLO) in QCD in a framework closely related to the one used by the CTEQ collaboration in Ref. [9]. We determine several sets of nuclear PDFs from a) $\ell A$ DIS + Drell-Yan (DY) data and b) $v A$ DIS data and c) the combined $\ell A$ DIS $+\mathrm{DY}+v A$ DIS data. We analyze and compare the resulting nuclear correction factors.

## 2. CTEQ Nuclear Parton distribution functions

The global nuclear PDF framework we use to analyze $\ell A$ DIS and DY and $v A$ DIS data was introduced in [ 8$]$. The parameterizations of the parton distributions in bound protons at the input scale of $Q_{0}=1.3 \mathrm{GeV}$

$$
\begin{equation*}
x f_{k}\left(x, Q_{0}\right)=c_{0} x^{c_{1}}(1-x)^{c_{2}} e^{c_{3} x}\left(1+e^{c_{4}} x\right)^{c_{5}} \tag{2.1}
\end{equation*}
$$

where $k=u_{v}, d_{v}, g, \bar{u}+\bar{d}, s, \bar{s}$ and

$$
\begin{equation*}
\bar{d}\left(x, Q_{0}\right) / \bar{u}\left(x, Q_{0}\right)=c_{0} x^{c_{1}}(1-x)^{c_{2}}+\left(1+c_{3} x\right)(1-x)^{c_{4}} \tag{2.2}
\end{equation*}
$$

are a generalization of the parton parameterizations in free protons used in the CTEQ proton analysis [9]. To account for a variety of nuclear targets, we introduce A-dependent fit parameters $c_{k}$

$$
\begin{equation*}
c_{k} \rightarrow c_{k}(A) \equiv c_{k, 0}+c_{k, 1}\left(1-A^{-c_{k, 2}}\right), k=\{1, \ldots, 5\} . \tag{2.3}
\end{equation*}
$$

The free proton PDFs are recovered in this framework in the limit $A \rightarrow 1$. From the input distributions, we can construct the PDFs for a general $(A, Z)$-nucleus

$$
\begin{equation*}
f_{i}^{(A, Z)}(x, Q)=\frac{Z}{A} f_{i}^{p / A}(x, Q)+\frac{(A-Z)}{A} f_{i}^{n / A}(x, Q) \tag{2.4}
\end{equation*}
$$

where the distributions of a bound neutron, $f_{i}^{n / A}(x, Q)$, are related to those of a proton by isospin symmetry.

We performed a global analysis of $\ell A$ DIS + DY data within this framework, determining the $A$-dependence of the parameters $c_{k}(A)$. In this analysis, we applied the same standard kinematic cuts $Q>2 \mathrm{GeV}$ and $W>3.5 \mathrm{GeV}$ as in [9] leaving 708 data points and we obtained a fit with $\chi^{2} /$ dof $=0.946$ with 32 free parameters (for further details see [8]).

To extract the nuclear effects it is useful to define a nuclear correction factor $R$ which is the ratio of the observable $(\mathbf{O})$ using nuclear PDF over free PDF

$$
\begin{equation*}
R[\mathbf{O}]=\frac{\mathbf{O}[\text { nuc. } \mathbf{P D F}]}{\mathbf{O}[\text { free } \mathbf{P D F}]} . \tag{2.5}
\end{equation*}
$$

We compared the nuclear correction factors $R$ for the structure function $\left[F_{2}^{\ell A}\right]$ in $\ell A$ DIS with the structure function $\left[F_{2}^{v A}\right]$ in $v A$ DIS. As first observed in [11], the nuclear correction factor $R\left[F_{2}^{\ell A}\right]$ does not describe the NuTeV $v F e$ data well. This raises the question whether the nuclear corrections in $\ell A$ DIS and $v A$ DIS are different.

For definite conclusions, we set up a global analysis of the combined $\ell A$ DIS $+\mathrm{DY}+v A$ DIS data where we included exclusively the neutrino DIS cross-section data coming from the NuTeV (iron) and Chorus (lead) experiments, respectively. Here we applied the same kinematic cuts as in the first analysis of the charged-lepton data leaving us with 3134 neutrino DIS cross-section data. In a fit to only the neutrino data we obtained a $\chi^{2} /$ dof of 1.33 with 34 free parameters (for further details see [10]).

As expected, the nuclear correction factors using NPDFs extracted from the $v A$ DIS data exhibit clear differences with the corresponding nuclear correction factors using NPDFs extracted from $\ell A$ DIS + DY data which are especially marked at low and intermediate Bjorken $x$.

Analyzing both data sets in a combined global analysis runs into the problem of an imbalance of the number of data points between the two data sets, since the $v A$ DIS data points would be dominant compared to the $\ell A$ DIS and DY data. Therefore, we introduced a weight parameter $w$ to combine the data sets

$$
\begin{equation*}
\chi^{2}=\sum_{l^{ \pm} A \text { data }} \chi_{i}^{2}+\sum_{v A \text { data }} w \chi_{i}^{2} . \tag{2.6}
\end{equation*}
$$

In the case $w=0$, only the $\ell A$ DIS and DY data are included and $w=\infty$ uses only the $v A$ DIS data. Varying the weight $w$, we tried to find a compromise fit which would describe both, $\ell A$ DIS + DY data and $v A$ DIS data, reasonably well. We refer to Table II in [10] for the resulting $\chi^{2}$ of the compromise fits with weights $w=0,1 / 7,1 / 2,1, \infty$ and to Figure 1 in [10] for the corresponding nuclear correction factors. As one can see, with increasing weight $w$ the description of the $\ell A$ DIS data gets worse and the one of the $v A$ DIS data improves.

In order to judge quantitatively on how well the compromise fits describe the data we use the $\chi^{2}$ goodness-of-fit criterion introduced in [12, 2]. We consider a fit to be a good compromise if its $\chi^{2}$ for the $\ell A$ DIS $+\mathrm{DY}+v A$ DIS data is within the $90 \%$ confidence level of the fits to a) only $\ell A$ DIS + DY data and b) only $v A$ DIS data. We define the $90 \%$ percentile $\xi_{90}$ used to define the $90 \%$ confidence level, by

$$
\begin{equation*}
\int_{0}^{\xi_{90}} P\left(\chi^{2}, N\right) d \chi^{2}=0.90 \tag{2.7}
\end{equation*}
$$

where $N$ is the number of degrees of freedom and $P\left(\chi^{2}, N\right)$ is the probability distribution

$$
\begin{equation*}
P\left(\chi^{2}, N\right)=\frac{\left(\chi^{2}\right)^{N / 2-1} e^{-\chi^{2} / 2}}{2^{N / 2} \Gamma(N / 2)} \tag{2.8}
\end{equation*}
$$

We can assign a $90 \%$ confidence level error band to the $\chi^{2}$ of the fits to the $\ell A$ DIS + DY and to the $v A$ DIS data

$$
\begin{equation*}
\chi_{l^{ \pm} A}^{2}=638+45.6, \quad \chi_{v A}^{2}=4192+138 \tag{2.9}
\end{equation*}
$$

Comparing the results of the fits with different weights, listed in Table II in [10], we conclude that there is no good compromise which is compatible with both $90 \%$ confidence level given in Eq. (2.9) (see details in [10]).

## 3. Conclusion

After performing a thorough global NPDF analysis of the combined charged-lepton DIS, DY and neutrino DIS data, we find that nuclear correction factors in $v A$ DIS and $\ell A$ DIS are different and there is no good compromise fit to the combined $\ell A$ DIS, DY and $v A$ DIS data. This has important consequences for global analyses of proton and NPDF, for models explaining the nuclear effects, and precision observables in the neutrino sector. The nCTEQ nuclear PDFs described here as well as the ones obtained in [13] are available at [14].

#### Abstract

We perform a global $\chi^{2}$-analysis of nuclear parton distribution functions using data from charged current neutrino-nucleus ( $\nu A$ ) deep inelastic scattering (DIS), charged-lepton-nucleus ( $\ell^{ \pm} A$ ) DIS, and the Drell-Yan (DY) process. We show that the nuclear corrections in $\nu A$ DIS are not compatible with the predictions derived from $\ell^{ \pm} A$ DIS and DY data. We quantify this result using a hypothesistesting criterion based on the $\chi^{2}$ distribution which we apply to the total $\chi^{2}$ as well as to the $\chi^{2}$ of the individual data sets. We find that it is not possible to accommodate the data from $\nu A$ and $\ell^{ \pm} A$ DIS by an acceptable combined fit. Our result has strong implications for the extraction of both nuclear and proton PDFs using combined neutrino and charged lepton data sets.

PACS numbers: 12.38.-t,13.15.+g,13.60.-r,24.85.+p

High statistics neutrino deep-inelastic scattering (DIS) experiments have generated significant interest in the literature as they provide crucial information for global fits of parton distribution functions (PDFs). The neutrino DIS data provide the most stringent constraints on the strange quark distribution in the proton, and allow for flavor decomposition of the PDFs which is essential for precise predictions of the benchmark gauge boson production processes at the LHC. Moreover, the neutrino experiments have been used to make precision tests of the Standard Model (SM). A prominent example is the extraction of the weak mixing angle $\theta_{W}$ in a PaschosWolfenstein type analysis [1]. A good knowledge of the neutrino DIS cross sections is also very important for long baseline experiments of the next generation which aim at measuring small parameters of the mixing matrix such as the mixing angle $\theta_{13}$ and eventually the CP violating phase $\delta$.

Due to the weak nature of neutrino interactions the use of heavy nuclear targets is unavoidable, and this complicates the analysis of the precision physics discussed above since model-dependent nuclear corrections must be applied to the data. Our present understanding of the nuclear corrections is mainly based on charged lepton-nucleus ( $\ell A$ ) DIS data. In the early 80's the European Muon Collaboration (EMC) [2] found that the nucleon structure functions $F_{2}$ for iron and deuterium differ. This discovery triggered a vast experimental program to investigate the nuclear modifications of the ratio $R\left[F_{2}^{\ell A}\right]=F_{2}^{\ell A} /\left(A F_{2}^{\ell N}\right)$ for a wide range of nuclear targets with atomic number $A$, see Tab. I. By now, such modifications have been established in a kinematic range from relatively small Bjorken $x\left(x \sim 10^{-2}\right)$ to large $x(x \sim 0.8)$ in the deep inelastic region with squared
momentum transfer $Q^{2}>1 \mathrm{GeV}^{2}$. The behavior of the ratio $R\left[F_{2}^{\ell A}\right]$ can be divided into four regions: (i) $R>1$ for $x \gtrsim 0.8$ (Fermi motion region), (ii) $R<1$ for $0.25 \lesssim x \lesssim 0.8$ (EMC region), (iii) $R>1$ for $0.1 \lesssim x \lesssim 0.25$ (anti-shadowing region), and (iv) $R<1$ for $x \lesssim 0.1$ (shadowing region), with different physics mechanisms explaining the nuclear modifications. The shadowing suppression at small $x$ occurs due to coherent multiple scattering inside the nucleus of a $q \bar{q}$ pair coming from the virtual photon [3] with destructive interference of the amplitudes [4]. The anti-shadowing region is theoretically less well understood but might be explained by the same mechanism with constructive interference of the multiple scattering amplitudes [4] or by the application of momentum, charge, and/or baryon number sum rules. Conversely, the modifications at medium and large $x$ are usually explained by nuclear binding and medium effects and the Fermi motion of the nucleons [5].

Instead of trying to address the origin of the nuclear effects, the data on nuclear structure functions can be analyzed in terms of nuclear PDFs (NPDFs) which are modified as compared to the free nucleon PDFs. Relying on factorization theorems in the same spirit as in the free nucleon case, the advantage of this approach is that the universal NPDFs can be used to make predictions for a large variety of processes in $\ell A, \nu A, p A$, and $A A$ collisions. In addition, the nuclear correction factors required for the interpretation of the neutrino experiments can be calculated in a flexible way, taking into account the precise observable, the nuclear $A$, and the scale $Q^{2}$. The factorization assumption in the nuclear environment is therefore a question of considerable theoretical and practical importance and global analyses of NPDFs based on $\ell A$ DIS and fixed target Drell-Yan (DY) data confirm its

Table I. The charged lepton DIS data sets together with DY and with neutrino DIS data sets used in the fit. The table details the specific nuclear targets, and the number of data points with kinematical cuts $\left(Q^{2}>4 G e V^{2}, W>3.5 G e V\right)$. References for the data sets are cited in Refs. [6, 7]
validity in the presently explored kinematic range.
However, in a recent analysis [6] of $\nu F e$ DIS data from the NuTeV collaboration we found that the nuclear correction factors are surprisingly different from the predictions based on the $\ell^{ \pm} F e$ charged-lepton results with important implications for global analyses of proton PDFs. This is not completely unexpected since the structure functions in charged current (CC) neutrino DIS and neutral current (NC) electron/muon DIS are distinct observables with different parton model expressions. From this perspective it is clear that the nuclear correction factors will not be exactly the same even for a universal set of

| $w$ | $l^{ \pm} A$ | $\chi^{2}(/ \mathrm{pt})$ | $\nu A$ | $\chi^{2}(/ \mathrm{pt})$ | total $\chi^{2}(/ \mathrm{pt})$ |

Table II. Summary table of a family of compromise fits.

NPDFs. Note also that some models in the literature predict differences between reactions in CC and NC DIS [8]. What is, however, unexpected is the degree to which the $R$ factors differ between the structure functions $F_{2}^{\nu F e}$ and $F_{2}^{\ell F e}$. In particular the lack of evidence for shadowing in neutrino scattering down to $x \sim 0.02$ is quite surprising.

The study in Ref. [6] left open the question, whether the neutrino DIS data could be reconciled with the charged-lepton DIS data by a better flavor separation of the NPDFs. In this letter, we address this question in the $A$-dependent framework of Ref. [7] by performing a global $\chi^{2}$-analysis of the combined data from $\nu A$ DIS, $\ell A$ DIS and the DY process listed in Table I.

When combining neutrino and charged-lepton + DY data into a compromise fit, we introduce a weight parameter $w$ into the $\chi^{2}$ via:

$$
\begin{equation*}
\chi^{2}=\sum_{l^{ \pm} A \text { data }} \chi_{i}^{2}+\sum_{\nu A \text { data }} w \chi_{i}^{2} . \tag{1}
\end{equation*}
$$

The $w$ factor allows us to adjust for the different number of points in the separate data sets, and provides a parameter that interpolates between the $\nu A$ and the $\ell^{ \pm} A+\mathrm{DY}$ data. We should stress that the $\chi^{2}$ cited in Table II and also in the text is the standard $\chi^{2}$; Eq. (1) is only used internally in the fitting procedure. We construct a set of compromise fits with weights $w=\left\{0, \frac{1}{7}, \frac{1}{2}, 1, \infty\right\}$ and study the dependence of the result on this weight. The fit to only neutrino data, denoted $w=\infty$ in Table II, is compatible with the results in [6]. Similarly, the fit to only charged-lepton + DY data, denoted $w=0$, agrees well with the analysis in [7].

We first compute the nuclear correction factors $R\left[F_{2}^{\ell F e}\right] \simeq F_{2}^{\ell F e} / F_{2}^{\ell N}$ and $R\left[F_{2}^{\nu F e}\right] \simeq F_{2}^{\nu F e} / F_{2}^{\nu N}[10]$ in the QCD parton model at next-to-leading order employing the NPDF fits in Tab. II for the numerator and free nucleon PDFs for the denominator. The $x$-dependence of $R\left[F_{2}^{\ell F e}\right]$ and $R\left[F_{2}^{\nu F e}\right]$ is shown in Fig. 1 a) and b), respectively, at $Q^{2}=5 \mathrm{GeV}^{2}$. Similar results hold at $Q^{2}=20 \mathrm{GeV}^{2}$ which we do not present here. We observe that the fit to only $\ell A$ DIS + DY data $(w=0)$ well describes the SLAC and BCDMS points in Fig. 1 a). The same is true for the fit to only $\nu A$ DIS data $(w=\infty)$ which is compatible with the results from the NuTeV experiment [9] exemplified in Fig. 1 b). However, comparing the results obtained with the $w=0$ and the

Figure 1. Predictions from the compromise fits for the nuclear correction factors $R\left[F_{2}^{\ell F e}\right] \simeq F_{2}^{\ell F e} / F_{2}^{\ell N}$ (left) and $R\left[F_{2}^{\nu F e}\right] \simeq$ $F_{2}^{\nu F e} / F_{2}^{\nu N}$ (right) as a function of $x$ for $Q^{2}=5 \mathrm{GeV}^{2}$. The data points displayed in figure a) are from BCDMS and SLAC experiments (for references see [7]) and those displayed in figure b) come from the NuTeV experiment [9].
$w=\infty$ fits one can see that they predict considerably different $x$-shapes.

The fits with weights $w=\left\{\frac{1}{7}, \frac{1}{2}, 1\right\}$ interpolate between these two incompatible solutions. As can be seen in Fig. 1 a) and b), with increasing weight the description of the $\ell F e$ data is worsened in favor of a better agreement with the $\nu F e$ points. This trend clearly demonstrates that the $\ell F e$ and the $\nu F e$ data pull in opposite directions. We identify the fits with $w=1 / 2$ or $w=1$ as the best candidates for a possible compromise.

To be able to decisively accept or reject the compromise fits, we apply a statistical goodness-of-fit criterion [11-13] based on the probability distribution for the $\chi^{2}$ given that the fit has $N$ degrees of freedom:

$$
\begin{equation*}
P\left(\chi^{2}, N\right)=\frac{\left(\chi^{2}\right)^{N / 2-1} e^{-\chi^{2} / 2}}{2^{N / 2} \Gamma(N / 2)} \tag{2}
\end{equation*}
$$

This allows us to define the percentiles $\xi_{p}$ via $\int_{0}^{\xi_{p}} P\left(\chi^{2}, N\right) d \chi^{2}=p \%$ where $p=\{50,90,99\}$. Here, $\xi_{50}$ serves as an estimate of the mean of the $\chi^{2}$ distribution and $\xi_{90}$, for example, gives us the value where there is only a $10 \%$ probability that a fit with $\chi^{2}>\xi_{90}$ genuinely describes the given set of data. In a global PDF fit, the best fit $\chi^{2}$ value often deviates from the mean value because the data come from different possibly incompatible experiments having unidentified, unknown errors which are not accounted for in the experimental systematic errors. For this reason we rescale the $\xi_{90}$ and $\xi_{99}$ percentiles relative to the best fit $\chi_{0}^{2}$ [11] to define $C_{90}=\chi_{0}^{2}\left(\xi_{90} / \xi_{50}\right)$ and $C_{99}=\chi_{0}^{2}\left(\xi_{99} / \xi_{50}\right)$. This defines our criterion: a fit with a given $\chi^{2}$ is compatible with the best fit with $\chi_{0}^{2}$ at $90 \%(99 \%)$ confidence if $\chi^{2}<C_{90}$ $\left(\chi^{2}<C_{99}\right)$. We apply it to both the total $\chi^{2}$ and the $\chi^{2}$ of the individual data sets.

For the $\ell A$ DIS + DY data we use the fit with $w=0$ as benchmark with $\chi_{0}^{2}=638$ and $N=677$ degrees of freedom (for 708 data points and 31 free parameters). The upper limits on the $\chi^{2}$ at $90 \%$ and $99 \%$ confidence level (C.L.) are then $C_{90}^{l^{ \pm} A}=684$ and $C_{99}^{l^{ \pm} A}=722$. The benchmark fit for the $\nu A$ DIS data $(w=\infty)$ uses 3134 data points with 33 free parameters resulting in $N=$

3101 and one finds $C_{90}^{\nu A}=4330$ and $C_{99}^{\nu A}=4445$. We see that none of the compromise fits satisfies both limits at the $90 \%$ C.L. which is usually used in global analyses of PDFs to define the uncertainty bands. At the $99 \%$ C.L., there are two fits $(w=1 / 2, w=1)$ which are below the $C_{99}^{\nu A}$ limit. However, only the $w=1 / 2$ fit satisfies the corresponding constraint from the chargedlepton benchmark fit.

We now apply our criterion also to the individual data sets with IDs between 1 and 40 in Table I. For the $\ell A$ DIS + DY data (ID $=[1,31]$ ) we determine the $31 C_{90}\left(C_{99}\right)$ limits by using the individual $\chi_{i}^{2}$ of the $w=0$ fit as $\chi_{0, i}^{2}$. For the $\nu A$ DIS data ( $\mathrm{ID}=[33,40]$ ) we proceed in a similar manner using the individual $\chi_{i}^{2}$ of the $w=\infty$ fit. The results of this detailed analysis are depicted in Fig. 2, where we show the quantity

$$
\begin{equation*}
\frac{\Delta \chi^{2}}{\Delta C_{90}}=\frac{\chi_{i}^{2}-\chi_{0, i}^{2}}{C_{90, i}-\chi_{0, i}^{2}} \quad(i=1, \ldots, 40) \tag{3}
\end{equation*}
$$

where $\chi_{i}^{2}$ represents the $\chi^{2}$-value of the $i$ 'th data set. In cases where $\chi_{i}^{2}>C_{90, i}$ the fit is not compatible with the best fit at the $90 \%$ level and $\Delta \chi^{2} / \Delta C_{90}>1$. The exact $90 \%$ C.L. limit is shown as a constant solid line and the dotted line represents the $99 \%$ confidence limit. The local application of the $\chi^{2}$ hypothesis-testing criterion reveals that even the compromise fit with weight $w=\frac{1}{2}$ which was considered acceptable at the $99 \%$ C.L. when looking at the nuclear correction factors and at the global change in $\chi^{2}$, cannot be accepted as a compromise solution as both the charged-lepton and neutrino DIS data on iron exceed the $99 \%$ limit.
In conclusion, the tension between the $\ell^{ \pm} F e$ and $\nu F e$ data sets leaves us with no possible compromise fit when investigating the results in detail, not even when using the $99 \%$ percentile as the limit as opposed to the more restrictive $90 \%$ limit which is usually used to construct the error PDFs. This detailed analysis confirms the preliminary conclusions of Refs. [6, 7] that there is no possible compromise fit which adequately describes the neutrino DIS data along with the charged-lepton data.

At face value, this conclusion differs from some results in the literature which argue the $\nu A$ and $\ell^{ \pm} A$ data are in

Figure 2. $\Delta \chi^{2} / \Delta C_{90}$ as defined in Eq. (3) for the 40 individual data sets. Results are shown for the $w=\frac{1}{2}$-fit (left) and the fit 'Ucor5' (right) with $w=1$. The solid and dashed lines indicate the $90 \%$ and $99 \%$ confidence limits. The highlighted data sets correspond to DIS $\ell^{ \pm} F e(\mathrm{ID}=8), \nu F e(\mathrm{ID}=35)$, and $\bar{\nu} F e(\mathrm{ID}=36)$.
accord [14]. Here, we believe an essential element in our analysis is the use of the correlated systematic errors of the $\nu A$ data. To highlight this point, we now repeat our analysis, but we combine the statistical and all systematic errors in quadrature (thereby neglecting the information contained in the correlation matrix) for $\nu A$ data for the $w=1$ fit with $Q^{2}>4 G e V$ (as before); we denote this the "Ucor 4 " fit, and we obtain $\chi^{2} / p t$ of 1.14 for $\ell^{ \pm} A$ and 1.00 for $\nu A$. We also use a $Q^{2}>5 \mathrm{GeV}$ fit (denoted "Ucor5") to mimic the cuts of Ref. [14]; here we obtain $\chi^{2} / p t$ of 1.14 for $\ell^{ \pm} A$ and 0.96 for $\nu A$.
If we examine the total $\chi^{2}$ values, we find the $\chi^{2} /$ dof $\sim$ 1 , and might be tempted to conclude we are able to fit both the $\nu A$ and $\ell^{ \pm} A$ data simultaneously. However, if we look at individual data sets and apply our hypothesis testing criteria, the picture is quite different. Fig. 2 b) displays the results for the Ucor5 fit. The higher $Q^{2}$ cut of the Ucor5 fit removes some of the very precise NuTeV data at small- $x$, thus resulting in an improved $\chi^{2}$ compared to Ucor 4 . Nevertheless, many of the $\ell^{ \pm} A$ data sets (ID $=3,4,5,6,8$ ) still lie outside the $99 \%$ CL percentile. Thus, we still conclude that there is no compromise fit for the $\nu A$ and $\ell^{ \pm} A$ data even if we relax the constraints by using uncorrelated errors.

Consequently, the nuclear correction factor for the neutrino DIS data are indeed incompatible with that of the charged lepton DIS and DY data, and this result depends crucially on the use of the precision correlated errors of the neutrino data. This result has important implications for both nuclear and proton PDFs. If we do not know the appropriate nuclear correction to relate different nuclear targets, our ability to extract PDFs is limited. For example, the CTEQ6.6 analysis [15] sidesteps this issues by removing most of the $\nu A$ data from the fit; however, they retain the NuTeV dimuon data since this data is critical to constraining the strange quark PDF. This underscores the importance of the $\nu A$ data for flavor differentiation.

Although the NuTeV data provides the tightest constraints due to their statistics, we note that this issue cannot be tied to a single data set. For example, we find that NuTeV is generally compatible with CCFR and CDHSW[16]. The CHORUS $\nu P b$ and $\bar{\nu} P b$ data have larger uncertainties, so they can be compatible with both
the $\ell^{ \pm} A$ data and the $\mathrm{NuTeV} \nu F e$ data because the $\Delta \chi^{2} / \Delta C_{90}<1$ for all weights. Compared to the theory predictions, NuTeV agrees well in the central $x$ region, but exhibits differences both for low $x$ at low $Q^{2}$, and also for very high $x(x \sim 0.65)$.

We have demonstrated that the $\nu A$ and $\ell^{ \pm} A$ data prefer different nuclear correction factors, and that there is no single "compromise" result that will simultaneously satisfy both data sets. While we have focused on the phenomenological aspects for the present study, this result has strong implications for the extraction of both nuclear and proton PDFs using combined neutrino and chargedlepton data sets. Possibilities include unexpectedly large higher-twist effects, or even non-universal nuclear effects; we leave such questions for a future study.

(Received 29 November 2010; published 11 March 2011)

#### Abstract

We extract parton distribution functions (PDFs) and structure functions from recent experimental data of polarized lepton-deeply inelastic scattering (DIS) on nucleons at next-to-leading order (NLO) quantum chromodynamics. We apply the Jacobi polynomial method to the Dokshitzer-Gribov-Lipatov-AltarelliParisi (DGLAP) evolution as this is numerically efficient. Having determined the polarized proton and neutron spin structure, we extend this analysis to describe ${ }^{3} \mathrm{He}$ and ${ }^{3} \mathrm{H}$ polarized structure functions, as well as various sum rules. We compare our results with other analyses from the literature.

## I. INTRODUCTION

A fundamental challenge of high energy particle physics is to understand the spin structure of protons, neutrons, and nuclei in terms of their parton constituents. The increasing precision of experimental data on inclusive polarized deeply inelastic scattering (DIS) of leptons from nucleons allows us to perform incisive QCD analyses of polarized structure functions to reveal the spin-dependent partonic structure function of the nucleon. Polarized DIS leptonnucleon scattering experiments have been performed at CERN, SLAC, DESY, and JLAB [1-13], and these processes have played a key role in our understanding of QCD and the spin structure of the nucleon [14-18]. There are several comprehensive analyses of the polarized DIS data in the literature [19-44]; this work provides a detailed picture of the spin structure of the nucleons.

The new precision experimental data from the HERMES and COMPASS Collaborations [12,13] of the spin structure function $g_{1}$ provides additional information that we shall use to study the spin structure and quark helicity distributions. We shall choose an approach based on the expansion of orthogonal polynomials; specifically, we will implement Jacobi polynomials as we use experimental data for each bin of $Q^{2}$ separately [43]. Previously [44], we applied the Jacobi polynomials to determine the polarized valon distributions using only the proton experimental data. In this analysis, both the unpolarized and polarized valon distributions were extracted, so more unknown parameters were required as compared to the present analysis. The Jacobi polynomial expansion has also been applied to a variety of QCD analyses [45-66], including the case of polarized parton distribution functions (PDFs) [44,67-73].

[^102]In the present study, we perform a NLO QCD analysis of the polarized deep inelastic data [3-13] in the $\overline{\mathrm{MS}}$ scheme and extract parametrizations of the polarized PDFs and structure functions. In Sec. II, we provide an overview of the Jacobi polynomials approach. In Sec. III we review the parametrization and evolution of the PDFs. In Sec. IV we present the results of our fit to the data, and in Sec. V we compute the associated structure functions and sum rules. Sec. IV contains the conclusions. We also provide an appendix which describes the FORTRAN code which is available.

## II. THE JACOBI POLYNOMIAL METHOD

We perform a NLO fit of the polarized parton distribution functions (PPDFs) using Jacobi polynomials to reconstruct the $x$-dependent quantities from their Mellin moments. The use of Jacobi polynomials has a number of advantages; specifically, it will allow us to factorize the $x$ and $Q^{2}$ dependence in a manner that allows an efficient parametrization and evolution of the structure functions.

For example, if we consider the spin structure function $x g_{1}\left(x, Q^{2}\right)$, we can expand this as

$$
\begin{equation*}
x g_{1}\left(x, Q^{2}\right)=x^{\beta}(1-x)^{\alpha} \sum_{n=0}^{N_{\max }} a_{n}\left(Q^{2}\right) \Theta_{n}^{\alpha, \beta}(x) \tag{1}
\end{equation*}
$$

Here, $\Theta_{n}^{\alpha, \beta}(x)$ are Jacobi polynomials of order $n$, and $N_{\max }$ is the maximum order of our expansion. In this instance, the Jacobi polynomials allow us to factor out the essential part of the $x$ dependence of the structure function into a weight function [45], and the $Q^{2}$ dependence is contained in the Jacobi moments $a_{n}\left(Q^{2}\right)$.

To be more specific, the $x$ dependence of the Jacobi polynomials can be written as

$$
\begin{equation*}
\Theta_{n}^{\alpha, \beta}(x)=\sum_{j=0}^{n} c_{j}^{(n)}(\alpha, \beta) x^{j} \tag{2}
\end{equation*}
$$

where the $c_{j}^{(n)}(\alpha, \beta)$ coefficients are combinations of $\Gamma$ functions involving $\{n, \alpha, \beta\}$. The Jacobi polynomials
satisfy an orthogonality relation with weight function $x^{\beta}(1-x)^{\alpha}$ as follows:

$$
\begin{equation*}
\int_{0}^{1} d x x^{\beta}(1-x)^{\alpha} \Theta_{k}^{\alpha, \beta}(x) \Theta_{l}^{\alpha, \beta}(x)=\delta_{k, l} \tag{3}
\end{equation*}
$$

Thus, given the Jacobi moments $a_{n}\left(Q^{2}\right)$, the polarized structure function $x g_{1}\left(x, Q^{2}\right)$ may be reconstructed from Eq. (1) [44].

We can compute the Jacobi moments $a_{n}\left(Q^{2}\right)$ using the orthogonality relation to invert Eq. (1) to obtain

$$
\begin{align*}
a_{n}\left(Q^{2}\right) & =\int_{0}^{1} d x x g_{1}\left(x, Q^{2}\right) \Theta_{k}^{\alpha, \beta}(x) \\
& =\sum_{j=0}^{n} c_{j}^{(n)}(\alpha, \beta) \mathbf{M}\left[x g_{1}, j+2\right] \tag{4}
\end{align*}
$$

In Eq. (4), we have substituted Eq. (1) for $x g_{1}\left(x, Q^{2}\right)$ and introduced the Mellin transform:

$$
\begin{equation*}
\mathbf{M}\left[x g_{1}, N\right] \equiv \int_{0}^{1} d x x^{N-2} x g_{1}\left(x, Q^{2}\right) \tag{5}
\end{equation*}
$$

We can now relate the polarized structure function $x g_{1}\left(x, Q^{2}\right)$ with its moments [44]

$$
\begin{align*}
x g_{1}\left(x, Q^{2}\right)= & x^{\beta}(1-x)^{\alpha} \sum_{n=0}^{N_{\max }} \Theta_{n}^{\alpha, \beta}(x) \\
& \times \sum_{j=0}^{n} c_{j}^{(n)}(\alpha, \beta) \mathbf{M}\left[x g_{1}, j+2\right] . \tag{6}
\end{align*}
$$

Given Eq. (6) for $x g_{1}\left(x, Q^{2}\right)$, we choose the set $\left\{N_{\text {max }}, \alpha, \beta\right\}$ to achieve optimal convergence of this series throughout the kinematic region constrained by the data. In practice, we find $N_{\max }=9, \alpha=3.0$, and $\beta=0.5$ to be sufficient.

## III. QCD ANALYSIS \& PARAMTRIZATION

## A. Parametrization

We consider a proton comprised of massless partons with helicity distributions $q_{ \pm}\left(x, Q^{2}\right)$ which carry momentum fraction $x$ with a characteristic scale $Q$. The difference $\delta q\left(x, Q^{2}\right)=q_{+}\left(x, Q^{2}\right)-q_{-}\left(x, Q^{2}\right)$ measures how much the parton of flavor $q$ "remembers" of the parent proton polarization. We will parametrize these polarized PDFs at initial scale $Q_{0}^{2}=4 \mathrm{GeV}^{2}$ using the following form:

$$
\begin{equation*}
x \delta q\left(x, Q_{0}^{2}\right)=\mathcal{N}_{q} \eta_{q} x^{a_{q}}(1-x)^{b_{q}}\left(1+c_{q} x\right) \tag{7}
\end{equation*}
$$

where the polarized PDFs are determined by parameters $\left\{\eta_{q}, a_{q}, b_{q}, c_{q}\right\}$, and the generic label $q=\left\{u_{v}, d_{v}, \bar{q}, g\right\}$ denotes the partonic flavors up-valence, down-valence, sea, and gluon, respectively. The normalization constants $\mathcal{N}_{q}$

$$
\begin{equation*}
\frac{1}{\mathcal{N}_{q}}=\left(1+c_{q} \frac{a_{q}}{a_{q}+b_{q}+1}\right) B\left(a_{q}, b_{q}+1\right) \tag{8}
\end{equation*}
$$

are chosen such that $\eta_{i}$ are the first moments of $\delta q_{i}\left(x, Q_{0}^{2}\right)$, $\eta_{i}=\int_{0}^{1} d x \delta q_{i}\left(x, Q_{0}^{2}\right)$, where $B(a, b)$ is the Euler beta function.

The total up and down PDFs are a sum of the valence plus sea distributions: $\delta u=\delta u_{v}+\delta \bar{q}$ and $\delta d=\delta d_{v}+\delta \bar{q}$. We will assume an $S U(3)$ flavor symmetry such that $\delta \bar{q} \equiv$ $\delta \bar{u}=\delta \bar{d}=\delta s=\delta \bar{s}$. While we could allow for an $S U(3)$ symmetry violation term by introducing $\kappa$ such that $\delta s=$ $\delta \bar{s}=\kappa \delta \bar{q}$, as the strange PDF is poorly constrained the results would be insensitive to the specific choice of $\kappa$.

As seen from Eq. (7), each of four polarized parton densities $q=\left\{u_{v}, d_{v}, \bar{q}, g\right\}$ contain four parameters $\left\{\eta_{q}, a_{q}, b_{q}, c_{q}\right\}$ which gives a total of 16 parameters that we must constrain. We now demonstrate that we can eliminate some of these parameters while maintaining sufficient flexibility to obtain a good fit.

## 1. First moments of $\delta u_{v}$ and $\delta d_{v}$

The parameters $\eta_{u_{v}}$ and $\eta_{d_{v}}$ are the first moments of the $\delta u_{v}$ and $\delta d_{v}$ polarized valence quark densities; these quantities can be related to $F$ and $D$ as measured in neutron and hyperon $\beta$ decays according to the relations [74]:

$$
\begin{gather*}
a_{3}=\int_{0}^{1} d x \delta q_{3}=\eta_{u_{v}}-\eta_{d_{v}}=F+D,  \tag{9}\\
a_{8}=\int_{0}^{1} d x \delta q_{8}=\eta_{u_{v}}+\eta_{d_{v}}=3 F-D, \tag{10}
\end{gather*}
$$

where $a_{3}$ and $a_{8}$ are non-singlet combinations of the first moments of the polarized parton densities corresponding to

$$
\begin{gather*}
q_{3}=(\delta u+\delta \bar{u})-(\delta d+\delta \bar{d})  \tag{11}\\
q_{8}=(\delta u+\delta \bar{u})+(\delta d+\delta \bar{d})-2(\delta s+\delta \bar{s}) \tag{12}
\end{gather*}
$$

A reanalysis of $F$ and $D$ with updated $\beta$-decay constants obtained [74] $F=0.464 \pm 0.008$ and $D=0.806 \pm 0.008$. With these values we find

$$
\begin{align*}
& \eta_{u_{v}}=+0.928 \pm 0.014  \tag{13}\\
& \eta_{d_{v}}=-0.342 \pm 0.018 \tag{14}
\end{align*}
$$

We make use of $\eta_{u_{v}}$ and $\eta_{d_{v}}$ to reduce the number of parameters by two.

## 2. Gluon and Sea Quarks

We find the factor $\left(1+c_{q} x\right)$ in Eq. (7) provides flexibility to obtain a good description of the data, particularly for the valence distributions $\left\{u_{v}, d_{v}\right\}$. Thus, we will make use of the $c_{q}$ coefficients for the up-valence and downvalence distributions; in contrast, we are able to set the values for $c_{\bar{q}}$ and $c_{g}$ to zero $\left(c_{\bar{q}}=c_{g}=0\right)$ while maintaining a good fit and eliminating two free parameters. For the parameters $\left\{c_{u_{v}}, c_{d_{v}}\right\}$ we find the fit improves if we use

TABLE I. Final parameter values and their statistical errors in the $\overline{\mathrm{MS}}$ scheme at the input scale $Q_{0}^{2}=4 \mathrm{GeV}^{2}$.

|  | $\eta_{u_{v}}$ | 0.928 ( fixed) |  | $\eta_{\bar{q}}$ | $-0.054 \pm 0.029$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $\delta u_{v}$ | $a_{u_{v}}$ | $0.535 \pm 0.022$ | $\delta \bar{q}$ | $a_{\bar{q}}$ | $0.474 \pm 0.121$ |
|  | $b_{u_{v}}$ | $3.222 \pm 0.085$ |  | $b_{\bar{q}}$ | 9.310 (fixed) |
|  | $c_{u_{v}}$ | 8.180 (fixed) |  | $c_{\bar{q}}$ | 0 |
|  | $\eta_{d_{v}}$ | -0.342 (fixed) |  | $\eta_{g}$ | $0.224 \pm 0.118$ |
| $\delta d_{v}$ | $a_{d_{v}}$ | $0.530 \pm 0.067$ | $\delta g$ | $a_{g}$ | $2.833 \pm 0.528$ |
|  | $b_{d_{v}}$ | $3.878 \pm 0.451$ |  | $b_{g}$ | 5.747 (fixed) |
|  | $c_{d_{v}}$ | 4.789 (fixed) |  | $c_{g}$ | 0 |

$\alpha_{s}\left(Q_{0}^{2}\right)=0.381 \pm 0.017$
$\chi^{2} /$ dof $=273.6 / 370=0.74$
nonzero values, but as these are relatively flat directions in $\chi$-space we shall fix the values as detailed in Table I.

Separately, we find the $b$ parameters control the large- $x$ behavior of the PDFs; thus, the sea quark and gluon distributions have large uncertainties in this region as they are dominated by the valence. To provide some guidance, we observe that for unpolarized parton densities in the large- $x$ region, a ratio of $b_{\bar{q}} / b_{g} \sim 1.6$ provides a good fit. Therefore, we impose this ratio on the polarized $b_{\bar{q}}$ and $b_{g}$ parameters to further reduce the free parameters. Additionally, we are able to extract reasonable constraints on the $a_{\bar{q}}$ and $a_{g}$ parameters; this is a benefit of the Jacobi polynomials.

Having fixed $\left\{\eta_{u_{v}}, \eta_{d_{v}}, c_{\bar{q}}, c_{g}\right\}$ and the ratio $b_{\bar{q}} / b_{g}$ in preliminary minimization, we then set the parameters $\left\{b_{\bar{q}}, b_{g}, c_{u_{v}}, c_{d_{v}}\right\}$ as indicated in Table I; this gives us a total of 9 unknown parameters, in addition to $\alpha_{s}\left(Q_{0}^{2}\right)$.

## B. DGLAP evolution

In the Jacobi polynomial approach the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) evolution equations are solved in Mellin space. The Mellin transform of the parton densities $q$ are defined analogous to that of Eq. (5):

$$
\begin{align*}
\mathbf{M}\left[\delta q\left(x, Q_{0}^{2}\right), N\right] \equiv & \delta q\left(N, Q_{0}^{2}\right)=\int_{0}^{1} x^{N-1} \delta q\left(x, Q_{0}^{2}\right) d x \\
= & \mathcal{N}_{q} \eta_{q}\left(1+c_{q} \frac{N-1+a_{q}}{N+a_{q}+b_{q}}\right) \\
& \times\left(N-1+a_{q}, b_{q}+1\right), \tag{15}
\end{align*}
$$

where $q=\left\{u_{v}, d_{v}, \bar{q}, g\right\}$, and $B$ is the Euler beta function.
In Mellin space, the twist-2 contributions to the polarized structure function $g_{1}\left(N, Q^{2}\right)$ can be represented in terms of the polarized parton densities and the coefficient functions $\Delta C_{i}^{N}$ by

$$
\begin{align*}
\mathbf{M}\left[g_{1}^{p}, N\right]= & \frac{1}{2} \sum_{q} e_{q}^{2}\left\{( 1 + \frac { \alpha _ { s } } { 2 \pi } \Delta C _ { q } ^ { N } ) \left[\delta q\left(N, Q^{2}\right)\right.\right. \\
& \left.\left.+\delta \bar{q}\left(N, Q^{2}\right)\right]+\frac{\alpha_{s}}{2 \pi} 2 \Delta C_{g}^{N} \delta g\left(N, Q^{2}\right)\right\} . \tag{16}
\end{align*}
$$

Here, the sum runs over quark flavors $\{u, d, s\}$, and $\{\delta q, \delta \bar{q}, \delta g\}$ are the polarized quark, antiquark, and gluon distributions, respectively.

The coefficient functions $\Delta C_{i}^{N}$ are the $N$ th moments of spin-dependent Wilson coefficients, and are given by [16]

$$
\begin{aligned}
\Delta C_{q}^{N}= & \frac{4}{3}\left\{-S_{2}(N)+\left(S_{1}(N)\right)^{2}+\left(\frac{3}{2}-\frac{1}{N(N+1)}\right) S_{1}(N)\right. \\
& \left.+\frac{1}{N^{2}}+\frac{1}{2 N}+\frac{1}{N+1}-\frac{9}{2}\right\} \\
\Delta C_{g}^{N}= & \frac{1}{2}\left[-\frac{N-1}{N(N+1)}\left(S_{1}(N)+1\right)-\frac{1}{N^{2}}+\frac{2}{N(N+1)}\right],
\end{aligned}
$$

with $\quad S_{1}(n)=\sum_{j=1}^{n} \frac{1}{j}=\psi(n+1)+\gamma_{E}, \quad S_{2}(n)=$ $\sum_{j=1}^{n} \frac{1}{j^{2}}=\left(\frac{\pi^{2}}{6}\right)-\psi^{\prime}(n+1), \quad \psi(n)=\Gamma^{\prime}(n) / \Gamma(n), \quad$ and $\psi^{\prime}(n)=d^{2} \ln \Gamma(n) / d n^{2}$.

In summary, we are able to express $x g_{1}^{p}$ in terms of 9 unknown parameters at an input scale of $Q_{0}^{2}=4 \mathrm{GeV}^{2}$. We now examine the fits to the spin structure functions to extract the polarized PDFs from the available data.

## IV. QCD FIT OF $x g_{1}\left(x, Q^{2}\right)$ DATA

Our analysis is performed using the QCD-PEGASUS program [75]. We work at NLO in the QCD evolution using $N_{f}=3$ in the fixed-flavor number scheme with massless partonic flavors $\{u, d, s\}$. We take the renormalization and factorization scales to be equal $\left(\mu_{R}=\mu_{F}\right)$, and we compute the strong coupling $a_{s}\left(Q^{2}\right)$ at NLO using a fourth-order Runge-Kutta integration. Our initial parametrizations (Eq. (7)) are chosen to be invertible in N -space, and this makes our fitting procedure numerically efficient.

For the proton data we use EMC [3], HERMES [5,12], SMC [8], E143 [9], E155 [11] and COMPASS [13], for the neutron data we use E142 [4], HERMES [5,12], and E154 [6,7], and for the deuteron data we use SMC [8], E143 [9], E155 [10], and HERMES [12]. This data is summarized in Table II.

We minimize the global $\chi^{2}[63,66,76]$,

$$
\begin{equation*}
\chi_{\text {global }}^{2}=\sum_{n} w_{n} \chi_{n}^{2}, \tag{17}
\end{equation*}
$$

where the sum $n$ runs over the different experiments, $w_{n}$ is a weight factor for the $n$th experiment, and $\chi_{n}^{2}$ is given by

$$
\begin{equation*}
\chi_{n}^{2}=\left(\frac{1-\mathcal{N}_{n}}{\Delta \mathcal{N}_{n}}\right)^{2}+\sum_{i}\left(\frac{\mathcal{N}_{n} g_{1, i}^{\exp }-g_{1, i}^{\text {theor }}}{\mathcal{N}_{n} \Delta g_{1, i}^{\exp }}\right)^{2} \tag{18}
\end{equation*}
$$

Here, $g_{1, i}^{\exp }, \Delta g_{1, i}^{\exp }$, and $g_{1, i}^{\text {theor }}$ denote the experimental measurement, the experimental uncertainty (statistical and systematic combined in quadrature) and theoretical value for the $i$ th data point, respectively. $\Delta \mathcal{N}_{n}$ is the experimental normalization uncertainty and $\mathcal{N}_{n}$ is an overall normalization factor for the data of experiment $n$. We allow for a relative normalization shift $\mathcal{N}_{n}$ between different

TABLE II. Published data points with the measured $x$ and $Q^{2}$ ranges, the number of data points (with a cut of $Q^{2} \geq 1.0 \mathrm{GeV}^{2}$ ), and the fitted normalization shifts $\mathcal{N}_{i}$.

| Experiment | $x$ range | $Q^{2}$ range $\left[\mathrm{GeV}^{2}\right]$ | \# of data points | $\mathcal{N}_{i}$ |

| Neutron |  |  | 85 |  |
| Total |  |  | 379 |  |

data sets within uncertainties $\Delta \mathcal{N}_{n}$ quoted by the experiments.
We minimize the above $\chi^{2}$ value with the 9 unknown parameters plus an undetermined $\alpha_{s}\left(Q_{0}^{2}\right)$. The values of these parameters are summarized in Table I. We find $\chi^{2} /$ d.o.f. $=273.6 / 370$ which yields an acceptable fit to the experimental data.

## V. PDF AND STRUCTURE FUNCTION ANALYSIS

We next present our polarized PDFs and perform comparisons with other recent parametrizations [28,31-34].

FIG. 1 (color online). The polarized parton distribution as function of $x$ and for different values of $Q^{2}$.

## A. Polarized PDFs

Figure 1 displays our polarized PDFs for a selection of $Q^{2}$ values. The up-valence $\left(x \delta u_{v}\right)$ and gluon ( $x \delta g$ ) distributions are positive, while the down-valence ( $x \delta d_{v}$ ) and sea $(x \delta \bar{q})$ distributions are negative. We observe that the evolution shifts all the distributions to smaller values of $x$, and tends to flatten out the peak for increasing $Q^{2}$. Figure 2 displays the extracted NLO polarized PDFs as compared with various parametrizations from the literature [28,38-40].

FIG. 2 (color online). The polarized parton distribution at $Q_{0}^{2}=4 \mathrm{GeV}^{2}$ as a function of $x$. Our fit is the solid curve. Also shown are the results of BB (dashed) [40], DSSV (dasheddotted) [38], GRSV (long dashed-dotted) [28], and AAC (dash-dashed-dotted) [39].

Examining the $x \delta u_{v}$ and $x \delta \bar{q}$ distributions we see that most of the fits are in agreement, with the possible exception of the de Florian-Sassot-Stratmann-Vogelsang (DSSV) [38] curves; for both distributions, the DSSV results approach zero more quickly than the other curves. For the $x \delta d_{v}$ distribution, all of the curves are comparable. The DSSV analysis employs results from semi-inclusive DIS (SI-DIS) data which can impose individual constraints on individual quark flavor distributions in the nucleon [38]. Finally, for the gluon distribution, the DSSV results have a sign change in the region of $x \sim 0.1$ while the other fits are positive. Our result for gluon distribution is located between the DSSV curve and the other fits [28,39,40]. In particular, we find the gluon polarization vanished more quickly for small $x$ values as compared with the other fits; we conjecture that using available asymmetry data in the low $x$ region may contribute to this difference.

FIG. 3 (color online). The polarized structure function $g_{1}^{p}$ as function of $Q^{2}$ in intervals of $x$. The error bars shown are the statistical and systematic uncertainties added in quadrature. Our fit is the solid curve. The values of the shift $\alpha$ are given in parentheses. Also shown are the results of BB (dashed) [31], GRSV (dashed-dotted) [28], LSS (dash-dot-dotted) [34], DNS (dash-dashed-dotted) [33], and AAC (long dashed-dotted) [32].

## B. $g_{1}$ Structure functions

Figure 3 displays results for the polarized structure function $x g_{1}^{p}$. For comparison, we display the results obtained by Blumlein and Bottcher (BB) [31]; Gluck, Reya, Stratmann, and Vogelsang (GRSV) [28]; Leader, Sidorov, Stamenov (LSS) [34]; de Florian, Navarro, Sassot (DNS) [33]; and the Asymmetry Analysis Collaboration (AAC) [32]. There is some spread in the analyses at low values of $x$; however, the data are generally well described within errors. As in the unpolarized case, the presence of scaling violations result a slope that varies with changing $x$ values; this is evident in Fig. 3 where we observe the $Q^{2}$ dependence of the structure function $g_{1}\left(x, Q^{2}\right)$.

Given the polarized proton PDFs, we can use isospin symmetry to obtain the corresponding neutron structure functions. In Fig. 4, we plot the neutron polarized structure function $x g_{1}^{n}$. We also display the NLO QCD curves obtained by Ref. [44] in the polarized valon model (PVM).

We can relate the deuteron structure function to that of the proton and neutron via
$\mathbf{M}\left[g_{1}^{d}, N\right]=\frac{1}{2}\left(1-\frac{3}{2} \omega_{D}\right)\left(\mathbf{M}\left[g_{1}^{p}, N\right]+\mathbf{M}\left[g_{1}^{n}, N\right]\right)$,
where $\omega_{D}=0.05 \pm 0.01$ is the $D$-state wave probability for the deuteron [77]. In Fig. 5 we present our results for the structure functions $x g_{1}^{p}\left(x, Q^{2}\right), x g_{1}^{n}\left(x, Q^{2}\right)$, and $x g_{1}^{d}\left(x, Q^{2}\right)$, and this compares favorably with the results of the BB [31], GRSV [28], LSS [34], DNS [33], and AAC [32] analyses.

FIG. 4 (color online). The polarized structure function $x g_{1}^{n}$ as function of $x$ and for a fixed value of $Q^{2}=5 \mathrm{GeV}^{2}$. The present fit is the solid curve. Also shown are the results of AK [44] (dashed) according to polarized valon model (PVM).

FIG. 5 (color online). The polarized structure function $x g_{1}^{p}, x g_{1}^{n}$ and $x g_{1}^{d}$ as a function of $x$ for selected values of $Q^{2}$. The data are well described by the fit (solid curve). Also shown are the QCD NLO curves obtained by BB (dashed) [31], GRSV (dotted) [28], LSS (dash-dotted) [34], AAC (dash-dot-dotted) [32], and DNS (dash-dash-dotted) [33].

FIG. 6 (color online). The non-singlet polarized structure function $x g_{1}^{N S}$ as function of $x$.

The non-singlet spin structure function $x g_{1}^{N S}\left(x, Q^{2}\right)$ is defined as [12]

$$
\begin{align*}
x g_{1}^{N S}\left(x, Q^{2}\right) & \equiv x g_{1}^{p}\left(x, Q^{2}\right)-x g_{1}^{n}\left(x, Q^{2}\right) \\
& =2\left[x g_{1}^{p}\left(x, Q^{2}\right)-\frac{x g_{1}^{d}\left(x, Q^{2}\right)}{1-\frac{3}{2} \omega_{D}}\right] \tag{20}
\end{align*}
$$

This is displayed in Fig. 6, and we compare with the HERMES data [12] for various $Q^{2}$ bins. In the second line of Eq. (20) we have related the structure function of the deuteron using isospin symmetry and the relation of Eq. (19).

## C. $g_{2}$ Structure function

We can now extract the structure function $x g_{2}$ via the Wandzura-Wilczek relation [78,79]:

POLARIZED DEEPLY INELASTIC SCATTERING (DIS) ...

FIG. 7 (color online). The polarized structure function $x g_{2}$ as function of $x$ for $Q^{2}=5 \mathrm{GeV}^{2}$.

$$
\begin{equation*}
g_{2}\left(x, Q^{2}\right)=-g_{1}^{p}\left(x, Q^{2}\right)+\int_{x}^{1} \frac{d y}{y} g_{1}^{p}\left(y, Q^{2}\right) . \tag{21}
\end{equation*}
$$

This relation remains valid in the presence of target mass corrections. In Fig. 7 we show our result for $x g_{2}$ and we compare it with the experimental data from E143 [9] and SMC [8].

## D. First moment of $\boldsymbol{g}_{\boldsymbol{1}}$ structure functions

We next use the polarized PDFs to compute the first moments, and compare with other recent analyses. We can obtain the first moment of $g_{1}^{p}$ by

$$
\begin{equation*}
\Gamma_{1}^{p}\left(Q^{2}\right) \equiv \int_{0}^{1} d x g_{1}^{p}\left(x, Q^{2}\right) \tag{22}
\end{equation*}
$$

The results of our fit are presented in Table III for selected values of $Q^{2}$, and these are compared with results from the literature in Table IV.

In the framework of QCD the spin of the proton can be expressed in terms of the first moment of the total quark

TABLE III. The first moments of polarized parton distributions, $\Delta u_{v}, \Delta d_{v}, \Delta \bar{q}, \Delta g$ and polarized structure functions $\Gamma_{1}^{p}$, $\Gamma_{1}^{n}, \Gamma_{1}^{d}$ in NLO in the $\overline{\mathrm{MS}}$ scheme for some different values of $Q^{2}$.

| $Q^{2}$ | $2 \mathrm{GeV}^{2}$ | $3 \mathrm{GeV}^{2}$ | $5 \mathrm{GeV}^{2}$ | $10 \mathrm{GeV}^{2}$ |
| :--- | ---: | ---: | ---: | ---: |

| $\Gamma_{1}^{d}$ | 0.035296 | 0.035965 | 0.036559 | 0.037115 |

TABLE IV. Comparison of the first moments of the polarized parton densities in NLO in the $\overline{\mathrm{MS}}$ scheme at $Q^{2}=4 \mathrm{GeV}^{2}$ for different sets of recent parton parametrizations. The second column ("Model") contains the first moments which are obtained from our new parametrization based on the Jacobi polynomials expansion method. The BB [40], GRSV [28], and AAC [32] results are also shown.

|  | Model | BB [40] | GRSV [28] | AAC [32] |
| :--- | ---: | ---: | ---: | ---: |
| $\Delta u_{v}$ | 0.928 | 0.928 | 0.9206 | 0.9278 |
| $\Delta d_{v}$ | -0.342 | -0.342 | -0.3409 | -0.3416 |
| $\Delta u$ | 0.874 | 0.866 | 0.8593 | 0.8399 |
| $\Delta d$ | -0.396 | -0.404 | -0.4043 | -0.4295 |
| $\Delta \bar{q}$ | -0.054 | -0.062 | -0.0625 | -0.0879 |
| $\Delta g$ | 0.224 | 0.462 | 0.6828 | 0.8076 |

and gluon helicity distributions and their orbital angular momentum, i.e.,

$$
\begin{equation*}
\frac{1}{2}=\frac{1}{2} \Delta \Sigma^{p}+\Delta g^{p}+L_{z}^{p} \tag{23}
\end{equation*}
$$

where $L_{z}^{p}$ is the total orbital angular momentum of all quarks and gluons. The contribution of $\frac{1}{2} \Delta \Sigma+\Delta g$ for typical value of $Q^{2}=4 \mathrm{GeV}^{2}$ is around 0.355 in our analysis. We can also compare this value in NLO with other recent analysis. The reported value from the BB model [40] is 0.569 , the AAC model [32] is 0.837 , and the GRSV model [28] is 0.785 , while the DSSV model [38] is approximately 0.1 . Since the values of $\frac{1}{2} \Delta \Sigma$ are comparable, we observe that the difference between the above reported values must come from different gluon distributions.

## E. Strong coupling constant

In this QCD analysis we extract $\alpha_{s}\left(Q_{0}^{2}\right)$ at NLO and obtain

$$
\begin{equation*}
\alpha_{s}\left(Q_{0}^{2}\right)=0.381 \pm 0.017 \tag{24}
\end{equation*}
$$

Rescaling this to the $Z$ boson mass scale we find

$$
\begin{equation*}
\alpha_{s}\left(M_{Z}^{2}\right)=0.1149 \pm 0.0015 \tag{25}
\end{equation*}
$$

The error given in the above equation does not include the relative systematics of the different classes of measurements. In Table V we provide a comparison of this value with other determinations from the literature computed at NLO and higher orders, including the current world average of $\alpha_{s}\left(M_{Z}^{2}\right)=0.1184 \pm 0.0007$.

## F. Nuclear polarized structure functions

Using the polarized PDF fit results, we examine the nucleon corrections factors for ${ }^{3} \mathrm{He}$ and ${ }^{3} \mathrm{H}$. The polarized structure functions $g_{1}^{3 \mathrm{He}}$ and $g_{1}^{3} \mathrm{H}$ can be composed from the polarized proton structure $g_{1}^{p}$ and the polarized neutron structure $g_{1}^{n}$ as follows:

ALI N. KHORRAMIAN et al.

$$
\begin{align*}
g_{1}^{3} \mathrm{He}\left(x, Q^{2}\right)= & \int_{x}^{3} \frac{d y}{y} \Delta f_{{ }_{3} \mathrm{He}}^{n}(y) g_{1}^{n}\left(\frac{x}{y}, Q^{2}\right) \\
& +2 \int_{x}^{3} \frac{d y}{y} \Delta f_{3_{\mathrm{He}}}^{p}(y) g_{1}^{p}\left(\frac{x}{y}, Q^{2}\right) \\
& -0.014\left[g_{1}^{p}\left(x, Q^{2}\right)-4 g_{1}^{n}\left(x, Q^{2}\right)\right],  \tag{26}\\
g_{1}^{{ }^{3} \mathrm{H}}\left(x, Q^{2}\right)= & 2 \int_{x}^{3} \frac{d y}{y} \Delta f_{3_{\mathrm{H}}}^{n}(y) g_{1}^{n}\left(\frac{x}{y}, Q^{2}\right) \\
& +\int_{x}^{3} \frac{d y}{y} \Delta f_{3 \mathrm{H}}^{p}(y) g_{1}^{p}\left(\frac{x}{y}, Q^{2}\right) \\
& +0.014\left[g_{1}^{p}\left(x, Q^{2}\right)-4 g_{1}^{n}\left(x, Q^{2}\right)\right] . \tag{27}
\end{align*}
$$

Here, $\Delta f_{3_{\mathrm{He}}}^{N}(y)$ and $\Delta f_{3_{\mathrm{H}}}^{N}(y)$ are the spin-dependent nucleon light-cone momentum distributions [87,88]. These functions parametrize the Fermi motion and the nucleon binding, and are readily calculated using the ground-state wave functions of ${ }^{3} \mathrm{He}$ and ${ }^{3} \mathrm{H}$. Note that the last term in above equations is important only in the large- $x$ region.

If we utilize isospin symmetry, we can equate $\Delta f_{{ }_{3} \mathrm{He}}^{p}(y)$ to $\Delta f_{{ }_{3} \mathrm{H}}^{n}(y)$, and also $\Delta f_{{ }_{3} \mathrm{He}}^{n}(y)$ to $\Delta f_{{ }_{3} \mathrm{H}}^{p}(y)$; thus, we are left with only two independent functions $\Delta f_{3 \mathrm{He}}^{p}(y)$ and $\Delta f_{{ }_{3} \mathrm{He}}^{n}(y)$. Using the results of Refs. [88-90], we express these distributions as

$$
\begin{gather*}
\Delta f_{{ }_{\mathrm{He}}}^{n}(y)=\frac{a^{n} e^{-\left(0.5\left(1-d^{n}\right)\left(-b^{n}+y\right)^{2} /\left(c^{n}\right)^{2}\right)}}{1+\frac{d^{n}\left(-b^{n}+y\right)^{2}}{\left(c^{n}\right)^{2}}},  \tag{28}\\
\Delta f_{{ }_{\mathrm{He}}}^{p}(y)=\frac{\sum_{i=0}^{4} a_{i}^{p} U_{i}(y)}{\sum_{i=0}^{4} b_{i}^{p} U_{i}(y)}, \tag{29}
\end{gather*}
$$

where $U_{n}(y)$ is a Chebyshev polynomial of the second type. The numerical coefficients of these equations are

PHYSICAL REVIEW D 83, 054017 (2011)
TABLE VI. Numerical coefficients for Eqs. (28) and (29), of $\Delta f_{{ }_{3} \mathrm{He}}^{n}(y)$ and $\Delta f_{{ }_{3} \mathrm{He}}^{p}(y)$ obtained from Refs. [88-90].

| $n$ | $p$ | $p$ |
| :--- | :--- | :--- |
| $a^{n}=5.650556817$ | $a_{0}^{p}=0.0148376$ | $b_{0}^{p}=4.15388$ |
| $b^{n}=0.986818274$ | $a_{1}^{p}=-0.0189575$ | $b_{1}^{p}=-4.75525$ |
| $c^{n}=0.064446823$ | $a_{2}^{p}=0.0121792$ | $b_{2}^{p}=2.68417$ |
| $d^{n}=0.807650292$ | $a_{3}^{p}=-0.0040397$ | $b_{3}^{p}=-0.800306$ |
|  | $a_{4}^{p}=0.000540845$ | $b_{4}^{p}=0.101095$ |

presented in Table VI. We can then use Eqs. (26) and (27) to obtain the polarized nucleon structure functions $g_{1}^{3} \mathrm{He}\left(x, Q^{2}\right)$ and $g_{1}{ }^{3} \mathrm{H}\left(x, Q^{2}\right)$.
To determine the $g_{1}^{3} \mathrm{He}$ and $g_{1}^{3} \mathrm{H}$ polarized structure functions we need the polarized light-cone distribution functions for proton and neutron in ${ }^{3} \mathrm{He}$, i.e., $\Delta f_{3_{\mathrm{He}}}^{p}$ and $\Delta f_{3_{\mathrm{He}}}^{n}$. In Figs. 8 and 9 we present our results using the parametrization of Eqs. (28) and (29), which is based on the numerical results of Ref. [90].

FIG. 8 (color online). The polarized light-cone distribution function for the proton in the ${ }^{3} \mathrm{He}$, based on the results of Ref. [88-90].

FIG. 9 (color online). The polarized light-cone distribution function for the neutron in the ${ }^{3} \mathrm{He}$, based on the results of Ref. [88-90].

FIG. 10 (color online). Analytical result for the polarized ${ }^{3} \mathrm{He}$ structure function v.s. $x$ for fixed $Q^{2}=2.5 \mathrm{GeV}^{2}$. The current fit is the solid curve. Also shown are the QCD NLO curves obtained by AK (dashed) [44] according to polarized valon model (PVM) and BB (dashed-dotted) [31].

In Figs. 10 and 11 we show our results for the $g_{1}{ }^{3} \mathrm{He}$ and $g_{1}^{3} \mathrm{H}$ polarized structure function, and compare with BB [31], and the PVM [44]. For the $g_{1}^{3} \mathrm{He}$ polarized structure function we see that our result coincides with the BB fit for $x$ values down to $\sim 10^{-2}$, and then falls off more quickly at very small $x$ values. The polarized valon model (PVM), while still a reasonable fit to the data, lies below both of the other fits. For the $g_{1}{ }^{3} \mathrm{H}$ polarized structure function, our fit

FIG. 11 (color online). Analytical result for the polarized ${ }^{3} \mathrm{H}$ structure function v.s. $x$ for fixed $Q^{2}=2.5 \mathrm{GeV}^{2}$. The current fit is the solid curve. Also shown are the QCD NLO curves obtained by AK (dashed) [44] according to polarized valon model (PVM) and BB (dashed-dotted) [31] for comparison.
coincides with the BB fit at both large and small $x$ values, but dips below it (closer to the PVM) for intermediate $x$ values. The differences between these curves come from the various data sets used, the constraints imposed, and the form of the parametrization. For example, in the AK fit [44], only 257 experimental data points were used as the neutron data were not included; in contrast, the present analysis uses 379 points which does include the neutron data. Furthermore, the AK fit used 15 free parameters while there are only 9 free parameters in the present analysis. These differences are reflected in the extractions of PPDFs, and a comparison of these different analyses may be indicative of the stability of the determined QCD parameters.

## G. Bjorken sum rule

We can also study the Bjorken sum rule [91] which relates the difference of the first moments of the proton and neutron spin structure functions to the axial vector coupling constant of the neutron $\beta$-decay,
$\int_{0}^{1}\left[g_{1}^{p}\left(x, Q^{2}\right)-g_{1}^{n}\left(x, Q^{2}\right)\right] d x=\frac{1}{6} g_{A}\left[1+O\left(\frac{\alpha_{s}}{\pi}\right)\right]$,
where $g_{A}=1.2670 \pm 0.0035$ [74], and the QCD radiative corrections are denoted as $O\left(\frac{\alpha_{s}}{\pi}\right)$. This sum rule can be generalized for the ${ }^{3} \mathrm{He}-{ }^{3} \mathrm{H}$ system as follows:

$$
\begin{equation*}
\int_{0}^{3}\left[g_{1}^{{ }^{3} \mathrm{H}}\left(x, Q^{2}\right)-g_{1}^{{ }^{3} \mathrm{He}}\left(x, Q^{2}\right)\right] d x=\frac{1}{6} \tilde{g}_{A}\left[1+O\left(\frac{\alpha_{s}}{\pi}\right)\right], \tag{31}
\end{equation*}
$$

where $\tilde{g}_{A}$ is the axial vector coupling constant of the Triton $\beta$ decay, with $\tilde{g}_{A}=1.211 \pm 0.002$ [92]. Taking the ratio of the Eqs. (30) and (31), we find

$$
\begin{equation*}
\frac{\int_{0}^{3}\left[g_{1}^{3} \mathrm{H}\left(x, Q^{2}\right)-g_{1}^{{ }^{3} \mathrm{He}}\left(x, Q^{2}\right)\right] d x}{\int_{0}^{1}\left[g_{1}^{p}\left(x, Q^{2}\right)-g_{1}^{n}\left(x, Q^{2}\right)\right] d x}=\frac{\tilde{g}_{A}}{g_{A}} . \tag{32}
\end{equation*}
$$

Given $g_{A}$ and $\tilde{g}_{A}$, we compute the above ratio to be 0.956 [88]. Note that the QCD radiative corrections are expected to cancel exactly in above equation. Using the Bjorken sum rules of Eqs. (30) and (31), we obtain the value 0.924 for the ratio of Eq. (32).

## VI. CONCLUSIONS

We have presented a fit to the polarized lepton-DIS data on nuclei at NLO QCD using the Jacobi polynomial method. Having extracted the polarized PDFs, we compute various nuclear structure functions $\left(g_{1}, g_{2}\right)$ and Bjorken sum rule. In general, we find good agreement with the experimental data, and our results are in accord with other determinations from the literature; collectively, this demonstrates progress of the field toward a detailed description of the spin structure of the nucleon.

Having demonstrated the compatibility of the Jacobi polynomial method with other approaches in the literature,
this study can serve as a foundation for addressing issues of polarized scattering processes from a complementary perspective. In particular, the Jacobi polynomial method offers the opportunity to examine efficiencies of different methods, and this work is in progress.

## ACKNOWLEDGMENTS

We thank S. Kumano and M. Miyama of the ACC Collaboration for allowing us to use their interpolation routines. A. N. K. thanks Johannes Blümlein for useful discussions, and is grateful to A. L. Kataev for the suggestion of the Jacobi polynomial method, the CERN TH-PH division for the hospitality where a portion of this work was performed, and Semnan University for financial support. We acknowledge financial support of the School of Particles and Accelerators, Institute for Research in Fundamental

Sciences (IPM). This work was partially supported by the U.S. Department of Energy under Grant No. DE-FG0204ER41299, and the Lightner-Sams Foundation.

## APPENDIX: FORTRAN CODE

A FORTRAN package containing our $g_{1}\left(x, Q^{2}\right)$ polarized structure functions for $\left\{p, n, d, N S,{ }^{3} \mathrm{He},{ }^{3} \mathrm{H}\right\} \quad$ and $x g_{2}^{p}\left(x, Q^{2}\right)$, as well as the polarized parton densities $\left\{u_{v}, d_{v}, g, \bar{q}\right\} . x \delta u_{v}\left(x, Q^{2}\right), x \delta d_{v}\left(x, Q^{2}\right), x \delta g\left(x, Q^{2}\right)$, and $x \delta \bar{q}\left(x, Q^{2}\right)$ at NLO in the $\overline{\mathrm{MS}}$ scheme, can be found at http://particles.ipm.ir/links/QCD.htm or obtained via email from the authors. These functions are interpolated using cubic splines in $Q^{2}$ and a linear interpolation in $\log \left(Q^{2}\right)$. The package includes an example program to illustrate the use of the routines.

#### Abstract

We investigate the nonsinglet spin-dependent structure function for polarized deep inelastic scattering (DIS) of leptons on nucleons in the next-to-leading-order (NLO) approximation. We perform a fit to extract the polarized parton distribution functions (PPDFs) and the nonsinglet spin structure function using the most recent proton and neutron DIS data. We demonstrate that our results yield good agreement with available observables.

Keywords: Nonsinglet polarized structure function; DGLAP equation.

## 1. Introduction

The investigation of the short-distance structure of the nucleon spin is a rich and developing field. Nucleons, by virtue of being composite particles, obtain their spin from a combination of the spin and orbital angular momentum of the underlying quarks and gluons. When the European Muon Collaboration (EMC) [1] uncovered the proton spin crisis more than 20 years ago, this stimulated worldwide interest on both the experimental and theoretical side to understand the spin structure of the nucleon. The remarkable growth of experimental measurements of exclusive polarized DIS of leptons in recent years [1-11] allows to perform incisive QCD analyses of the polarized structure functions and reveal the spin-dependent partonic structure of nucleons.

In the present paper we perform a fit of the polarized proton, neutron and deuteron experimental data to extract a new parameterization of the polarized quark and gluon distributions. In this fit, we determine the polarized parton densities together with QCD coupling constant. Finally, we compare our polarized nonsinglet structure functions with available experimental data.
The organization of this paper is as follows. In Section 2 we outline the theoretical background of the

[^103]QCD analysis. The construction of the nonsinglet spindependent structure function is described in Section 3, and Section 4 contains our conclusions.

## 2. Theoretical background of the QCD analysis

The QCD parton model is a versatile tool for the investigation of unpolarized scattering processes [12]. In light of these successes, the parton model has been extended to scattering of polarized particles as well. We consider a proton comprised of massless partons with positive and negative helicity distributions $q_{ \pm}\left(x, Q^{2}\right)$ which carry fractional momentum fraction $x$ with a characteristic scale $Q$. The difference

$$
\begin{equation*}
\delta q\left(x, Q^{2}\right)=q_{+}\left(x, Q^{2}\right)-q_{-}\left(x, Q^{2}\right), \tag{1}
\end{equation*}
$$

measures how much the parton of flavor $q$ "remembers" of the parent proton polarization; there is a corresponding definition for the antiquarks and gluons as well.

At NLO, the spin-dependent structure functions $g_{1}^{p}$ can be written as a linear combination of $\delta q, \delta \bar{q}$, and $\delta g$ :

$$
\begin{align*}
& g_{1}^{p}\left(x, Q^{2}\right)=\frac{1}{2} \sum_{q} e_{q}^{2}\left\{\delta q\left(x, Q^{2}\right)+\delta \bar{q}\left(x, Q^{2}\right)\right. \\
& \left.+\frac{\alpha_{s}\left(Q^{2}\right)}{2 \pi}\left[\delta C_{q} \otimes(\delta q+\delta \bar{q})+2 \delta C_{g} \otimes \delta g\right]\right\}, \tag{2}
\end{align*}
$$

where $\delta C_{q}, \delta C_{g}$ are the spin-dependent quark and gluon Wilson coefficients, and $e_{q}$ are the electric charges of the
light quark-flavors $q=u, d, s$. We choose to work in the $\overline{M S}$ factorization scheme. The functions $g_{1}^{p}$ and $g_{1}^{n}$ differ only in their nonsinglet components that are related though isospin symmetry, which effectively exchanges the $u$ and $d$ quarks.

We now summarize the key features of our QCD analysis. The polarized parton densities are parametrized at a starting scale $Q_{0}$ and evolved to higher factorization scales using a numerical solution of the polarized NLO DGLAP evolution equations. Our calculation is performed with the Fortran package QCD-PEGASUS[13] which provides accurate solutions of the evolution equations for polarized and unpolarized parton distributions of hadrons in perturbative QCD. We choose a starting scale of $Q_{0}=4 \mathrm{GeV}^{2}$, and take the QCD coupling as free parameter which is fit to the data.

The QCD DGLAP equations are solved in Mellin space where the Mellin transform are defined as:

$$
\begin{align*}
\mathbf{M}\left[\delta f_{i}\left(x, Q^{2}\right)\right](N) & =\delta f_{i}\left(N, Q^{2}\right) \\
& =\int_{0}^{1} x^{N-1} \delta f_{i}\left(x, Q^{2}\right) d x \tag{3}
\end{align*}
$$

and

$$
\begin{align*}
\mathbf{M}\left[x g_{1}\left(x, Q^{2}\right)\right](N) & =g_{1}^{p}\left(N, Q^{2}\right) \\
& =\int_{0}^{1} x^{N-2} g_{1}^{p}\left(x, Q^{2}\right) d x \tag{4}
\end{align*}
$$

where $f_{i}=q_{v}, d_{v}, \bar{q}, g$.
Therefore, the leading (twist-2) contributions to the structure function $g_{1}\left(N, Q^{2}\right)$ can be represented in Mellin-N space by [12]

$$
\begin{align*}
& g_{1}^{p}\left(N, Q^{2}\right)=\frac{1}{2} \sum_{q} e_{q}^{2}\left\{( 1 + \frac { \alpha _ { s } } { 2 \pi } \Delta C _ { q } ^ { N } ) \left[\delta q\left(N, Q^{2}\right)\right.\right. \\
& \left.\left.\quad+\delta \bar{q}\left(N, Q^{2}\right)\right]+\frac{\alpha_{s}}{2 \pi} 2 \Delta C_{g}^{N} \delta g\left(N, Q^{2}\right)\right\} \tag{5}
\end{align*}
$$

In Eq. 5 above, $\delta q\left(N, Q^{2}\right)$ is the quark helicity distribution for quarks of flavor $q$. Correspondingly, $\delta \bar{q}\left(N, Q^{2}\right)$ is the anti-quark helicity distribution. Also in Eq. (5), $\delta q\left(N, Q^{2}\right)=\delta q_{v}\left(N, Q^{2}\right)+\delta \bar{q}\left(N, Q^{2}\right), \delta \bar{q}\left(N, Q^{2}\right)$ and $\delta g\left(N, Q^{2}\right)$ are moments of the polarized parton distributions in a proton. $\Delta C_{q}^{N}$ and $\Delta C_{g}^{N}$ are the $N$-th moments of spin-dependent Wilson coefficients given by

$$
\begin{align*}
\Delta C_{q}^{N}= & \frac{4}{3}\left[-S_{2}(N)+\left(S_{1}(N)\right)^{2}+\left(\frac{3}{2}-\frac{1}{N(N+1)}\right)\right. \\
& \left.\times S_{1}(N)+\frac{1}{N^{2}}+\frac{1}{2 N}+\frac{1}{N+1}-\frac{9}{2}\right] \tag{6}
\end{align*}
$$

and

$$
\begin{equation*}
\Delta C_{g}^{N}=\frac{1}{2}\left[-\frac{N-1}{N(N+1)}\left(S_{1}(N)+1\right)-\frac{1}{N^{2}}+\frac{2}{N(N+1)}\right] \tag{7}
\end{equation*}
$$

with $S_{k}(N)$ defined as in Ref. [12].

The centerpiece of our approach is the Jacobi polynomial expansion; this method was developed and applied to a variety of QCD analyses for unpolarized [14-26] and polarized applications [27-30]. In this approach, we expand the structure functions in terms of Jacobi polynomials $\Theta_{m}^{\alpha, \beta}$ :

$$
\begin{equation*}
x g_{1}^{N_{\max }}\left(x, Q^{2}\right)=x^{\beta}(1-x)^{\alpha} \sum_{n=0}^{N_{\max }} a_{n}\left(Q^{2}\right) \Theta_{n}^{\alpha, \beta}(x) \tag{8}
\end{equation*}
$$

with

$$
\begin{equation*}
a_{n}\left(Q^{2}\right)=\sum_{j=0}^{n} c_{j}^{(n)}(\alpha, \beta) \mathbf{M}\left[x g_{1}\right](j+2) \tag{9}
\end{equation*}
$$

This relates the $g_{1}^{p, n}\left(x, Q^{2}\right)$ structure function with their moments [28]. Obviously in Eq.(9), the $Q^{2}$-dependence of the polarized structure function is defined by the $Q^{2}$ dependence of the moments. In this analysis we use $N_{\max }=9, \alpha=3.0$ and $\beta=0.5$.

The spin-dependent structure functions for the deuteron in Mellin- N space can be decomposed as follows:

$$
\begin{equation*}
g_{1}^{d}\left(N, Q^{2}\right)=\frac{1}{2}\left(1-\frac{3}{2} w_{D}\right)\left[g_{1}^{p}\left(n, Q^{2}\right)+g_{1}^{n}\left(N, Q^{2}\right)\right] \tag{10}
\end{equation*}
$$

where $\omega_{D}=0.05 \pm 0.01$ is the $D$-state wave probability for the deuteron [31]. Using the Mellin-N moments for the proton, neutron and deuteron spin structure functions of Eq. (9), we can perform a fit to extract the unknown parameters.

For the present analysis we use the following data sets: 179 proton data points from EMC[1], HERMES[3, 8], SMC[5], E143[7], E155[4] and COMPASS[2]; 85 neutron data points from E142[11], HERMES[3, 8] and E154[9, 10]; 115 deuteron data points from SMC[5], E143 [7], E155[6] and HERMES[3]. The data sets contain both statistical and systematic errors, and the systematic errors are partly correlated; this leads to an overestimation of the true uncertainty when the statistical and systematic errors are added in quadrature. Additionally, the normalization error is generally specified separately. Using these uncertainties, we fit to an effective $\chi^{2}$ as detailed in Refs. [23, 26]. Additional details are presented in Ref. [27]. In Fig.1, we compare the fit results for the structure functions $g_{1}^{p}\left(x, Q^{2}\right)$ and $g_{1}^{n}\left(x, Q^{2}\right), g_{1}^{d}\left(x, Q^{2}\right)$ at $Q^{2}=5 \mathrm{GeV}^{2}$ with the data, to illustrate the fit quality for the different targets as an example. Furthermore, also the results of the BB [32], GRSV [33], LSS [34], and AAC [35] analyses are shown.

Figure 1: The polarized structure function $x g_{1}^{p, n, d}$ as a function of $x$ in comparison with data from HERMES[3], SMC[5], E142 [11], E143[7], E154[9, 10] and E155 [4]. Also shown are the QCD NLO curves obtained by BB (dashed) [32], GRSV (dashed-dotted) [33], LSS (dashed-dotted-dotted) [34], and AAC (dashed-dashed-dotted) [35] for comparison.

## 3. Nonsinglet spin-dependent structure function

Having investigated the proton, neutron and deuteron spin structure functions, we now turn to the nonsinglet spin-dependent structure function: [3]

$$
\begin{align*}
x g_{1}^{N S}\left(x, Q^{2}\right) & \equiv x g_{1}^{p}\left(x, Q^{2}\right)-x g_{1}^{n}\left(x, Q^{2}\right) \\
& =2\left[x g_{1}^{p}\left(x, Q^{2}\right)-\frac{x g_{1}^{d}\left(x, Q^{2}\right)}{1-\frac{3}{2} \omega_{D}}\right] \tag{11}
\end{align*}
$$

In Fig.2, the $x$ dependence of $x g_{1}^{N S}\left(x, Q^{2}\right)$ is presented for different values of $Q^{2}$ and compared with data from HERMES[3], SMC[5], E143[7]. The nonsinglet structure function shows a behavior similar to that of the deuteron and neutron. The HERMES data provide improved constraints on the $x$ dependence of $x g_{1}^{N S}$. As shown, the data are well described within the errors by our analysis.

The integrals for $g_{1}^{p}, g_{1}^{d}, g_{1}^{n}$ and $g_{1}^{N S}$ calculated at $Q_{0}^{2}=2.5$ and $5 \mathrm{GeV}^{2}$, are given in Table 1 together

Figure 2: The nonsinglet polarized structure function $x g_{1}^{N S}$ as a function of $x$ in comparison with data from HERMES[3], SMC[5], E143[7]. The data are well described by our QCD curves.
with HERMES[3] results. They are computed for $x=$ [0.021, 0.9].

Fig. 3 shows the cumulative integral of $g_{1}^{p}, g_{1}^{n}, g_{1}^{d}$ and $g_{1}^{N S}$ as a function of the lower integration limit $x$, evaluated at $Q^{2}=5 \mathrm{GeV}^{2}$. There is satisfactory agreement between our results and the HERMES[3] data.

## 4. Conclusions

We have performed a QCD analysis of the inclusive polarized DIS charged-lepton-nucleon scattering data at NLO , and extracted the spin structure function $g_{1}\left(x, Q^{2}\right)$ for the proton, neutron, and deuteron. We have used an expansion in Jacobi polynomials to facilitate the analysis, and then defined an effective global $\chi^{2}$ to obtain an acceptable fit [27].

We have also used the above results to construct the nonsinglet spin-dependent structure function $g_{1}^{N S}$, which is in good agreement with the experimental data. As this data is not an input to the fit, this result is evidence of the applicability and universality of the fit.

A FORTRAN package containing the polarized structure functions, as well as the parton densities, can be found in http://particles.ipm.ir/links/QCD.htm.

| $\int g_{1} d x$ | HERMES | MODEL |
| :---: | :---: | :---: |
| $Q^{2}=2.5 \mathrm{GeV}^{2}$ |  |  |
| p | 0.1201 | 0.1179 |

#### Abstract

Global analyses of parton distribution functions (PDFs) have provided incisive constraints on the up and down quark components of the proton, but constraining the other flavor degrees of freedom is more challenging. Higher-order theory predictions and new data sets have contributed to recent improvements. Despite these efforts, the strange quark parton distribution function has a sizable uncertainty, particularly in the small $x$ region. We examine the constraints from experiment and theory, and investigate the impact of this uncertainty on LHC observables. In particular, we study $W / Z$ production to see how the $s$ quark uncertainty propagates to these observables, and examine the extent to which precise measurements at the LHC can provide additional information on the proton flavor structure.

## I. INTRODUCTION

## A. Motivation

Parton distribution functions (PDFs) provide the essential link between the theoretically calculated partonic cross sections, and the experimentally measured physical cross sections involving hadrons and mesons. This link is crucial if we are to make incisive tests of the standard model (SM), and search for subtle deviations which might signal new physics.

Recent measurements of charm production in neutrino deeply inelastic scattering (DIS), visible as dimuon final states, provide important new information on the strange quark distribution, $s(x)$, of the nucleon [1-16]. We show that despite these recent advances in both the precision data and theoretical predictions, the relative uncertainty on the heavier flavors remains large. We will focus on the strange quark and show the impact of these uncertainties on selected LHC processes.

The production of $W / Z$ bosons is one of the "benchmark" processes used to calibrate our searches for the Higgs boson and other "new physics" signals. We will examine how the uncertainty of the strange quark PDF influences these measurements, and assess how these uncertainties might be reduced.

[^104]
## B. Outline

The outline of the presentation is as follows. In Sec. II, we examine the experimental signatures that constrain the strange quark parton distribution. In Sec. III we consider the impact of $s$ quark PDF uncertainties on $W / Z$ production at the LHC, and in Sec. IV we summarize our results. Additional details on PDF fits to dimuon data at next-to-leading order (NLO) are provided in the Appendix.

## II. CONSTRAINING THE PDF FLAVOR COMPONENTS

## A. Extracting the strange quark PDF

In previous global analyses, the predominant information on the strange quark PDF $s(x)$ came from the difference of (large) inclusive cross sections for neutral and charged current DIS. For example, at leading order (LO) in the parton model one finds that the difference between the neutral current (NC) and charged current (CC) DIS $F_{2}$ structure function is proportional to the strange PDF. Specifically if we neglect the charm PDF and isospinviolating terms, we have [17]

$$
\begin{equation*}
\Delta F_{2}=\frac{5}{18} F_{2}^{\mathrm{CC}}-F_{2}^{\mathrm{NC}} \sim \frac{x}{6}[s(x)+\bar{s}(x)] . \tag{1}
\end{equation*}
$$

Because the strange distributions are small compared to the large up and down PDFs, the $s(x)$ extracted from this measurement has large uncertainties. Lacking better information, it was commonly assumed the distribution was of the form

$$
\begin{equation*}
s(x)=\bar{s}(x) \sim \kappa[\bar{u}(x)+\bar{d}(x)] / 2 \tag{2}
\end{equation*}
$$

with $\kappa \sim 1 / 2$.

FIG. 1 (color online). Relative uncertainty of the strange quark PDF as a function of $x$ for $Q=2 \mathrm{GeV}$. The inner band is for the CTEQ6.1 PDF set, and the outer band is for the CTEQ6.6 PDF set. The band is computed as the envelope of $s_{i}(x) / s_{0}(x)$ where $s_{0}(x)$ is the central PDF for each set; for CTEQ6.1, $i=[1,40]$, and for CTEQ6.6, $i=[1,44]$.

This approach was used, for example, in the CTEQ6.1 PDFs [18]. In Fig. 1 we show the relative uncertainty band of the strange quark PDF for the 40 CTEQ6.1 PDF error sets relative to the central value. We observe that over much of the $x$ range the relative uncertainty on the strange PDF is $\leq 5 \%$. The relation of Eq. (2) tells us that this uncertainty band in fact reflects the uncertainty on the up and down sea which is well constrained by DIS measurements; this does not reflect the true uncertainty of $s(x)$.

Beginning with CTEQ6.6 PDFs [19] the neutrinonucleon dimuon data were included in the global fits to more directly constrain the strange quark; thus, Eq. (2) was not used, and two additional fitting parameters were introduced to allow the strange quark to vary independently of the up and down sea. We also display the relative uncertainty band for the CTEQ6.6 PDF set in Fig. 1. We now observe that the relative error on the strange quark is much larger than for the CTEQ6.1 set, particularly for $x<0.01$ where the neutrino-nucleon dimuon data do not provide any constraints. We expect this is a more accurate representation of the true uncertainty.

This general behavior is also exhibited in other global PDF sets with errors [20-23]. For example, the NNPDF Collaboration uses a parametrization-free method for extracting the PDFs; it observes a large increase in the $s(x)$ uncertainty in the small $x$ region which is beyond the constraints of the $\nu$-DIS experiments. (Cf., in particular, Fig. 13 of Ref [21].)

Thus, there is general agreement that the strange quark PDF is poorly constrained, particularly in the small $x$ region.

## B. Constraints from CCFR and NuTeV

The primary source of information on the strange quark at present comes from high-statistics neutrino-nucleon DIS measurements; in particular, the CCFR and NuTeV dimuon experiments have been used to determine the strange

TABLE I. We display the $\chi^{2} / \mathrm{DoF}$ for selected data sets using the CTEQ6M PDF set [12], and a variant of this (labeled "free") which allows for a modified strange quark PDF to accommodate the neutrino dimuon data.

| $\chi^{2} /$ DoF | CTEQ6M | Free |
| :--- | :---: | :---: |
| CCFR $\nu$ dimuon | 1.02 | 0.72 |
| CCFR $\bar{\nu}$ dimuon | 0.58 | 0.59 |
| NuTeV $\nu$ dimuon | 1.81 | 1.44 |
| NuTeV $\bar{\nu}$ dimuon | 1.48 | 1.13 |
| BCDMS $F_{2}^{p}$ | 1.11 | 1.11 |
| BCDMS $F_{2}^{d}$ | 1.10 | 1.11 |
| H1 96/97 | 0.94 | 0.94 |
| H1 98/99 | 1.02 | 1.03 |
| ZEUS 96/97 | 1.14 | 1.15 |
| NMC $F_{2}^{p}$ | 1.52 | 1.49 |
| NMC $F_{2}^{d} / F_{2}^{p}$ | 0.91 | 0.91 |
| CCFR $F_{2}$ | 1.70 | 1.88 |
| CCFR $F_{3}$ | 0.42 | 0.42 |
| E605 | 0.82 | 0.83 |
| NA51 | 0.62 | 0.52 |
| CDF $\ell$ asymmetry | 0.82 | 0.82 |
| E866 | 0.39 | 0.38 |
| D0 jets | 0.71 | 0.67 |
| CDF jets | 1.48 | 1.47 |
| Total $\chi^{2}$ | 2173 | 2133 |

quark PDF with improved accuracy $[6,8,9,16,24-26]$. Neutrino-induced dimuon production $\left(\nu N \rightarrow \mu^{+} \mu^{-} X\right)$ proceeds primarily through the Cabibbo favored $s \rightarrow c$ or $\bar{s} \rightarrow \bar{c}$ subprocess. Hence, this provides information on $s$ and $\bar{s}$ directly; this is in contrast to $\Delta F_{2}$ of Eq. (1). CCFR has $5030 \nu$ and $1060 \bar{\nu}$ dimuon events, and NuTeV has $5012 \nu$ and $1458 \bar{\nu}$ dimuon events, and these cover the approximate range $x \sim[0.01,0.4]$. Additionally, NuTeV used a sign-selected beam to separate the $\nu$ and $\bar{\nu}$ events in order to separately extract $s(x)$ and $\bar{s}(x)$.

## 1. Constraints on $s+\bar{s}$

In Table I we illustrate how the bulk of the data used in the global fits are relatively insensitive to the strange quark distribution. The first column (labeled "CTEQ6M") lists the $\chi^{2} /$ DoF for a variety of data sets used in the CTEQ6M fit [12]. We have also shown the CCFR and NuTeV dimuon data sets in the table, but these were not used in the CTEQ6M fit. The second column (labeled "free") lists results of refitting all the data-including the dimuon data-with a flexible strange quark PDF instead of imposing the relation of Eq. (2); this allows the strange quark PDF to accommodate the dimuon data. Comparing the two columns, we observe that the change of the strange PDF allowed for a greatly improved fit of the dimuon data, while the other data sets are virtually insensitive to this change. ${ }^{1}$

[^105]

FIG. 2 (color online). We plot $\chi^{2} / \chi_{0}^{2}$ for the dimuon and the inclusive I data sets evaluated as a function of the strange asymmetry $\left[S^{-}\right] \times 10^{4}$. The fits are denoted with $\square$ for the dimuons and $\boldsymbol{\Delta}$ for inclusive I. Quadratic approximations to the fits are displayed by the solid (red) line for the dimuons and the dashed (green) line for inclusive I.

This exercise demonstrates that most of the data sets of the global analysis are insensitive to the details of the strange quark PDF.

## 2. Constraints on $s-\bar{s}$

The dimuon data can also provide information on the $s(x)$ and $\bar{s}(x)$ quark PDFs separately. In Fig. 2 we display the relative $\chi^{2}$ for the dimuon and "inclusive I" data sets as a function of the strange asymmetry $\left[S^{-}\right]$, where

$$
\begin{equation*}
\left[S^{-}\right] \equiv \int_{0}^{1} x[s(x)-\bar{s}(x)] d x \tag{3}
\end{equation*}
$$

The inclusive I data sets (cf. Ref. [27]) contain the data that are sensitive to $\left[S^{-}\right]$; specifically, the data sets are (a) the neutrino $x F_{3}$ data from CCFR and CDHSW as neutrino $x F_{3}$ is proportional to the difference of quark and antiquark PDFs, and (b) the CDF $W$-asymmetry measurement which can receive contributions from the $s g \rightarrow W c$ subprocess. Figure 2 clearly shows that the dimuon data provide the strongest constraints on the strange asymmetry $\left[S^{-}\right]$.

## C. HERMES

The HERMES experiment measured the strange PDF via charged kaon production in positron-deuteron DIS [28]; these results are displayed in Fig. 3. For comparison, the strange quark and total sea distributions from CTEQ6L are also plotted.

FIG. 3 (color online). The strange parton distribution $x S(x)=$ $x[s(x)+\bar{s}(x)]$ from the measured Hermes multiplicity for charged kaons evolved to $Q^{2}=2.5 \mathrm{GeV}^{2}$. The dotted green curve is a Hermes 3-parameter fit: $S(x)=x^{-0.924} e^{-x / 0.0404}(1-$ $x$ ), the dashed blue curve is the sum of light antiquarks $x(\bar{u}+\bar{d})$ from CTEQ6L, the dash-dotted blue curve is $x S(x)$ from CTEQ6L, and the solid red curve is the $x S(x)$ from CTEQ6.6. Hermes data points and fit are from Ref. [28].

The HERMES data suggest that the $x$ dependence of the strange quark distribution is quite different from the form assumed for the CTEQ6 set. In particular, HERMES obtains a strange quark distribution that is suppressed in the region $x \gtrsim 0.1$ but then grows quickly for $x<0.1$ and exceeds the CTEQ6L value in the small $x$ region by more than a factor of 2 .

To gauge the compatibility of this result with the displayed PDFs, we can replace the initial $s(x)$ distribution with the form preferred by HERMES, and then evaluate the shift of the $\chi^{2}$ with this additional constraint. A preliminary investigation with this procedure indicates that the HERMES $s(x)$ distribution could strongly influence two data sets of the global fits. The first set is the neutrinonucleon dimuon data which control $s(x)$ in the intermediate $x$ region. The second set is the HERA measurement of $F_{2}$ in the small $x$ region where the statistical errors are particularly small.

In Fig. 3 we also show $x S(x)$ from CTEQ6.6; while the HERMES data are below the CTEQ6.6 result in the $x \sim 0.1$ region, they agree quite well at both the higher and lower $x$ values.

While these comparisons are sufficient to gauge the general influence of the Hermes result, a complete analysis that includes the Hermes data dynamically in the global fit is required to draw quantitative conclusions.

## D. CHORUS

The CHORUS experiment [29-31] measured the neutrino structure functions $F_{2}, x F_{3}, R$ in collisions of signselected neutrinos and antineutrinos with a lead target (lead-scintillator CHORUS calorimeter) in the CERN Super Proton Synchrotron (SPS) neutrino beam line. The
experiment collected over $3 \mathrm{M} \nu_{\mu}$ and $1 \mathrm{M} \bar{\nu}_{\mu}$ charged current events in the kinematic range $0.01<x<0.7$, $0.05<y<0.95,10<E_{\nu}<100$.

These data were analyzed in the context of a global fit in Ref. [32] which was based on the CTEQ6.1 PDFs. This analysis made use of the correlated systematic errors and found that the CHORUS data are generally compatible with the other data sets, including the NuTeV data. Thus, the CHORUS data are consistent with the strange distribution extracted in CTEQ6.1.

## E. NOMAD

The NOMAD experiment measured neutrino-induced charm dimuon production to directly probe the $s$ quark PDF [33-35]. Protons from the CERN SPS synchrotron ( 450 GeV ) struck a beryllium target to produce a neutrino beam with a mean energy of 27 GeV . NOMAD used an ironscintillator hadronic calorimeter to collect a very high statistics ( 15 K ) neutrino-induced charm dimuon sample [34].

Using kinematic cuts of $E_{\mu 1}, E_{\mu 2}>4.5 \mathrm{GeV}, 15<$ $E_{\nu}<300 \mathrm{GeV}$, and $Q^{2}>1 \mathrm{GeV}^{2}$, NOMAD performed a leading-order QCD analysis of 2714 neutrino- and 115 antineutrino-induced opposite sign dimuon events [33]. The ratio of the strange to nonstrange sea in the nucleon was measured to be $\kappa=0.48_{-0.07-0.12}^{+0.09+0.17}$; this is consistent with the values used in the global fits (cf. Fig. 4).

The data analysis is continuing, and it will be very interesting to include this data set into the global fits as the large dimuon statistics have the potential to strongly influence the extracted PDFs.

## F. MINER $\boldsymbol{\nu}$ A

The cross sections in neutrino DIS experiments from NuTeV, CCFR, CHORUS and NOMAD have been mea-

FIG. 4 (color online). $\kappa(x, Q)$ vs $x$ for $Q=1.5 \mathrm{GeV}$ for a selection of PDFs, where $\kappa(x, Q)$ is defined in Eq. (4). The curves (top to bottom) are CTEQ6.6 (solid, red), CTEQ6.5 (dotted, black), and CTEQ6.1 (dashed, purple). The wider (blue) band represents the uncertainty for CTEQ6.6 as computed by Eq. (5), the inner (green) band represents uncertainty given by the envelope of $\kappa(x, Q)$ values obtained with the 44 CTEQ6.6 error sets.
sured using heavy nuclear targets. In order to use these measurements in a global analysis of proton PDFs, these data must be converted to the corresponding proton or isoscalar results [36-42]. For example, the nuclear correction factors used in the CTEQ6 global analysis were extracted from $\ell^{ \pm} N$ DIS processes on a variety of nuclei, and then applied to $\nu N$ DIS on heavy nuclear targets. In a series of recent studies it was found that the $\ell^{ \pm} N$ nuclear correction factors could differ substantially from the optimal $\nu N$ nuclear correction factors [39-43].

Furthermore, the nuclear corrections depend to a certain degree on the specific observable as they contain different combinations of the partons; the nuclear correction factors for dimuon production will not be exactly the same as the ones for the structure function $F_{2}$ or $F_{3}$. The impact of varying the nuclear corrections on the strange quark PDF has to be done in the context of a global analysis which we leave for a future study.

The MINER $\nu$ A experiment has the opportunity to help resolve some of these important questions as it can measure the neutrino DIS cross sections on a variety of light and heavy targets. It uses the NuMI beam line at Fermilab to measure low energy neutrino interactions to study neutrino oscillations and also the strong dynamics of the neutrino-nucleon interactions. MINER $\nu \mathrm{A}$ completed construction in 2010, and it has begun data collection. MINER $\nu$ A can measure neutrino interactions on a variety of targets including plastic, helium, carbon, water, iron, and lead. For $4 \times 10^{20}$ protons on target it can generate over 1 M charged current events on plastic.

These high-statistics data on a variety of nuclear targets could allow us to accurately characterize the nuclear correction factors as a function of the nuclear $A$ from helium to lead. These data will be very useful in resolving questions about the nuclear corrections, and we look forward to the results in the near future.

## G. CDF and DO

At the Tevatron, the CDF [44] and D0 [45] Collaborations measured $W c$ final states in $p \bar{p}$ at $\sqrt{S}=$ 1.96 TeV using the semileptonic decay of the charm and the correlation between the charge of the $W$ and the charm decay. Additionally, a recent study has investigated the impact of the $W+$ dijet cross section on the strange PDF [46]. These measurements are especially valuable for two reasons. First, there are no nuclear correction factors as the initial state is $p$ or $\bar{p}$. Second, this is in a very different kinematic region as compared to the fixed-target neutrino experiments. Thus, these have the potential to constrain the strange quark PDF in a manner complementary to the $\nu N$ DIS measurements; however, the hadron-hadron initial state is challenging. Using approximately $1 \mathrm{fb}^{-1}$ of data, both CDF and D0 find their measurements to be in agreement with theoretical expectations of the standard model. Updated analyses with larger data sets are in progress and it
will be interesting to see the impact of these improved constraints on the strange quark PDF.

## H. Strange quark uncertainty

The combination of the above results underscores the observation that our knowledge of the strange quark is limited. To illustrate this point in another manner, in Fig. 4 we display $\kappa(x, Q)$ for a selection of PDF sets. Here, we define

$$
\begin{equation*}
\kappa(x, Q)=\frac{s(x, Q)}{[\bar{u}(x, Q)+\bar{d}(x, Q)] / 2} \tag{4}
\end{equation*}
$$

which is essentially a differential version of the $\kappa$ parameter of Eq. (2); this allows us to gauge the amount of the strange PDF inside the proton compared to the average up and down sea quark PDFs. If we had exact $S U(3)$ symmetry we would expect $\bar{u}=\bar{d}=\bar{s}$ and $\kappa(x, Q) \sim 1$. As the strange quark is heavier than the up and down quarks, we expect this component to be suppressed relative to the up and down quarks, and we would predict $\bar{u} \simeq \bar{d}>\bar{s}$ which would yield $\kappa(x, Q)<1$. Thus, $\kappa(x, Q)$ is a measure of the $S U(3)$ breaking across the $x$ and $Q$ range.

In Fig. 4 we observe that the CTEQ6.1 and CTEQ6.5 PDF sets have $\kappa(x, Q) \sim 1 / 2$; this was by design as the constraint of Eq. (2) was used to set the initial $s(x)$ distribution. The exception is CTEQ6.6 which did not impose Eq. (2); we observe that this set has $\kappa(x, Q) \sim 1 / 2$ for $x \sim 0.1$ (where the dimuon DIS data have smaller uncertainties), but is a factor of 2 larger than the other PDF sets for small $x$ values. In Fig. 4 we also show the uncertainty on $s(x)$ computed as [12]

$$
\begin{equation*}
\Delta X=\frac{1}{2} \sqrt{\sum_{i=1}^{N_{p}}\left[X\left(S_{i}^{+}\right)-X\left(S_{i}^{-}\right)\right]^{2}}, \tag{5}
\end{equation*}
$$

which is shown as a wider (blue) band; ${ }^{2}$ this results in a band which is larger than simply taking the spread of the 44 CTEQ6.6 error PDFs [inner (green) band].

In order to show the effect of the Dokshitzer, Gribov, Lipatov, Altarelli, Parisi evolution on the strange distribution, we display $\kappa(x, Q)$ for CTEQ6.1 and CTEQ6.6 at both a low and high $Q$ scale in Fig. 5. As we explore higher scales, the production of $s(x)$ by gluon splitting moves $\kappa(x, Q)$ toward the $S U(3)$-symmetric limit. This trend is especially pronounced at low $x$ values. Thus, as the LHC $W / Z$ production is centered in the range $x \sim 0.01$, we will be particularly interested in the $\kappa(x, Q)$ changes in this region.

These results reflect the relevant $x$ range of the constraints on the strange quark PDF, and how they depend on the $Q$ scale. In the next section we will investigate the

[^106]

FIG. 5 (color online). $\kappa(x, Q)$ vs $x$ showing the evolution from low to high scales. The solid (red) lines are for CTEQ6.6, and the dashed (purple) lines are for CTEQ6.1. The lower pair of lines (red and purple) are for $Q=1.5 \mathrm{GeV}$ and the upper for $Q=80 \mathrm{GeV}$.
implications of this uncertainty on the Drell-Yan $W / Z$ boson production at the LHC.

## III. IMPLICATIONS FOR DRELL-YAN $W / Z$ PRODUCTION AT THE LHC

The Drell-Yan production of $W^{ \pm}$and $Z$ bosons at hadron colliders can provide precise measurements for electroweak observables such as the $W$ boson mass $[47,48]$ and width, the weak mixing angle in $\gamma^{*} / Z$ production [49], and the lepton asymmetry in $W$ production. These results can measure fundamental parameters of the standard model and constrain the Higgs boson mass. If a Higgs boson is found at the LHC, Drell-Yan $W / Z$ boson production will help in the search for deviations of the SM and to reveal new physics signals [50-52]. For instance, new heavy gauge bosons could be discovered in the invariant lepton distribution, or new particles and interactions might leave a footprint in the Peskin-Takeuchi $S$ and $T$ parameters [53].

Furthermore, the $W$ and $Z$ boson cross section benchmark processes are intended to be used for detector calibration and luminosity monitoring [54]; to perform these tasks it is essential that we know the impact of the PDF uncertainties on these measurements. The impact on these benchmark processes, and the Higgs boson production, were studied in Refs. [55-57]. In the following, we will investigate the influence of the PDFs on the rapidity distributions of the Drell-Yan production process. Conversely, it may be possible to use the $W / Z$ production process to further constrain the parton distribution functions in general, and the strange quark PDF, in particular. As noted in Ref. [49], when looking for new physics signals it is important not to mix the information used to constrain the PDFs and the new physics as this would lead to circular reasoning.

As we move from the Tevatron to the LHC scattering processes, the kinematics of the incoming partons changes
considerably; in Fig. 6 we show the momentum fractions $x_{A}$ and $x_{B}$ of the incoming parton $A$ and parton $B$ for the Tevatron Run-2 $(\sqrt{S}=1.96 \mathrm{TeV})$ and the LHC with $\sqrt{S}=$ 7 TeV and $\sqrt{S}=14 \mathrm{TeV}$. The solid (red) lines show the range of $x_{A}$ and $x_{B}$ probed by $W^{ \pm}$and $Z$ boson production. At the Tevatron, values of $x_{A, B}$ down to $2 \times 10^{-3}$ are probed for large rapidities of $y_{W / Z}=3$. However, at the LHC much smaller values of $x_{A}$ and $x_{B}$ become important due to the larger CMS energy and broader rapidity span. For $\sqrt{S}=7 \mathrm{TeV}$, the PDFs are probed for $x$ values as small as $2 \times 10^{-4}$ for rapidities up to $\sim 4.5$. With $\sqrt{S}=$ 14 TeV , even larger rapidities of $y \sim 5$ and smaller values of $x_{A / B}$ of $4 \times 10^{-5}$ might be reached.

## A. LHC measurements

The importance of the PDF uncertainties to the LHC measurements was already evident in the 2010 and preliminary 2011 data.

ATLAS presented measurements of the Drell-Yan $W / Z$ production at the $\sqrt{S}=7 \mathrm{TeV}$ with $35 \mathrm{pb}^{-1}$ [58]. These results include not only the measurement of total cross section and transverse distributions, but also a first measurement of the rapidity distributions for $Z \rightarrow l^{+} l^{-}$as well as $W^{+} \rightarrow l^{+} \nu_{l}$ and $W^{-} \rightarrow l^{-} \bar{\nu}_{l}$. Additionally, ATLAS has used $W / Z$ production to infer constraints on the strange quark distribution, and it measures $r_{s}=0.5(s+\bar{s}) / \bar{d}=$ $1.00_{-0.28}^{+0.25}$ at $Q^{2}=1.9 \mathrm{GeV}^{2}$ and $x=0.023$ [59].

FIG. 6 (color online). Parton momentum fractions $x_{A}$ and $x_{B}$ accessible in $W$ and $Z$ boson production in the Tevatron Run-2 ( $\sqrt{S}=1.96 \mathrm{TeV}$ ), and at the LHC $(\sqrt{S}=\{7,14\} \mathrm{TeV})$. The accessible ranges of $x_{A}$ and $x_{B}$ are shown by the solid lines. The contours of the constant rapidity $y$ are shown by the inclined dotted lines.

CMS has measured the rapidity and transverse momentum distributions for $Z \rightarrow l^{+} l^{-}$production [60] and inclusive $W / Z$ production [61] using $36 \mathrm{pb}^{-1}$ of data. Additionally CMS has measured the weak mixing angle [49], the forward-backward asymmetry in $\gamma^{*} / Z$ production [62], and the lepton charge asymmetry in $W$ production [63,64].

LHCb has measured the $W$ charge asymmetry in Refs. [65,66]. These measurements show, already with these data samples, the PDF uncertainties are important and can be the leading source of measurement uncertainty.

Additionally, CMS has analyzed $W+c$ production which is directly sensitive to the $s$ and $\bar{s}$ contribution of the proton; the results for the $36 \mathrm{pb}^{-1}$ data sample are given in Ref. [67].

## B. Strange contribution to $W / Z$ production

Because the proton-proton LHC has a different initial state and a higher CMS energy than the Tevatron, the relative contributions of the partonic subprocesses of the $W^{ \pm} / Z$ production change significantly. At the LHC, the contributions of the second generation quarks $\{s, c\}$ are greatly enhanced. Additionally, the $W^{+}$and $W^{-}$rapidity distributions are no longer related by a simple $y \rightarrow-y$ reflection symmetry due to the $p p$ initial state. In Fig. 7 we display the contributions from the different partonic cross sections which contribute to $W^{ \pm}$and $Z$ production at LO.

Figure 7(a) shows the rapidity distribution at the Tevatron. For $W^{+}\left(W^{-}\right)$production, the $u \bar{d}(\bar{u} d)$ channel (dotted black lines) contributes $90 \%$ of the cross section, while in $Z$ production the $u \bar{u}$ (dotted black line) and $d \bar{d}$ (dash-dotted black line) subprocesses contribute $93 \%$ of the cross section. The first generation quarks $\{u, d\}$ therefore dominate the production process while contributions from strange quarks [(red) dashed and (blue) dash-dotted lines] are comparably small with $5 \%$ for $W^{ \pm}$and $5 \%(s \bar{s})$ for $Z$ boson production.

At the LHC, subprocesses containing strange quarks are considerably more important as shown in Fig. 7(b) for a CMS energy of 7 TeV and in Fig. 7(c) for 14 TeV . For $W^{-}$ production (left plots), the (blue) dash-dotted lines show the $\bar{u} s$ channel while the (red) dashed lines show the $\bar{c} s$ contribution. At 14 TeV the $\bar{c} s \rightarrow W^{-}$subprocess contributes $28 \%$ to the cross section, while the $\bar{u} s \rightarrow W^{-}$subprocess contributes only $2 \%$ as this is suppressed by the off-diagonal Cabibbo-Kobayashi-Maskawa matrix entry. For $W^{+}$production channels, the $u \bar{s}$ channel [(blue) dash-dotted lines] contributes only $2 \%$, while the $c \bar{s}$ channel [(red) dashed lines] yields $21 \%$. Notice the absolute values of the $\bar{c} s \rightarrow W^{-}$and $c \bar{s} \rightarrow W^{+}$contributions are the same; however, the relative contribution is smaller for $W^{+}$ production due to the larger up quark valence contribution in the $u \bar{d} \rightarrow W^{+}$subprocess as compared to $\bar{u} d \rightarrow W^{-}$.

The rapidity distributions of the total $W^{-}$and $W^{+}$boson production differ markedly at the LHC because of the

FIG. 7 (color online). Partonic contributions to the differential cross section of on-shell $W^{ \pm} / Z$ boson production at LO as a function of the vector boson rapidity. Partonic contributions containing a strange or antistrange quark are denoted by (red) dashed and (blue) dash-dotted lines. The solid lines show the total contribution.
different valence quark contributions from $u$ and $d$. This effect is also present in the $\bar{u} s \rightarrow W^{-}$and $u \bar{s} \rightarrow W^{+}$ [(blue) dash-dotted lines] subprocess. We will comment more on this feature in the following subsection.

Comparing Fig. 7(a) with Fig. 7(c), we note the LHC explores a much larger rapidity range. For channels containing strange quarks, $\left|y_{W / Z}\right|$ can be measured up to $y \approx$ 4.5 at the LHC, compared to $y \approx 2.5$ at the Tevatron; therefore smaller values of $x$ of the strange quark distribution can be probed.

Additionally, as at the Tevatron, we can use $W^{-}$production to probe the strange quark PDF while using $W^{+}$ production to probe the antistrange PDF.

While the LO illustration of Fig. 7 provides a useful guide, in Fig. 8 we display the strange quark contribution to the differential cross section $d^{2} \sigma / d M / d y$ of on-shell $W^{-}$, $W^{+}, Z$ boson production computed at next-to-next-toleading order (NNLO) using the VRAP program [68]. We display the LHC results for $W^{ \pm}$and $Z$ with $\sqrt{S}$ of both 7 TeV and 14 TeV , where the (yellow) band represents
the strange quark initiated contributions to the total differential cross section.

The figures impressively highlight the large contribution of the strange and antistrange quark subprocesses at the LHC. Consequently it is essential to constrain the strange PDF if we are to make accurate predictions and to perform precision measurements. Figure 8 also demonstrates clearly the very different rapidity profiles of the strange quark (arising from the sea distribution) compared to the $u$ and $d$ quark terms which are dominated by the valence distributions. This property is most evident for the case of $W^{+}$production. Here, the dominant $u \bar{d}$ contribution has a twin-peak structure due to the harder valence distribution, while the $c \bar{s}$ distribution has a single peak centered at $y=0$. The total distribution is then a linear combination of the twin-peak and single-peak distributions, and these are weighted by the corresponding PDF.

Therefore, a detailed measurement of the rapidity distribution of the $W^{ \pm} / Z$ bosons can yield information about the contributions of the $s$ quark relative to the $u, d$ quarks.

FIG. 8 (color online). Contribution of the strange quark to $W^{ \pm} / Z$ production at the LHC.

As this is a relative measurement, rather than an absolute cross section measurement, it is reasonable to expect that this could be achieved with high precision once sufficient statistics are collected. Consequently, this is an ideal measurement where the LHC data could lead to stronger constraints on the PDFs.

## C. PDF uncertainty of the $W / Z$ rapidity distributions

To estimate the influence of the PDF uncertainties (and, in particular, the strange quark PDF ) on the $W / Z$ production process and its differential distributions at the LHC, we will use the different PDF sets within CTEQ6.6 as well as compare the sets of different PDF groups.

In Fig. 9(a), we display the differential cross section $d^{2} \sigma / d M / d y$ for $W^{ \pm} / Z$ boson production at the LHC at $\sqrt{S}=7 \mathrm{TeV}$ using the 44 error PDF sets of CTEQ6.6. To better resolve these PDF uncertainties, we plot the ratio of the differential cross section $d^{2} \sigma / d M / d y$ compared to the central value in Fig. 9(b). We observe that the uncertainty due to the PDFs as measured by this band is between $\pm 3 \%$ and $\pm 4 \%$ for central boson rapidities of $-3 \leq y_{W / Z} \leq$ +3 . For larger rapidities, the PDF uncertainties increase dramatically, but the cross section vanishes.

For comparison, in Fig. 9(c) we display the (yellow) band of CTEQ6.6 error PDFs together with the results using other contemporary PDF sets. The (yellow) band shows the span of the 44 CTEQ6.6 error PDFs of Fig. 9(b), and the solid lines show the rapidity distribution from the
selection of PDFs; all have been scaled to the central value for the CETQ6.6 set. ${ }^{3}$ We observe that the choice of PDF sets can result in differences ranging up to $\pm 8 \%$ for $-2 \leq$ $y_{W / Z} \leq+2$ and even up to $\pm 10 \%$ for $-3 \leq\left|y_{W / Z}\right| \leq 3$, which is well beyond the $\pm 3 \%$ and $\pm 4 \%$ range displayed in Fig. 9(b); note the different scales used in Figs. 9(b) and 9(c). However, if we compute the PDF uncertainty band using Eq. (5) as specified by Ref. [12] we find an estimated uncertainty of $\sim 15 \%$ (depending on the rapidity) which generally does encompass the range of PDFs displayed in Fig. 9(c).

While the band of error PDFs provides an efficient method to quantify the uncertainty, the range spanned by the different PDF sets illustrates there are other important factors which must be considered to encompass the full range of possibilities.

## D. Correlations of the $\boldsymbol{W} / \boldsymbol{Z}$ rapidity distributions

The leptonic decay modes of the $W / Z$ bosons provide a powerful tool for precision measurements of electroweak parameters such as the $W$ boson mass. As the leptonic

[^107]
(a) $d^{2} \sigma / d M / d y$ in $\mathrm{pb} / \mathrm{GeV}$ for $p p \rightarrow W^{-}+X$ (left), $p p \rightarrow W^{+}+X$ (middle), and $p p \rightarrow Z, \gamma^{*}+X$ (right) production at the LHC for 7 TeV with CTEQ6.6 using the VRAP program [68] at NNLO.

(c) $d^{2} \sigma / d M / d y$ for $\left\{W^{-}, W^{+}, Z\right\}$ production at the LHC for $\sqrt{S}=7 \mathrm{TeV}$ with a selection of PDFs using the VRAP program at NNLO. The (yellow) band is for the CTEQ6.6 set [19], and the other curves are for the central values of different PDF sets (see $t e x t)$. All plots are scaled by the central value for the CETQ6.6 set. Note the scale of this figure is larger than for Fig. 9 b .

FIG. 9 (color online). PDF uncertainty bands for on-shell $W^{-}$(left plots), $W^{+}$(middle plots), and $Z$ (right plots) production at the LHC for $\sqrt{S}=7 \mathrm{TeV}$.
decay of the $W$ boson contains a neutrino ( $W \rightarrow \ell \nu$ ), this process must be modeled to account for the missing neutrino. The $W$ mass can then be measured by studying the transverse momentum distribution of the decay lepton $\ell$ or the transverse mass of the $\ell \nu$ pair. Performing this measurement, the Drell-Yan $Z$ boson production process is used to calibrate the leptonic $W$ process because the $Z$ can decay into two visible leptons $Z \rightarrow \ell^{+} \ell^{-}$. This method works to the extent that the production processes of the $W$ and $Z$ bosons are correlated.

One possible measure to gauge the correlation of the PDF uncertainty is the ratio of the $W$ and $Z$ boson differential cross section. We compute $d^{2} \sigma / d M / d y$ for $W^{ \pm}$ compared to $Z$, and divide by the central PDF results to see the uncertainty band on a relative scale. Schematically we define

$$
\begin{equation*}
R^{ \pm}=\left[\frac{d \sigma\left(W^{ \pm}\right)}{d \sigma(Z)}\right] /\left[\frac{d \sigma\left(W^{ \pm}\right)}{d \sigma(Z)}\right]_{0}, \tag{6}
\end{equation*}
$$

where the " 0 " subscript denotes the "central" PDF set. The resulting distributions are displayed in Fig. 10(a) for $W^{-}$production and in Fig. 10(b) for $W^{+}$production. The left plot in each figure shows the distributions for the CTEQ6.5 PDF set, and the right plot the distributions for CTEQ6.6. We observe that the uncertainty band is generally $\pm 1 \%$ for central rapidities of $-2 \leq y_{W / Z}<+2$; this is smaller than in the previous case, where the absolute uncertainty was investigated. For larger rapidity ( $\left|y_{W / Z}\right|>2$ ) the uncertainty band exceeds the $\pm 1 \%$ range of the plot.

In Fig. 10, we plot the sum of the differential $W^{+}$and $W^{-}$cross sections with respect to the differential $Z$ boson

FIG. 10 (color online). Ratios of the differential $W^{ \pm}$and $Z$ production cross section as defined in Eqs. (6) and (7) at the LHC for $\sqrt{S}=7 \mathrm{TeV}$.
cross section, again normalized to the distribution of the central PDF set. We define

$$
\begin{equation*}
R=\left[\frac{d \sigma\left(W^{+}+W^{-}\right)}{d \sigma(Z)}\right] /\left[\frac{d \sigma\left(W^{+}+W^{-}\right)}{d \sigma(Z)}\right]_{0} \tag{7}
\end{equation*}
$$

for both the CTEQ6.5 and CTEQ6.6 PDFs.
The contrast in Fig. 10(c) is striking. For the CTEQ6.5 PDFs, we observe that $W^{ \pm}$and $Z$ processes are strongly correlated, while for the CTEQ6.6 the spread of the PDF band is substantially larger. For example, the double ratio for CTEQ6.5 has a spread of approximately $\pm 0.2 \%$ within the central rapidity range of $-3 \leq y_{W / Z} \leq+3$, while the uncertainty for CTEQ6.6 is much wider in this rapidity region.

The primary difference that is driving this result is the different strange PDF. For CTEQ6.5 the strange quark was
defined by Eq. (2) while CTEQ6.6 introduced two extra fitting parameters which allowed the strange PDF to vary independently from the up and down sea. Thus, the uncertainty of the CTEQ6.6 distributions more accurately reflects the true uncertainty.

Another means to see how the additional freedom of the strange quark introduces a decorrelation of the $W^{ \pm}$and $Z$ processes is evident in Fig. 11 which displays the correlation of the $W^{ \pm}$and $Z$ boson cross sections for a selection of CTEQ PDFs. Except for CTEQ6.6, all the PDFs make use of Eq. (2) and yield results that lie along a straight line in the $\left\{\sigma_{W}, \sigma_{Z}\right\}$ plane. Because CTEQ6.6 does not use Eq. (2), the freedom of the strange quark PDF is reflected in the freedom of the $W^{ \pm}$and $Z$ cross sections values.

The above examples demonstrate the subtle features inherent in evaluating the PDF uncertainties. For precision measurements it is important to better constrain the parton

FIG. 11 (color online). Correlation of the $W^{ \pm}$and $Z$ cross sections for a selection of PDF sets. Figure taken from Ref. [19].
distributions at the LHC, in particular, the strange and antistrange quark PDFs.

## IV. CONCLUSION

We have investigated the constraints of the strange and antistrange PDFs and their impact on the Drell-Yan $W / Z$ boson production at the LHC.

Specifically, we observe that the strange quark is rather poorly constrained, particularly in the low $x$ region which is sensitive to $W / Z$ production at the LHC. Improved analyses from neutrino DIS measurements could help reduce this uncertainty. Conversely, precision measurements of $W / Z$ production at the LHC may provide input to the global PDF analyses which could further constrain these distributions.

In particular, the rapidity distribution of the $W / Z$ bosons provides an incisive measure of the mix of valence and sea quarks, and the prospect of measuring this at the LHC in the near future is excellent.

## APPENDIX: PDF FITS WITH THE DIMUON DATA

We have repeated the LO analysis of Ref. [27] and extended this using the NLO calculation for dimuon production $[74,75]$. We have performed a series of fits to the data which includes the dimuon data. The results of the $\left\{A, B^{+}, B, B^{-}, C\right\}$ fits ${ }^{4}$ using the LO dimuon analysis are shown in Table II, and those with the NLO analysis are in Table III. The fits are sorted left-to-right by the integrated strange quark asymmetry $\left[S^{-}\right]$(scaled by $10^{4}$ ). The cells display the $\chi^{2}$ relative to $\chi_{0}^{2}$ for the indicated data set where we choose $\chi_{0}^{2}$ to be the $\chi^{2}$ value from the LO- $B$ fit; this allows us to compare the incremental changes as we shift [ $S^{-}$] and alter the constraints. The values in parentheses are the $\chi^{2} / \mathrm{DoF}$ for each data subset. The $B$ fit is the overall best fit to the data. The $B^{+}$and $B^{-}$sets modify the $B$ fit using the Lagrange multiplier method to determine the ranges of the $\left[S^{-}\right.$] parameter defined in Eq. (3).

For example, the LO $B^{+}$fit demonstrates that we can increase $\left[S^{-}\right.$] from 15.98 to 54.85 , but the dimuon $\chi^{2}$ increases by $33 / 174 \sim 21 \%$ while the overall $\chi^{2}$ increases by only $39 / 2465 \sim 2 \%$; thus, the shift of [ $S^{-}$] is strongly constrained by the dimuon data, and the remaining data are relatively insensitive to this quantity.

Comparing the NLO- $B$ fit to the LO- $B$ fit we note that $\chi^{2} /$ DoF has decreased both for the dimuon set and the entire data set; while this decrease is not dramatic, it is encouraging to see that the proper NLO treatment of the data results in an improved fit. As before, we observe that for the NLO $B^{+}$fit, we can increase $\left[S^{-}\right.$] from 13.72 to 63.75, but the dimuon $\chi^{2}$ increases by $92 / 174 \sim 53 \%$ while the overall $\chi^{2}$ increases by only $106 / 2465 \sim 4 \%$; again, the shift of $\left[S^{-}\right]$is primarily constrained by the dimuon data.

In Fig. 2 we have plotted the ratio $\chi^{2} / \chi_{0}^{2}$ for the individual dimuon and inclusive I data sets [27] evaluated

[^108]TABLE II. Fit results using the LO dimuon calculation. We present the integrated strange quark asymmetry [ $S^{-}$], and the cells display $\chi^{2} / \chi_{0}^{2}$, and the values in parentheses are the $\chi^{2} /$ DoF for each data subset. Note $\chi_{0}^{2}$ is calibrated from the LO $B$ fit.

for a series of NLO $B$ fits as a function of the strange asymmetry $\left[S^{-}\right] \times 10^{4}$. This plot allows us to see the contribution of each data set as we shift the strange asymmetry. Again the inclusive I data sets are essentially
unchanged as the treatment of the dimuons only affects these data indirectly. As before, this data set is mildly sensitive to the dimuons, and weakly prefers larger values of $\left[S^{-}\right.$.

# Heavy Quarks: lessons learned from HERA and Tevatron 

Fredrick Olness, ${ }^{\text {a* }}$ Ingo Schienbein, ${ }^{\text {b }}$<br>${ }^{\text {a }}$ Southern Methodist University, Dallas, TX 75275-0175 USA<br>${ }^{\text {b }}$ Laboratoire de Physicque Subatomique et de Cosmologie, Université Joseph Fourier Grenoble 1, CRNS/IN2P3, Institut National Polytechnique de Grenoble, 38026 Grenoble, France

#### Abstract

We review some of the recent developments which have enabled the heavy quark mass to be incorporated into both the calculation of the hard-scattering cross section and the PDFs. We compare and contrast some of the schemes that have been used in recent global PDF analyses, and look at issues that arise when these calculations are extended to NNLO.

## 1. Introduction

The production of heavy quarks in high energy processes has become an increasingly important subject of study both theoretically and experimentally. The theory of heavy quark production in perturbative Quantum Chromodynamics (PQCD) is more challenging than that of light parton (jet) production because of the new physics issues brought about by the additional heavy quark mass scale. The correct theory must properly take into account the changing role of the heavy quark over the full kinematic range of the relevant process from the threshold region (where the quark behaves like a typical "heavy particle") to the asymptotic region (where the same quark behaves effectively like a parton, similar to the well known light quarks $\{u, d, s\}$ ).

We review theoretical methods which have been advanced to improve existing QCD calculations of heavy quark production, and the impact on recent experimental results from HERA and the Tevatron.

The ACOT renormalization scheme provides a mechanism to incorporate the heavy quark mass into the theoretical calculation of heavy quark production both kinematically and dynamically. In 1998 Collins [1] extended the factorization theorem to address the case of heavy quarks; this work provided the theoretical foundation that allows us to reliably compute heavy quark processes

[^109]throughout the full kinematic realm.

### 1.1. NLO DIS calculation

Figure 1 displays characteristic Feynman graphics for the first few orders of DIS heavy quark production. If we consider the DIS production of heavy quarks at $\mathcal{O}\left(\alpha_{S}^{1}\right)$ this involves the LO $Q V \rightarrow Q$ process and the NLO $g V \rightarrow Q \bar{Q}$ process.

Figure 1. Characteristic Feynman graphs which contribute to DIS heavy quark production: a) the LO $\mathcal{O}\left(\alpha_{S}^{0}\right)$ quark-boson scattering $Q V \rightarrow Q$, b) the NLO $\mathcal{O}\left(\alpha_{S}^{1}\right)$ gluon-boson scattering $g V \rightarrow$ $Q \bar{Q}$, and c) the NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ boson-gluon scattering $g V \rightarrow g Q \bar{Q}$.

The key ingredient provided by the ACOT scheme is the subtraction term (SUB) which removes the "double counting" arising from the regions of phase space where the LO and NLO contributions overlap. Specifically, the subtraction
term is:
$\sigma_{S U B}=f_{g} \otimes \tilde{P}_{g \rightarrow Q} \otimes \sigma_{Q V \rightarrow Q}$
$\sigma_{S U B}$ represents a gluon emitted from a proton $\left(f_{g}\right)$ which undergoes a collinear splitting to a heavy quark ( $\tilde{P}_{g \rightarrow Q}$ ) convoluted with the LO quark-boson scattering $\sigma_{Q V \rightarrow Q}$. Here, $\tilde{P}_{g \rightarrow Q}(x, \mu)=\frac{\alpha_{s}}{2 \pi} \ln \left(\mu^{2} / m_{c}^{2}\right) P_{g \rightarrow c}(x)$ where $P_{g \rightarrow c}(x)$ is the usual $\overline{M S}$ splitting kernel.

### 1.2. When do we need Heavy Quark PDFs

The novel ingredient in the above calculation is the inclusion of the heavy quark PDF contribution which resums logs of $\ln \left(\mu^{2} / m_{Q}^{2}\right)$. One can ask the question: When do we need to consider such terms? The answer is illustrated in Figure 2 where we compare the DGLAP evolved $\operatorname{PDF} f_{c}(x, \mu)$ with the single splitting perturbative result.

The DGLAP PDF evolution sums a nonperturbative infinite tower of logs while the SUB contribution removes the perturbative single splitting component which is already included in the NLO contribution. Hence, at the PDF level the difference between the heavy quark DGLAP evolved PDF $f_{Q}$ and the single-splitting perturbative $\tilde{f}_{Q}$ will indicate the contribution of the higher order logs which are resummed into the heavy quark PDF. Here, we shall find it convenient to define $\tilde{f}_{Q}=f_{g} \otimes \tilde{P}_{g \rightarrow Q}$ which represents the PDF of a heavy quark $Q$ generated from a single perturbative splitting.

For $\mu \sim m_{Q}$ we see that $f_{Q}$ and $\tilde{f}_{Q}$ match quite closely, whereas $f_{Q}$ and $\tilde{f}_{Q}$ differ significantly for $\mu$ values a few times $m_{Q}$. While the details will depend on the specific process, in general we find that for $\mu$ scales 3 to 5 times $m_{Q}$ the terms resummed by the heavy quark PDF can be significant.

## 2. The ACOT Renormalization Scheme

### 2.1. Massive vs. Massless Evolution

Another useful result that arises from the proof of Collins [1] is that we can use mass-independent (massless) evolution kernels to evolve the heavy quark PDFs without any loss of accuracy as compared to a mass-dependent (massive) evolution

Figure 2. Comparison of the DGLAP evolved charm $\operatorname{PDF} f_{c}(x, \mu)$ with the perturbatively computed single splitting (SUB) $f_{c}(x, \mu)=f_{g}(x, \mu) \otimes$ $\tilde{P}_{g \rightarrow c}$ charm evolution vs. $\mu$ in GeV for two representative values of $x$.
kernel. [ 2]. Specifically, Collins demonstrated that consistent application of the formalism correctly resums the massive contributions up to higher-twist corrections $\mathcal{O}\left(\Lambda_{Q C D}^{2} / Q^{2}\right)$ and that there are no errors of order $\mathcal{O}\left(m_{Q}^{2} / Q^{2}\right)$.
This result is illustrated in Figure 3 where we compare the results of a NLO DIS heavy quark production calculation using massless and massive DGLAP evolution kernels. In Fig. 3a) we see that while the choice of massive or massless kernels significantly changes the individual $L O$ and $S U B$ contributions, the difference $L O-S U B$ which contributes to the total ( $T O T=L O-$

Figure 3. Comparison of heavy quark DIS structure function for mass-dependent (massive) and massindependent (massless) evolution.
$S U B+N L O$ ) is minimal. This numerically verifies that the choice of massive or massless evolution kernels is purely a scheme choice which has no physical content.

While we see this result demonstrated numerically in Figure 3, the underlying reason for this result is closely related to the previous observations made regarding Figure 2. The LO result is given by $L O \sim f_{Q} \otimes \sigma_{Q \rightarrow Q}$ and the subtraction term is given by $S U B \sim f_{g} \otimes \tilde{P}_{g \rightarrow Q} \otimes \sigma_{Q \rightarrow Q}$. If we expand the DGLAP equation for $f_{Q}$ in the region $\mu \sim m_{Q}$ we find $f_{Q} \sim f_{g} \otimes \tilde{P}_{g \rightarrow Q}+\mathcal{O}\left(\alpha_{s}^{2}\right)$; thus, we have $L O \sim f_{g} \otimes \tilde{P}_{g \rightarrow Q} \otimes \sigma_{Q \rightarrow Q}+\mathcal{O}\left(\alpha_{S}^{2}\right)$. We observe that while $L O$ and $S U B$ individually depend on the specific splitting kernels, the combination $L O-S U B$ is insensitive to whether we use the massive or massless kernel. ${ }^{2}$

Therefore, we conclude that so long as the splitting kernels $P_{a \rightarrow b}$ are matched between the DGLAP evolution and the definition of the subtractions (SUB), the choice of a massive or massless DGLAP evolution kernel was purely a choice of scheme and the physical results are invariant.

### 2.2. S-ACOT

In a complementary application, it was observed that the heavy quark mass could be set to zero in certain pieces of the hard scattering terms without any loss of accuracy. This modi-

[^110]fication of the ACOT scheme goes by the name Simplified-ACOT (S-ACOT) and can be summarized as follows.

S-ACOT: For hard-scattering processes with incoming heavy quarks or with internal onshell cuts on a heavy quark line, the heavy quark mass can be set to zero ( $m_{Q}=0$ ) for these pieces [3].

If we consider the case of NLO DIS heavy quark production, this means we can set $m_{Q}=0$ for the LO terms ( $Q V \rightarrow Q$ ) as this involves an incoming heavy quark, and we can set $m_{Q}=0$ for the SUB terms as this has an on-shell cut on an internal heavy quark line. Hence, the only contribution which requires calculation with $m_{Q}$ retained is the NLO $g V \rightarrow Q \bar{Q}$ process.

Figure 4 displays a comparison of a calculation using the ACOT scheme with all masses retained vs. the S-ACOT scheme; as promised, these two results match throughout the full kinematic region.

### 2.3. ACOT- $\chi$

In the conventional implementation of the heavy quark PDFs, we must "rescale" the Bjorken $x$ variable as we have a massive parton in the final state. The original rescaling procedure is to make the substitution $x \rightarrow x\left(1+m_{c}^{2} / Q^{2}\right)$ which provides a kinematic penalty for producing the heavy charm quark in the final state [4]. As the charm is pair-produced by the $g \rightarrow c \bar{c}$ process, there are actually two charm quarks in the final

Figure 4. Comparison of schemes for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number (FFN), and Zero-Mass Variable Flavor Number (ZM-VFN) schemes. The ACOT and S-ACOT results are virtually identical.
state-one which is observed in the semi-leptonic decay, and one which goes down the beam pipe with the proton remnants. Thus, the appropriate rescaling is not $x \rightarrow x\left(1+m_{c}^{2} / Q^{2}\right)$ but instead $x \rightarrow \chi=x\left(1+\left(2 m_{c}\right)^{2} / Q^{2}\right)$; this rescaling is implemented in the ACOT- $\chi$ scheme, for example [ $5,6,7]$. The factor $\left(1+\left(2 m_{c}\right)^{2} / Q^{2}\right)$ represents a kinematic suppression factor which will suppress the charm process relative to the lighter quarks.

### 2.4. Numerical Comparison

Having introduced the various theoretical issues which enter the calculation of the heavy quark process, we illustrate the numerical size of these choices for the case of DIS heavy quark production.

In Figure 5 we display the charm structure function $F_{2}^{c}(x, \mu)$ for a variety of schemes and orders. LO represents the $\mathcal{O}\left(\alpha_{s}^{0}\right) Q V \rightarrow Q$ process. NLO includes the $\mathcal{O}\left(\alpha_{s}^{1}\right)$ processes (primarily $g V \rightarrow Q \bar{Q}$ ) in the massless approximation. In the Fixed-Flavor-Scheme (FFS) the heavy quark PDF is set to zero; hence, at $\mathcal{O}\left(\alpha_{s}^{1}\right)$ this only receives contributions from $g V \rightarrow Q \bar{Q}$. The ACOT and S-ACOT schemes are virtually identical-the curves are indistinguishable in this plot. Finally,

Figure 5. Calculation of DIS heavy quark production for a variety of schemes.
the implementation of the $\chi$-prescription for the S-ACOT scheme (the ACOT- $\chi$ would yield identical results) provides some additional suppression in the region $\mu \sim m_{Q}$. To this order, our best theoretical estimate of the true cross section would be either the ACOT- $\chi$ or equivalently S-ACOT- $\chi$.
To see the effect of these different results in the context of a global fit we display the results for the CTEQ6M and CTEQ6HQ PDFs sets in Table 1. Both the fits using a consistent application of the ACOT and $\overline{M S}$ schemes yield good results. In contrast, if we mismatch the scheme used in the PDF with that in the cross section calculation we observe a dramatic increase in the $\chi^{2}$ values obtained. This result underscores the importance of using properly matched calculations.

### 2.5. Heavy Quarks at the Tevatron

In the previous discussion we have primarily focused on DIS production of heavy quarks for illustrative purposes as the formalism is easier to layout when there is only a single hadron in the initial state. Nevertheless, the same principles that we have used in the the DIS case can be applied to that of the hadron-hadron initial state as appropriate for the Tevatron and the LHC.
Historically, the predictions of b-production at hadron-hadron colliders have been a challenge; the early results from the Tevatron were a factor of 2 to 3 larger than the theoretical predictions. NLO QCD corrections to the $\mathrm{LO} g g \rightarrow Q \bar{Q}$

| Set | \# points | CTEQ6HQ | CTEQ6M | 6M $\otimes$ GM | 6HQ $\otimes$ ZM |
| :---: | :---: | :---: | :---: | :---: | :---: |
| ZEUS | 104 | 0.91 | 0.98 | 2.84 | 3.72 |
| H1 | 484 | 1.02 | 1.04 | 1.50 | 1.22 |
| TOTAL | 1925 | 1.04 | 1.06 | 1.26 | 1.30 |

Table 1
Table of $\chi^{2}$ per point for the individual HERA data sets, and for the TOTAL of all data sets. (Non-HERA data sets are not displayed.) The results are shown for CTEQ6HQ PDF using the General Mass (GM) ACOT scheme, and CTEQ6M PDF using the zero-mass (ZM) $\overline{M S}$ scheme. We note the increased $\chi^{2}$ for mixed schemes using CTEQ6M with the GM ACOT scheme, and the CTEQ6HQ with the ZM scheme.
process were formidable and yielded large corrections $[8,9,10,11,12]$. It is interesting to observe that if the heavy quark PDF is taken into account so that the LO contribution consists of both $g g \rightarrow Q \bar{Q}$ and $g Q \rightarrow g Q$, then the computed NLO contributions (with appropriate subtractions) are thereby reduced suggesting improved convergence of the perturbation theory $[13,14,15,16,17,18]$.

Ref. [ 19] performs a systematic comparison of the GM-VFNS and ZM-VFNS using results of an updated analysis of hadronic b-production at the Tevatron. Figure 6 displays these results for the Tevatron in the central rapidity region as compared with the CDF data [ 20,21 ]. The result is that the finite mass effects moderately enhance the $p_{T}$ distribution in the region $p_{T} \sim 2 m_{H}$ by about $20 \%$, and this enhancement decreases at larger $p_{T}$. For intermediate to large $p_{T}$ values ( $p_{T}>m_{H}$ ) the three calculations (GM-VFNS, ZM-VFNS, FFN) match quite closely, and are in good agreement with the data. Conversely, if we use the FFN result with the historic values for the PDF and $\alpha_{S}$ we find this prediction is roughly a factor of 3 below the data.

The excellent agreement between data and theory for this process is an important achievement and represents the culmination of many years of effort by both the theoretical and experimental community.

## 3. Schemes used for Global Analysis

The ACOT scheme and variants were used for the CTEQ series of global PDF fits. ${ }^{3}$ For the MRST/MSTW series of global PDF fits the

[^111]

Figure 6. From Ref. [ 19], the transverse momentum distribution $d \sigma / d p_{T}$ for $p \bar{p} \rightarrow B X$ at $\sqrt{s}=1.96 \mathrm{TeV}$. The results are shown for the General Mass (GM) Variable Flavor Number (VFN) scheme and the Zero Mass (ZM) Variable Flavor Number (VFN) scheme. Additionally, results are shown for the Fixed Flavor Number (FFN) scheme with both recent PDFs (dot-dashed line) and the historical PDFs (dotted line). The data is from the CDF collaboration [ 20, 21].

Figure 7. Diagrammatic comparison of TR and ACOT type schemes for the case of DIS. This diagram is schematic to emphasize the similarities and differences. The leading-order (LO) process is a $\mathcal{O}\left(\alpha_{s}^{0}\right)$ boson scattering from a heavy quark, e.g. $\gamma Q \rightarrow Q$; the NLO $\mathcal{O}\left(\alpha_{S}^{1}\right)$ correction arises from $\gamma g \rightarrow Q \bar{Q}$, and the NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ correction arises from $\gamma g \rightarrow Q \bar{Q} g$.

Thorne-Roberts (TR) scheme was used. As these two sets of PDFs are widely used it is of interest to compare and contrast these approaches. Figure 7 displays a diagrammatic comparison of the TR [ 22, 23] and ACOT type schemes. While these schemes may appear quite different at first glance, they differ by higher-order terms which will be reduced as we increase the order of our perturbation theory.

In perturbation theory, we compute our observables to a fixed order $N$ in $\alpha_{S}$; hence, we truncate the perturbation expansion at $\mathcal{O}\left(\alpha_{S}^{N}\right)$, and we have neglected terms of order $\mathcal{O}\left(\alpha_{S}^{N+1}\right)$. In brief, the difference between these two approaches amounts to adding different $\mathcal{O}\left(\alpha_{S}^{N+1}\right)$ higher order terms. Thus, these two approaches will agree on the contributions up to $\mathcal{O}\left(\alpha_{S}^{N}\right)$. We will now review the motivation and consequences of adding the differing higher order terms.

### 3.1. Leading-Order (LO) $\left(\alpha_{S}^{0}\right)$

If we work at Leading-Order ${ }^{4}$ (LO) $\alpha_{S}^{0}$, when the heavy quark PDF is an "active" parton (typically $\mu>m_{H}$ ) the LO contribution is $\gamma+Q \rightarrow Q$. However, when the heavy quark PDF is not an "active" parton (typically $\mu<m_{H}$ ) the LO contribution vanishes. For the ACOT scheme, no higher order terms are added to this results. Hence for scales $\mu<m_{H}$, the LO answer is zero and we expect large corrections to this result at NLO. For the TR scheme, a portion of the $\gamma g \rightarrow Q \bar{Q}$ contribution is added; for $\mu<m_{H}$ the full $\gamma g \rightarrow Q \bar{Q}$ term is included, and for $\mu>m_{H}$ the $\gamma g \rightarrow Q \bar{Q}$ term frozen at $\mu=Q=m_{H}$ to avoid any difficulty with large logarithms of the form $\ln \left(m_{H} / \mu\right)$.

Consequently, in the $\mu<m_{H}$ region the TR

[^112]scheme yields a finite LO result while the ACOT scheme yields zero. While both schemes formally agree at $\mathcal{O}\left(\alpha_{S}^{0}\right)$, clearly the $\mathcal{O}\left(\alpha_{S}^{1}\right)$ terms can be important, particularly in the $\mu<m_{H}$ region.

### 3.2. Next-to-Leading-Order (NLO) $\left(\alpha_{S}^{1}\right)$

If we work at $\mathrm{NLO}\left(\alpha_{S}^{1}\right)$, for the low $\mu$ region we now include $\gamma g \rightarrow Q \bar{Q}$ as well as the $\gamma+Q \rightarrow Q$ process. ${ }^{5}$ If we again look in the region $\mu<m_{H}$, we find that while the ACOT scheme yielded zero at LO, it now obtains a finite result at NLO. For the TR scheme, in addition to the above terms, a portion of the $\gamma g \rightarrow g Q \bar{Q}$ contribution is added; again, for $\mu>m_{H}$ the $\gamma g \rightarrow g Q \bar{Q}$ term is frozen at $\mu=Q=m_{H}$ to avoid any difficulty with large logarithms.

As before, both the TR scheme and ACOT scheme formally agree at $\mathcal{O}\left(\alpha_{S}^{1}\right)$, but they will differ by the separate NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ terms that have been included. In contrast to the LO case where the ACOT scheme yielded zero for $\mu<m_{H}$, both schemes give finite results in all kinematic regions; hence, the relative difference will be reduced.

### 3.3. General Comparisons at Order $\alpha_{S}^{N}$

Let us make some observations regarding these schemes at a general order in perturbation $\mathcal{O}\left(\alpha_{S}^{N}\right)$. We observe that for a given set of processes calculated to $\alpha_{s}^{N}$, we can implement the TR scheme to $\mathcal{O}\left(\alpha_{S}^{N-1}\right)$ and the ACOT scheme to $\mathcal{O}\left(\alpha_{S}^{N}\right)$. For example, at NLO we note that the ACOT scheme involves only graphs of order $\alpha_{s}^{1}$ while TR utilizes graphs of order $\alpha_{s}^{2}$. At present we know the $\mathcal{O}\left(\alpha_{S}^{2}\right)$ massive neutral current process $(\gamma g \rightarrow g Q \bar{Q} ; \gamma Q \rightarrow g g Q$ and associated graphs); hence, this allows us to compute the TR scheme to $\mathcal{O}\left(\alpha_{S}^{1}\right)$ and the ACOT scheme to $\mathcal{O}\left(\alpha_{S}^{2}\right)$. In contrast, the massive charged current process is known only to $\mathcal{O}\left(\alpha_{S}^{1}\right)$; hence, this allows us to compute the TR scheme to $\mathcal{O}\left(\alpha_{S}^{0}\right)$ and the ACOT scheme to $\mathcal{O}\left(\alpha_{S}^{1}\right)$.

We note that recent improvements of theoretical techniques have enabled significant advances in the calculation higher-order heavy quark pro-

[^113]cesses. For example, Ref. [ 25] has obtained the asymptotic results for $F_{L}^{Q \bar{Q}}(x, \mu)$ at the 3-loop order, and recently Ref. [ 26] has extended this work for the case of $F_{2}^{Q \bar{Q}}(x, \mu)$.

In general, the TR scheme achieves in practice the same highest asymptotic order as ACOT by some modeling of terms below $Q^{2}=m_{Q}^{2}$ which become (relatively) unimportant at high $Q^{2}$. As we move to higher order calculations, the differences between these schemes will be reduced as they arise from uncalculated higher-order contributions.

## 4. NNLO and Beyond

Although NLO is the state-of-the-art for many calculations, improved experimental precision demands that we strive toward a NNLO accuracy. When we consider PDFs for heavy quarks at NNLO, there are a number of new elements that enter.

One consequence is that the PDFs are no longer continuous across the heavy flavor threshold. Even more, when matching charm and bottom across their thresholds, they start from negative values as illustrated in Figure 8. The matching conditions have been computed by a number of groups [ 27, 28], and at NNLO PDFs will have

Figure 8. The b-quark PDF $x f_{b}(x, Q)$ with NNLO matching conditions for 3 choices of $x$.
discontinuities of order $\mathcal{O}\left(\alpha_{S}^{2}\right)$ when we transition from $N_{F}$ to $N_{F}+1$ flavors. While we may be uncomfortable with discontinuities in our PDFs, we are reminded that the PDFs are not physical observables, but instead are only theoretical constructs which depend on (arbitrary) renormalization schemes and scales. ${ }^{6}$

At NLO, the point $\mu=m_{Q}$ is special because $f_{a}^{N_{F}}\left(x, m_{Q}\right)=f_{a}^{N_{F}+1}\left(x, m_{Q}\right)$; this is because the constant term in the matching equation happens to be zero at NLO. Because of this "accident" it was common to use $\mu=m_{Q}$ as both the Matching Point and the Transition Point.

At NNLO the point $\mu=m_{Q}$ no longer has these special properties as the transition from $N_{F}$ to $N_{F}+1$ will necessarily have discontinuities at any value of $\mu$; hence, it may be desirable to choose the Matching Point and the Transition Point at different values of $\mu$. As these two point are not usually distinguished, let us highlight their key features.

Matching Point $\mu_{M}$ : The value of $\mu$ where the $N_{F}+1$ scheme is defined in terms of the $N_{F}$ scheme by a relation of the form: $f_{a}^{N_{F}+1}(x, \mu)=A_{a b} \otimes f_{b}^{N_{F}}(x, \mu)$.
Transition Point $\mu_{T}$ : The value of $\mu$ where the user chooses to transition from the $N_{F}$ scheme to the $N_{F}+1$ scheme.

Figure 9 schematically represents how each calculation with a set number of flavors $N_{F}$ has a particular region of applicability where it is best suited to describe the "true" physics. The complete description of the physics throughout the full kinematic range will therefore consist of a patchwork of schemes which are "sewn together."

The Transition Point: It is easy to imagine situations where we would not want to automatically transition between schemes at $\mu=m_{Q}$. For example, consider we are analyzing data in the range $\mu \in[2,5] \mathrm{GeV}$. The bulk of the range is in the $N_{F}=4$ flavor region as $\mu>m_{c} \sim 1.3 \mathrm{GeV}$,

[^114]

Figure 9. The upper figure schematically represents how each calculation with a set number of flavors $N_{F}$ has a region of applicability. The transition from the $N_{F}-1$ scheme to the $N_{F}$ scheme should be in the vicinity of the $m_{N_{F}}$ mass, but need not occur exactly at $\mu=m_{N_{F}}$. The lower figure illustrates that multiple PDFs can coexist for $\mu \geq m_{N_{F}}$ with matching performed at $\mu=m_{N_{F}}$.
but a small portion of the range extends above the $N_{F}=5$ flavor region as $\mu>m_{b} \sim 4.5 \mathrm{GeV}$. In the region $\mu \in[4.5,5] \mathrm{GeV}$ it would be inconvenient to be forced to transition to a $N_{F}=5$ scheme because 1) the b-quark clearly plays no substantive role in this kinematic range, and 2) both the PDFs and $\alpha_{s}(\mu)$ will have discontinuities at $\mu=m_{b}$.

Clearly it is more reasonable to have the option to work consistently in a $N_{F}=4$ flavor scheme even for $\mu \gtrsim m_{b}$. If PDFs were generated such that the $N_{F}=4$ and $N_{F}=5$ schemes co-exist in the region $\mu \sim m_{b}$, then the user could select $N_{F}$ by choice.
The lower portion of Figure 9 illustrates how this might be implemented. The PDFs can be generated such that the $N_{F}$ scheme is available for all $\mu \geq m_{N_{F}}$. Thus, for $\mu=5 \mathrm{GeV}$ the user
would have access to schemes with $N_{F}=\{3,4,5\}$ and can select the scheme by specifying $N_{F}$ in addition to $\{x, \mu\}$. Therefore, the user could analyze their $\mu \in[2,5] \mathrm{GeV}$ data set consistently in a single $N_{F}=4$ scheme, and choose to transition to the $N_{F}=5$ scheme at a higher $\mu$ value to be specified by the user.

The Matching Point: Although the Matching Point can be set to any $\mu$ value in the region of $m_{N_{F}}$, we shall argue that the choice $\mu_{M}=m_{N_{F}}$ is optimal.

First, we note that the Matching Point should be at or below the Transition Point $\left(\mu_{T} \geq \mu_{M}\right)$ if we desire to avoid downward DGLAP evolution (which can be unstable). Therefore, if we perform the matching at the heavy quark mass we have the reasonable constraint: $\mu_{T} \geq \mu_{M}=m_{N_{F}}$.

Second, the matching conditions which define $f_{a}^{N_{F}+1}$ in terms of $f_{a}^{N_{F}}$ are of the form $f_{a}^{N_{F}+1}=$ $A_{a b} \otimes f_{b}^{N_{F}}$ with
$A_{a b}=\delta_{a b}+\frac{\alpha_{s}}{2 \pi} P_{b \rightarrow a}\left[\ln \left(\frac{\mu^{2}}{m_{Q}^{2}}\right)+c_{b \rightarrow a}\right]$
up to $O\left(\alpha_{s}^{2}\right)$. Here, $P_{b \rightarrow a}$ is the DGLAP splitting kernel and $c_{b \rightarrow a}$ is a constant. ${ }^{7}$ The choice $\mu_{M}=m_{N_{F}}$ eliminates the logarithmic terms thus simplifying the calculation.

We also observe that shifting the Matching Point from $m_{Q}$ to $2 m_{Q}$ does not suppress the heavy quark PDF as the logarithmic terms compensate for evolution between $m_{Q}$ and $2 m_{Q}$.

## 5. Conclusions:

The computation of heavy quark production has historically been challenging both theoretically and experimentally. On the theoretical side, the heavy quark introduces an additional mass scale which complicates the calculations. On the experimental side, the data for heavy quark production has typically differed from the theoretical

[^115]predictions by a significant factor. Recent theoretical developments enable us to incorporate the heavy quark mass into the calculation both dynamically and kinematically. These calculations have been used to produce matched PDFs incorporating the full mass dependence. Updated analyses show improved agreement between data and theory for both HERA and Tevatron measurements.
Improved experimental precision will demand NNLO accuracy from the theoretical calculations, and this introduces a number of issues not present at the NLO order. There is progress underway on both the PDFs and the hard-scattering calculations, and this should ensure we are well prepared for the upcoming LHC data.
Acknowledgments: We would like to thank John Collins, Gustav Kramer, Stefan Kretzer, Pavel Nadolsky, M.H. Reno, Davison Soper, Robert Thorne, Wu-Ki Tung, Ji Young Yu, for valuable discussion. F.I.O. acknowledges the hospitality of CERN, DESY, and the Université Joseph Fourier, Grenoble where a portion of this work was performed. #### Abstract

The 2011 Les Houches workshop was the first to confront LHC data. In the two years since the previous workshop there have been significant advances in both soft and hard QCD, particularly in the areas of multi-leg NLO calculations, the inclusion of those NLO calculations into parton shower Monte Carlos, and the tuning of the non-perturbative parameters of those Monte Carlos. These proceedings describe the theoretical advances that have taken place, the impact of the early LHC data, and the areas for future development.

Report of the SM and NLO Multileg and SM MC Working Groups for the Workshop "Physics at TeV Colliders", Les Houches, France, 31 May-8 June, 2011.

## Part I

## INTRODUCTION

The workshop in 2011 was the first for which the long-awaited LHC data (at 7 TeV ) was available for analysis and comparison to theory. Even though of limited statistical power compared to the ultimate goals of the LHC, this data accesses a very wide kinematic range, and probes regions where multiple scales are important. The presence of large scales for some processes, on the TeV level, points to the importance of electroweak corrections, which have been calculated only for some of the important processes. The first hints of a Higgs boson have now been observed. In order to search for signs of New Physics, as well as to completely understand the Standard Model at the LHC, it is important to understand the perturbative framework at the LHC. The data taken so far provides many challenges for perturbative QCD predictions; and it is clear that New Physics, if it is present in current data, is hiding well.

On the theoretical side, there has been a great deal of productivity in the area of multi-particle calculations at next-to-leading order (NLO) and next-to-next-to-leading order (NNLO). NLO is the first order at which the normalization, and in some cases the shape, of perturbative cross sections can be considered reliable [1]. A full understanding for both Standard Model and beyond the Standard Model physics at the LHC requires the development of fast, reliable programs for the calculation of multi-parton final states at NLO. There have been many advances in the development of NLO techniques, especially in the area of automation $[2,3,4,5,6,7,8,9,10,11,12]$.

Some of these approaches also allow for relatively easy [13, 14, 12] and/or automatic [15] inclusion of the NLO matrix elements into parton shower Monte Carlo programs. For more details we refer to the individual contributions in these proceedings.

A prioritized list of NLO (and some NNLO) cross sections was assembled at Les Houches in 2005 [16] and added to in 2007 [17] and 2009 [18]. This list includes cross sections which are experimentally important, and which are theoretically feasible (if difficult) to calculate. As we stand now, basically all NLO $2 \rightarrow 3$ and $2 \rightarrow 4$ cross sections of interest have been calculated, see Tables 12 below, and even some processes which were not on the 2009 wishlist are available at NLO, see e.g. [19, 20, 21, 22, 23, 24, 25]. The success of automation techniques means that future NLO calculations of similar complexity can be completed without the man-years of labor previously required. Thus, we do not add to the NLO wish list in 2011. Instead, we comment on calculations needed at NNLO, and processes at NLO for which it is important to calculate the impact of electroweak corrections, and/or the
influence of interference effects with other processes with the same final state.
For many of the processes calculated at the LHC (such as for Higgs production), it is important either to apply a veto for the production of extra jets, or to bin the analysis results according to the jet multiplicity. While such cuts are useful for dealing with the experimental backgrounds, the exclusivity of the cross sections results in increases to the theoretical uncertainties obtained for the corresponding inclusive results, see e.g. [26]. The impact of such cuts is explored in the contribution of Stewart and Tackmann in these proceedings.

Much of the complexity for multi-parton NLO processes consists of the calculation of the nonleading color contributions. Such contributions typically contribute only at the level of a few percent and approximations to the non-leading color contributions should be accurate within a percent or so [70, 71, [51]. So it may be more time-prudent for groups carrying out such calculations to estimate the non-leading color effects before carrying out the full calculation.

To reach full utility, the codes for any of these complex NLO calculations should be made public and/or the authors should generate ROOT ntuples providing the parton level event information from which experimentalists can assemble any cross sections of interest. Where possible, decays (with spin correlations) should be included. A ROOT output option is especially useful where the creation of a user-friendly NLO program may be very time-consuming. We now have some experience with the use of ROOT ntuples with both MCFM and Blackhat+Sherpa calculations. The latter, in particular, does not exist as a public program, while ROOT tuples have been made available for NLO W/Z +n jet multiplicities (with $n$ up to 4 ) for $W / Z+$ jets, and (also for $n$ up to 4 ) for inclusive jet production. The estimation of the correct scale for use in multi-parton NLO calculations, and the proper evaluation of the uncertainty on this scale, is more complex than for simpler calculations. The use of ROOT ntuples can make these evaluations easier to carry out. A contribution describing their use has been included in these proceedings.

While NLO is sufficient for most predictions, it is also crucial to understand certain critical cross sections at NNLO. To date, NNLO calculations have been carried out primarily for processes in $e^{+} e^{-}$ annihilation [72, 73, 74], and in hadronic collisions for $2 \rightarrow 1$ processes, with the exception of VH [75, 76, 77] and $\gamma \gamma$ production [78].

To calculate a $2 \rightarrow 2$ scattering process at NNLO, the divergent contributions arising from the treelevel $2 \rightarrow 4$, the one-loop $2 \rightarrow 3$ and the two-loop $2 \rightarrow 2$ subprocesses have to be properly subtracted and cancelled, such that the finite remainders can be combined into a parton-level event generator. To combine the three contributions, an infra-red subtraction scheme for unresolved real radiation is required. Several approaches have been used and are being further developed: antenna subtraction [79], which currently is extended to hadronic and semi-hadronic initial states [80, 81, 82, 83, 84], a method based on sector decomposition appplied to real radiation [85, 86, 87] where the decomposition is guided by the physical singularity structure [88, 89], $q_{T}$-subtraction [90], which is very elegant but appplicable only to colourless final states, and the one of [91] described in these proceedings.

Further, two-loop amplitudes are interesting in their own right from a field theory point of view, for example to study asymptotic behaviour, or to gain insights into the all-order infared structure of massless field theories.

Below we construct a table of calculations needed at the LHC, and which are feasible within the next few years. Certainly, results for inclusive cross sections at NNLO will be easier to achieve than differential distributions, but most groups are working towards a partonic Monte Carlo program capable of producing fully differential distributions for measured observables.

- $t \bar{t}$ production:
needed for accurate background estimates, top mass measurement, top quark asymmetry (which is zero at tree level, so NLO is the leading non-vanishing order for this observable, and a discrepancy of theory predictions with Tevatron data needs to be understood). Several groups are already well

Table 1: The updated experimenter's wishlist for LHC processes

| Calculations beyond NLO added in 2007 |  |
| :--- | :--- |
| 13. $g g \rightarrow W^{*} W^{*} \mathcal{O}\left(\alpha^{2} \alpha_{s}^{3}\right)$ | backgrounds to Higgs |
| normalization of a benchmark process |  |
| 14. NNLO $p p \rightarrow t \bar{t}$ |  |
| 15. NNLO to VBF and $Z / \gamma+$ jet |  |
| Calculations including electroweak effects |  |
| 16. NNLO QCD+NLO EW for $W / Z$ | precision calculation of a SM benchmark |
| NLO EW to $W / Z$ | $[65,66$ |
| NLO EW to $W / Z+$ jet |  |
| NLO EW to $W H / Z H$ | $[67,6]$ |
| $[69]$ |  |

Table 2: The updated experimenter's wishlist for LHC processes continued
on the way to complete NNLO results for $t \bar{t}$ production [92, 93, 94, 95].

- $W^{+} W^{-}$production:
importand background to Higgs search. At the LHC, $g g \rightarrow W W$ is the dominant subprocess, but $g g \rightarrow W W$ is a loop-induced process, such that two loops need to be calculated to get a reliable estimate of the cross section. Advances towards the full two-loop result are reported in [96, 97].
- inclusive jet/dijet production:

NNLO parton distribution function (PDF) fits are starting to become the norm for predictions and comparisons at the LHC. Paramount in these global fits is the use of inclusive jet production to tie down the behavior of the gluon distribution, especially at high $x$. However, while the other essential processes used in the global fitting are known to NNLO, the inclusive jet production cross section is only known at NLO. Thus, it is crucial for precision predictions for the LHC for the NNLO corrections for this process to be calculated, and to be available for inclusion in the global PDF fits. First results for the real-virtual and double real corrections to gluon scattering can be found in [98, 99].

- $\mathrm{V}+1$ jet production:
$W / Z / \gamma+$ jet production form the signal channels (and backgrounds) for many key physics processes, for both SM and BSM. In addition, they also serve as calibration tools for the jet energy scale and for the crucial understanding of the missing transverse energy resolution. The two-loop amplitudes for this process are known [100, 101], therefore it can be calculated once the parts involving unresolved real radiation are available.
- $\mathrm{V}+\gamma$ production:
important signal/background processes for Higgs and New Physics searches. The two-loop helicity amplitudes for $q \bar{q} \rightarrow W^{ \pm} \gamma$ and $q \bar{q} \rightarrow Z^{0} \gamma$ recently have become available [102].
- Higgs+1 jet production:

As mentioned previously, events in many of the experimental Higgs analyses are separated by the number of additional jets accompanying the Higgs boson. In many searches, the Higgs +0 jet and Higgs +1 jet bins contribute approximately equally to the sensitivity. It is thus necessary to have the same theoretical accuracy for the Higgs +1 jet cross section as already exists for the inclusive Higgs cross section, i.e. NNLO. The two-Loop QCD Corrections to the Helicity Amplitudes for $H \rightarrow 3$ partons are already available [103].

The contributions in this document are arranged as follows. In section II various developments concerning techniques for NLO and NNLO calculations are described, in particular in view of providing
automated tools for NLO corrections. In section III, issues related to parton distribution functions are discussed. Section IV contains phenomenological studies of observables and uncertainties, based on theory input where higher order corrections obtained by different approaches are available. Section V includes phenomenological studies on the definition of experimental observables and corrections applied to data. Finally Section VI discusses issues related to the tuning of Monte Carlos and standardised Monte Carlo output formats.

## Part II

## NLO AUTOMATION AND (N)NLO TECHNIQUES

## 1. PJFRY - A C++ PACKAGE FOR TENSOR REDUCTION OF ONE-LOOP FEYNMAN INTEGRALS ${ }^{1}$

#### Abstract

The C++ package PJFry 1.0.0 [104, 105] - a one loop tensor integral library is introduced. We use an algebraic approach to tensor reduction. As a result, the tensor integrals are presented in terms of scalar one- to four-point functions, which have to be provided by an external library, e.g. QCDLoop/FF or OneLOop or LoopTools/FF. The reduction is implemented until five-point functions of rank five. A numerical example is shown, including a special treatment for small or vanishing inverse four-point Gram determinants. Future modules of PJFry might cover the treatment of $n$-point functions with $n \geq 6$; the corresponding formulae are worked out. Further, an extremely efficient approach to tensor reduction relies on evaluations of complete contractions of the tensor integrals with external momenta. For this, we worked out an algorithm for the analytical evaluation of sums over products of signed minors with scalar products of chords, i.e. differences of external momenta. As a result, the usual multiple sums over tensor coefficients are replaced for the numerical evaluation by compact combinations of the basic scalar functions.

### 1.1 PJFry

The goal of the C++ package PJFry is a stable and fast open-source implementation of one-loop tensor reduction of Feynman integrals

$$
\begin{equation*}
I_{n}^{\mu_{1} \cdots \mu_{R}}=C(\epsilon) \int \frac{d^{d} k}{i \pi^{d / 2}} \frac{\prod_{r=1}^{R} k^{\mu_{r}}}{\prod_{j=1}^{n}\left(k-q_{j}\right)^{2}-m_{j}^{2}+i \epsilon}, \tag{1}
\end{equation*}
$$

suitable for any physically relevant kinematics ${ }^{2}$ The algorithm was invented in [105]. PJFry performs the reduction of 5 -point 1 -loop tensor integrals up to rank 5 . The 4 - and 3 -point tensor integrals are obtained as a by-product. Main features are:

- Any combination of internal or external masses
- Automatic selection of optimal formula for each coefficient
- Leading ()$_{5}$ are eliminated in the reduction

[^116]- Small ()$_{4}$ are avoided using asymptotic expansions where appropriate
- Cache system for tensor coefficients and signed minors
- Interfaces for C, C++, FORTRAN and Mathematica
- Uses QCDLoop [109, 110] or OneLOop [111] for 4-dim scalar integrals
- Available from the project webpage https://github.com/Vayu/PJFry/ [104, 105]

The installation of PJFry may be performed following the instructions given at the project webpage. The project subdirectories are ./src - the library source code ./mlink - the MathLink interface
./examples - the FORTRAN examples of library use, built with make check
A build on Unix/Linux and similar systems is done in a standard way by sequential performing ./configure, make, make install. See the INSTALL file for a detailed description of the ./configure options.

The functions for tensor coefficients for up to rank $R=5$ pentagon integrals are declared in the Mathematica interface:

```
In:= Names["PJFry`*"]
Out={A0v0, B0v0, B0v1, B0v2, C0v0, C0v1, C0v2, C0v3, \
D0v0, D0v1, D0v2, D0v3, D0v4, E0v0, E0v1, E0v2, \
EOv3, EOv4, EOv5, GetMu2, SetMu2}
```

The C++ and Fortran interface syntax is very close to that of e.g. LoopTools/FF:
E0v3[i,j,k,p1s,p2s,p3s,p4s,p5s,s12,s23,s34,s45,s15,m1s,m2s,m3s,m4s,m5s,ep=0]
where 3
i, $\mathrm{j}, \mathrm{k}$ are indices of the tensor coefficient $(0<i \leq j \leq k<n)$,
$\mathrm{p} 1 \mathrm{~s}, \mathrm{p} 2 \mathrm{~s}, \ldots$ are squared external masses $p_{i}^{2}$,
s12, s23, ... are Mandelstam invariants $\left(p_{i}+p_{j}\right)^{2}$,
$\mathrm{m} 1 \mathrm{~s}, \mathrm{~m} 2 \mathrm{~s}, \ldots$ are squared internal masses $m_{i}^{2}$,
$\mathrm{ep}=0,-1,-2$ selects the coefficient of the $\epsilon$-expansion.
The average evaluation time per phase-space point on a 2 GHz Core 2 laptop for the evaluation of all 81 rank 5 tensor form-factors amounts to 2 ms .

A numerical example is shown, for a configuration as in figure 1, in figures 2 and 3 for a five-point rank $R=4$ tensor coefficient in a region, where one of the 4-point sub-Gram determinants vanishes [at $x=0]$ :
$E_{3333}\left(0,0,-6 \times 10^{4}(x+1), 0,0,10^{4},-3.5 \times 10^{4}, 2 \times 10^{4},-4 \times 10^{4}, 1.5 \times 10^{4}, 0,6550,0,0,8315\right)$
The red curve is produced with standard PJFry, and the blue one with Passarino-Veltman [PV] reduction [112]; we mention that for the case treated here $(x \rightarrow 0)$, the PV reduction is no standard option. Our expansion in terms of higher dimensional scalar 3-point functions in case of vanishing 4-point subGram determinants uses only functions $I_{3}^{d+2 l}$ [105]. These are tensor coefficients of the pure $g^{\mu \nu}$ type [113], and so our method is different from others with a mixed numerical approach [114] or with use of additional tensor coefficients [115].

Tensor reduction by PJFry is used as one option of the GoSam package [12]. An older version of the algorithm, as described in [116], has been implemented independently in [11].

[^117]

Fig. 1: Momenta definitions for PJFry.

### 1.2 POTENTIAL UPGRADES

### 1.21 Tensor reduction for higher-point functions

So far, PJFry is foreseen for 5-point functions and simpler ones. The extension to 6-point functions is known from e.g. [114, 115, [116]. In [107] we solve analytically generalized recursions for $n \geq 6$, derived in [114]:

$$
\begin{equation*}
I_{n}^{\mu_{1} \mu_{2} \ldots \mu_{R}}=-\sum_{r=1}^{n} C_{r}^{\mu_{1}}(n) I_{n-1}^{\mu_{2} \cdots \mu_{R}, r} \tag{2}
\end{equation*}
$$

where in $I_{n-1}^{\mu, \cdots, r}$ the line $r$ is scratched. The coefficients for 6-point functions are:

$$
\begin{equation*}
C_{r}^{s, \mu}(6)=\sum_{i=1}^{5} \frac{1}{\binom{0}{s}_{6}}\binom{0 r}{s i}_{6} q_{i}^{\mu_{1}}, s=0 \ldots 6, \tag{3}
\end{equation*}
$$

where the $q_{i}$ are chords, and $\binom{0 r}{s i}_{6}$ etc. are signed minors with arbitrary $s$. For the 7-point and 8-point functions, we found several representations, among them

$$
\begin{equation*}
C_{r}^{s t, \mu}(7)=\sum_{i=1}^{6} \frac{1}{\binom{(t)^{2}}{s t}_{7}}\binom{s t i}{s t r}_{7} q_{i}^{\mu} \tag{4}
\end{equation*}
$$

and

$$
\begin{equation*}
C_{r}^{s t u, \mu}(8)=\sum_{i=1}^{7} \frac{1}{\binom{s t u}{s t u}_{8}}\binom{\text { stui }}{\text { stur }}_{8} q_{i}^{\mu} \tag{5}
\end{equation*}
$$

The upper indices $s, t$ and $u$ stand for the redundancy of the solutions and can be freely chosen.

### 1.22 Evaluation of contracted tensor integrals using sums over signed minors

The contraction of a tensor integral with chords may be written as a sum over basic scalar integrals (at a stage where they are free of tensor coefficient indices), multiplied by (multiple) sums over chords times

Fig. 2: Absolute accuracy of $E_{3333}$ in the region of vanishing sub-Gram determinant. Blue curve: conventional Passarino-Veltman reduction, red curve: PJFry.
signed minors. If one may perform these sums algebraically, the method becomes very efficient. And this has been systematically worked out in [106], see also [108].

We reproduce here two 7-point examples.
The rank $R=2,3$ integrals become by contraction

$$
\begin{align*}
q_{a, \mu} q_{b, \nu} I_{7}^{\mu \nu} & =\sum_{r, t=1}^{7} K^{a b, r t} I_{5}^{r t},  \tag{6}\\
q_{a, \mu} q_{b, \nu} q_{c, \lambda} I_{7}^{\mu \nu \lambda} & =\sum_{r, t, u=1}^{7} K^{a b c, r t u} I_{4}^{r t u}, \tag{7}
\end{align*}
$$

where $I_{5}^{r t}$ and $I_{4}^{r t u}$ are scalar 5- and 4-point functions, arising from the 7-point function by scratching lines $r, t, \ldots$ In the general case, we have at this stage higher-dimensional integrals $I_{n}^{d+2 l}, n=2, \ldots, 5$, to be further reduced following the known scheme, if needed. Here, the $I_{5}^{r t}$ have to be expressed by 4 -point functions.

The expansion coefficients are factorizing here,

$$
\begin{align*}
K^{a b, r t} & =K^{a, r} K^{b, r t},  \tag{8}\\
K^{a b c, r t u} & =-K^{a, r} K^{b, r t} K^{c, r t u} \tag{9}
\end{align*}
$$

and the sums over signed minors have been performed analytically:

$$
\begin{gather*}
K^{a, r}=\frac{1}{2}\left(\delta_{a r}-\delta_{7 r}\right),  \tag{10}\\
K^{b, r t}=\sum_{j=1}^{6}\left(q_{b} q_{j}\right) \frac{\left(\begin{array}{c}
r s t \\
r s)_{7}
\end{array}\right.}{\binom{r s}{r s}_{7}} \equiv \frac{\Sigma_{b}^{1, s t u}}{\binom{r s}{r s}_{7}}=\frac{1}{2}\left(\delta_{b t}-\delta_{7 t}\right)-\frac{1}{2} \frac{\binom{r s}{t s}_{7}}{\binom{r s}{r s}}\left(\delta_{b r}-\delta_{7 r}\right), \tag{11}
\end{gather*}
$$

Fig. 3: Relative accuracy of $E_{3333}$ in the region of vanishing sub-Gram determinant. At $x \sim 0.0015$, PJFry switched to the asymptotic expansion.

$$
\begin{align*}
K^{a, s t u} & =\sum_{i=1}^{6}\left(q_{a} q_{i}\right)\binom{0 s t u}{0 s t i}_{7} \equiv \Sigma_{a}^{2, s t u}  \tag{12}\\
& =\frac{1}{2}\left\{\binom{s t u}{s t 0}_{7}\left(Y_{a 7}-Y_{77}\right)+\binom{0 s t}{0 s t}_{7}\left(\delta_{a u}-\delta_{7 u}\right)-\binom{0 s t}{0 s u}_{7}\left(\delta_{a t}-\delta_{7 t}\right)-\binom{0 t s}{0 t u}_{7}\left(\delta_{a s}-\delta_{7 s}\right)\right\}
\end{align*}
$$

with

$$
\begin{equation*}
Y_{j k}=-\left(q_{j}-q_{k}\right)^{2}+m_{j}^{2}+m_{k}^{2} \tag{13}
\end{equation*}
$$

Conventionally, $q_{7}=0$.
The sums may be found in eqns. (A.15) and (A.16) of [106]. The $s$ is redundant and fulfils $s \neq r, b, 7$ in $K^{b, r t}$. In $K_{0}^{a, s t u}$ it is $s, t, u=1, \ldots 7$ with $s \neq u, t \neq u$.

## 2. THE GOSAM APPROACH TO AUTOMATED ONE-LOOP CALCULATIONS ${ }^{4}$

#### Abstract

We describe the GoSAM framework for the automated computation of multiparticle scattering amplitudes at the one-loop level. The amplitudes are generated explicitly in terms of Feynman diagrams, and can be evaluated using either $d$-dimensional reduction at the integrand level or tensor decomposition. GoSAM can be used to compute one-loop QCD and EW corrections to Standard Model processes, and it is ready to link generic model files for theories Beyond the Standard Model.

[^118]
### 2.1 Introduction and General Motivations

In the last few years we observed major advances in the direction of constructing packages for fully automated one-loop calculations, which profited from the new developments in the field of NLO QCD calculations [17, 18]. The continuous improvement of the techniques for one-loop computations led to important new results for processes with many particles [51, 70, 117, 71, 53, 48, 49, 50, 54, 62, 63, 23, 118, 25, 56, 57, 21, 22, 20, 19].

Very advanced calculations have been performed with improved algebraic reduction methods based on Feynman-diagrammatic algorithms, as well as with new numerical techniques based on the idea of reconstructing one-loop amplitudes from their unitarity cuts. These theoretical developments found an ideal counterpart in the integrand-level reduction algorithm, that allows for the reduction of any scattering amplitudes to scalar master integrals, simply by evaluating numerically the integrand at given fixed values of the integration momentum. In both scenarios, to tackle the increase in the complexity and in the number of diagrams that contribute to the amplitudes, automation becomes indispensable for processes with many external legs.

The purpose of the present document is to illustrate the main features of GoSam [12], a new framework which allows the automated calculation of one-loop scattering amplitudes for multi-particle processes. This approach combines the automated algebraic generation of $d$-dimensional unintegrated amplitudes obtained via Feynman diagrams, with the numerical integrand-level reduction provided by the $d$-dimensional extension [119, 120, 6] of the OPP integrand-level reduction method [121, 122, 123] and improved tensorial techniques [124, 125].

The integrands of the one-loop amplitudes are generated via Feynman diagrams, using QGRAF [126], FORM [127], spinney [128] and haggies [129]. The only task required from the user is the preparation of an "input card" to start the generation of the source code and its compilation, without having to worry about internal details of the code generation. The individual program tasks are efficiently managed by python scripts. Concerning the reduction, the program offers the possibility to use either the $d$-dimensional extension of the OPP method, as implemented in SAMURAI [6], or tensor reduction as implemented in Golem95C [130, 131] interfaced through tensorial reconstruction at the integrand level [124].

### 2.2 Algebraic approach to Automation

There are several approaches to the automated computation of multi-particle scattering amplitudes at the one-loop level, which provide different recipes for the construction of multi-purpose tools. The goal of such tools is the evaluation of one-loop scattering amplitudes for any choice of particles in the initial and final states, in a fully automated manner.

In the algebraic approach to multi-purpose automation, amplitudes can be generated from Feynman diagrams by employing tools for algebraic manipulation: already some time ago, the idea of automating NLO calculations has been pursued by public programs like FeynArts [132] and QGRAF [126] for diagram generation and FormCalc/LoopTools [133] and GRACE [3] for the automated calculation of NLO corrections, primarily in the electroweak sector.

When we combine the algebraic generation with the integrand-level reduction, the set of algebraic operations required are quite different with respect to a traditional tensorial reduction. Since the target is to provide the numerical value of the numerator function at given values of integration momentum, we should aim at expressions for the unintegrated numerator that are easily evaluated numerically. To achieve this task, for example, expressions in terms of spinor products are particularly convenient.

We briefly list here some of the advantages of the "algebraic approach": i) the algebraic generation is executed separately from the numerical reduction, therefore algebraic manipulations are possible before starting the numerical integration; CPU-time can be spent, once for all at the beginning of the calculation, to optimize and reduce the size of the integrands that will be evaluated numerically several times
later on during the reduction; ii) the algebraic method allows us to group sets of diagrams and cache all factors that do not depend on the integration momentum; iii) easy access to sub-parts of the computation; subsets of diagrams can be easily added or removed from the final results, simplifying comparisons and tests; iv) computer algebra can be performed in dimension $d$ using alternative regularization schemes; v) the choice between different reduction algorithms can be performed at run-time, providing flexibility and internal cross-checks. In the next section we will briefly illustrate how these properties are used within GoSAM.

Important progress in a similar direction has been also recently achieved by means of FeynArts, FormCalc and LoopTools [134, 2] to provide amplitudes that can be processed using the integrand-level reduction provided by CutTools [135] and/or SAMURAI [6] or with the traditional Passarino-Veltman reduction [112].

### 2.3 A brief introduction to GoSAM

GoSAM produces in a fully automated way all the code required to perform the calculation of virtual one-loop amplitudes. The only task left to the user is the preparation of an "input card" which contains all the information related to the particular process namely initial and final particles, model, helicities, selection rules to exclude particular sets of diagrams, regularization scheme. The card also contains flags to select the preferred reduction methods and some optimization flags to adapt the diagram generation to the needs of the user.

There are three main steps that GoSAM follows in order to prepare the code for the calculation: the generation of diagrams that contribute to the process, the optimization and algebraic manipulation to simplify their expressions, and the writing of a FORTRAN code ready to be used within a phase-space integration. It is important to remember that these steps will only be performed once. After the code is generated, the reduction of unintegrated amplitudes to linear combinations of scalar (master) integrals is fully embedded in the process and can be performed with different options, all available at run-time. Only the last part, namely the reduction and evaluation of master integrals, will be repeated for all the different phase-space points that contribute to the cross-section.

### 2.31 Diagram Generation

For the diagram generation both at tree level and one-loop level we employ QGRAF [126] which we complemented by adding another filter over diagrams implemented in Python. This gives several advantages since it increases the ability of the code to distinguish certain classes of diagrams and group them according to the sets of their propagators, in order to fully optimize the reduction.

At this stage GoSAm generates three sets of output files: an expression for each diagram for FORM [127], Python code for drawing each diagram, and Python code for computing the properties of the diagram. Information about the model is either read from the built-in Standard Model of QGRAF or can be defined by the user by means of LanHEP [136] or an Universal FeynRules Output (UFO) file [137]

The Python program automatically performs several operations: diagrams whose color factor turns out to be zero are dropped; the number of propagators containing the loop momentum, the tensor rank and the kinematic invariants of the associated loop integral are computed; diagrams with a vanishing loop integral associated are detected and flagged for the diagram selection; all propagators and vertices are classified for the diagram selection; diagrams containing massive quark self-energy insertions or closed massless quark loops are specially flagged.

During this phase, GoSAM also generates a ETEX file which contains, among other useful information of the generated process, the drawings of all contributing diagrams. To achieve this task, we use our own implementation of the algorithms described in Ref. [138] and Axodraw [139] to actually draw the diagrams.

### 2.32 Lorentz Algebra

Concerning the algebraic operations performed by GoSAM to render the integral suitable for efficient numerical evaluation, one of the primary goals is to split the $(4-2 \varepsilon)$ dimensional algebra into strictly four-dimensional objects and symbols representing the higher-dimensional remainder. All external vectors (momenta and polarisation vectors) are kept in four dimensions; internal vectors, however, are kept in the $d$-dimensional vector space.

We adopt the conventions used in [128], where $\hat{k}$ denotes the four dimensional projection of an in general $d$ dimensional vector $k$. The $(d-4)$ dimensional orthogonal projection is denoted as $\tilde{k}$. For the integration momentum $q$ we introduce in addition the symbol $\mu^{2}=-\tilde{q}^{2}$, such that

$$
\begin{equation*}
q^{2}=\hat{q}^{2}+\tilde{q}^{2}=\hat{q}^{2}-\mu^{2} . \tag{14}
\end{equation*}
$$

We also introduce suitable projectors by splitting the metric tensor

$$
\begin{equation*}
g^{\mu \nu}=\hat{g}^{\mu \nu}+\tilde{g}^{\mu \nu}, \quad \hat{g}^{\mu \nu} \tilde{g}_{\nu \rho}=0, \quad \hat{g}_{\mu}^{\mu}=4, \quad \tilde{g}_{\mu}^{\mu}=d-4 \tag{15}
\end{equation*}
$$

Once all propagators and all vertices have been replaced by their corresponding expressions, according to the model file, all vector-like quantities and metric tensors are split into their four-dimensional and their orthogonal part. As we use the 't Hooft algebra, $\gamma_{5}$ is defined as a purely four-dimensional object, $\gamma_{5}=i \epsilon_{\mu \nu \rho \sigma} \hat{\gamma}^{\mu} \hat{\gamma}^{\nu} \hat{\gamma}^{\rho} \hat{\gamma}^{\sigma}$. By applying the usual anti-commutation relation for Dirac matrices we can always separate the four-dimensional and $(d-4)$-dimensional parts of Dirac traces.

While the $(d-4)$-dimensional traces are reduced completely to products of $(d-4)$-dimensional metric tensors, the four-dimensional part, which will be reduced numerically, is treated such that the number of terms in the resulting expression is kept as small as possible.

### 2.33 Treatment of rational terms $R_{2}$

Instead of relying on the construction of $R_{2}$ from specialized Feynman rules [123, 140, 141, 142, 143], we can generate the $R_{2}$ part along with all other contribution using automated algebraic manipulations. The code offers the option between the implicit and explicit construction of the $R_{2}$ terms. The implicit construction treats the $4-$ and $(d-4)$ dimensional numerators on equal grounds: they are generated algebraically and reduced numerically. The explicit construction of $R_{2}$ is based on the fact that the $(d-4)$ dimensional part of the numerator function contains expressions for the corresponding integrals that are relatively simple and known explicitly. Therefore, after separating it using the algebraic manipulation described before, the $(d-4)$ dimensional part is computed analytically whereas the purely four-dimensional part is passed to the numerical reduction. This approach also allows for an efficient calculation of the part $R_{2}$ alone.

### 2.34 Reduction to scalar (master) integrals

GoSAM allows to choose at run-time (i.e. without re-generating the code) the preferred method of reduction. Available options include the integral-level $d$-dimensional reduction, as implemented in SAMURAI, or traditional tensor reduction as implemented in Golem95C interfaced through tensorial reconstruction at the integrand level, or a combination of both. Concerning the scalar (tensorial) integrals, GoSAM allows to choose among a variety of options, including QCDLoop [109], OneLoop [111], Golem95C [130], plus the recently added P JFRY [108]. Among these codes, OneLoop and Golem95C also fully support complex masses.

### 2.4 Installation and Usage

GoSam can be used within a standard Linux/Unix environment. In order to work, it requires some programs to be installed on the system: these include a recent version of Python (version $\geq 2.6$ ), Java
( $\geq 1.5$ ), a Fortran 95 compiler, FORM (version $\geq 3.3$ ), and QGRAF. Further, at least one of the libraries SAMURAI or Golem95C needs to be present at the time the code is compiled.

To facilitate this task, we have prepared a package containing SAMURAI and Golem95C together with the libraries for the integrals: OneLOop, QCDLoop, and FF. The package, which is called gosam-contrib-1.0.tar.gz is available for download from

```
http://projects.hepforge.org/gosam/.
```

The installation procedure is facilitated by the use of Autotools.
The user can download the GoSAM code either as a tar-ball or from the subversion repository at http://projects.hepforge.org/gosam/. The installation of GoSam is controlled by Python Distutils and can be performed by simply running the command

```
python setup.py install
```

In order to generate the code for a process, the user needs to prepare an input file (process card) which contains:

- process specific information, such as a list of initial and final state particles, their helicities (optional) and the order of the coupling constants;
- scheme specific information, such as the regularisation and renormalisation schemes, the underlying model, masses and widths which are set to zero;
- system specific information, such as paths to programs and libraries or compiler options;
- optional information for optimisations within the code generation.

Assuming that the process card is called myprocess.in, the generation of the code can be started by simply running the command gosam.py myprocess.in. All further steps are controlled by makefiles which are automatically generated by GoSAM: the command make compile generates the source code and compiles all files relevant for the production of the matrix element. The code can be tested with the program test. f 90 (located in the subdirectory matrix) which provides, for a random phase-space point, the tree-level LO matrix element and the NLO result for the finite part, single and double poles. Examples of process cards for a selection of benchmark processes are provided with the main distubution.

For more details about the usage and installation of GoSAM, we refer the user to a more technical presentation [144] or to the original publication [12] and the user manual which accompanies the code.

### 2.5 Examples of Applications

The BLHA interface [145] allows to link GoSAM to a general Monte Carlo event generator, which is responsible for supplying the missing ingredients for a complete NLO calculation of a physical cross section. Among those, SHERPA [146] offers the possibility to compute the LO cross section and the real corrections with both the subtraction terms and the corresponding integrated counterparts [147]. Using the BLHA interface, we linked GoSAM with SHERPA to compute the physical cross section for $W^{ \pm}+1$-jet at NLO, which is described in Section 18 .

The codes produced by GoSam have been tested on several processes of increasing complexity, some of which are shown in Table 1. The full list of processes produced by GoSam and compared to the literature where available is given in Ref. [12].

As an example of the usage of GoSam with a model file different from the Standard Model, we calculated the QCD corrections to neutralino pair production in the MSSM. The model file has been imported using the UFO interface. In this calculation, we combined the one-loop amplitude with the real radiation corrections to obtain results for differential cross sections. For the infrared subtraction terms

| $e^{+} e^{-} \rightarrow u \bar{u}$ | $[148]$ |
| :--- | :--- |
| $e^{+} e^{-} \rightarrow t \bar{t}$ | $[149,150]$, own analytic calculation |
| $u \bar{u} \rightarrow d \bar{d}$ | $[15$, 8] |
| $g g \rightarrow g g$ | $[152]$ |
| $g g \rightarrow g Z$ | $[153]$ |
| $b g \rightarrow H b$ | $[154,8]$ |
| $\gamma \gamma \rightarrow \gamma \gamma(\mathrm{W}$ loop) | $[15]$ |
| $\gamma \gamma \rightarrow \gamma \gamma \gamma \gamma$ (fermion loop) | $[156]$ |
| $p p \rightarrow t \bar{t}$ | $[8]$, MCFM [157, 158] |
| $p p \rightarrow W^{ \pm} j$ (QCD corr.) | $[157,158]$ |
| $p p \rightarrow W^{ \pm} j$ (EW corr.) | for IR poles: [65, 159] |
| $p p \rightarrow W^{ \pm} t$ | $[157,158]$ |
| $p p \rightarrow W^{ \pm} j j$ | $[157,158]$ |
| $p p \rightarrow W^{ \pm} b \bar{b}$ (massive b) | $[157,158$ |
| $e^{+} e^{-} \rightarrow e^{+} e^{-} \gamma(\mathrm{QED})$ | $[160]$ |
| $p p \rightarrow H t t \bar{t}$ | $[8]$ |
| $p p \rightarrow Z t \bar{t}$ | $[10]$ |
| $p p \rightarrow W^{+} W^{+} j j$ | $[56$, v3] |
| $p p \rightarrow b \bar{b} b \bar{b}$ | $[62,63]$ |
| $p p \rightarrow W^{+} W^{-} b \bar{b}$ | $[8,161]$ |
| $p p \rightarrow t \bar{t} b \bar{b}$ | $[8,161]$ |
| $u \bar{d} \rightarrow W^{+} g g g$ | $[161]$ |

Table 3: Some of the processes computed and checked with GoSAm
we employed MadDipole [162], while the real emission part is calculated using MadGraph/MadEvent [163]. The virtual matrix element is renormalized in the $\overline{M S}$ scheme, while massive particles are treated in the on-shell scheme. The renormalization terms specific to the massive MSSM particles have been added manually. In Fig $\sqrt[4]{ }$ we show the differential cross section for the $m_{\chi_{1}^{0} \chi_{1}^{0}}$ invariant mass, where we employed a jet veto to suppress large contributions from the channel $q g \rightarrow \chi_{1}^{0} \chi_{1}^{0} q$ which opens up at order $\alpha^{2} \alpha_{s}$, but for large $p_{T}^{j e t}$ belongs to the distinct process of neutralino pair plus one hard jet production at leading order.

Fig. 4: Comparison of the NLO and LO $m_{\chi_{1}^{0} \chi_{1}^{0}}$ distributions for the process $p p \rightarrow \chi_{1}^{0} \chi_{1}^{0}$ with a jet veto on jets with $p_{T}^{j e t}>20 \mathrm{GeV}$ and $\eta<4.5$. The band gives the dependence of the result on $\mu=\mu_{F}=\mu_{R}$ between $\mu_{0} / 2$ and $2 \mu_{0}$. We choose $\mu_{0}=m_{Z}$.

## Conclusions and Outlook

Several groups are currently working at the development of automated multi-purpose tools for one-loop calculations. For quite a long time, tree-level calculation have been fully automated and included in flexible multi-process tools [164, 165]. The level of automation achieved by one-loop calculations is suggesting the possibility of a similar success also at the next-lo-leading order. The target is to build efficient and flexible NLO programs which can be used to tackle the increasing need of precision required by the experimental collaborations.

GoSam is a flexible and broadly applicable tool for the fully automated evaluation of one-loop scattering amplitudes. In this approach, scattering amplitudes are generated in terms of Feynman diagrams and their reduction to master integrals can be performed in several ways, which can be selected at run-time. GoSAm can be used to calculate one-loop corrections both in QCD and electro-weak theory and offers the flexibility to link general model files for theories Beyond the Standard Model. The code performed well in reproducing a wide range of examples and we are looking forward to tackle more challenging calculations and interfacing with other existing tools in the near future.

## 3. AUTOMATION AND NUMERICAL LOOP INTEGRATION ${ }^{5}$

### 3.1 INTRODUCTION

Numerical methods are nowadays routinely used in fully differential fixed-order perturbative calculations for the integration over the phase-space of the final-state particles. The use of numerical methods for the phase-space integration allows the flexibility to compute any infrared-safe observable for a given process within a single numerical program. It is thus natural to investigate if numerical methods can also be applied for the loop integration in the virtual corrections [166, 167, $168,169,170,171,172,173$ [174, 175, 176]. A major breakthrough was achieved recently by showing that the numerical method is compatible in efficency with the commonly used approaches based on cut techniques and generalised unitarity or on Feynman graphs [70, [51, 53, 22, 20, 52, 117, 56, 54, 50, 48, 177, 111, 5, 178, 8, 12]. The implementation of the numerical method for the loop integration is process-independent and offers therefore the flexibility to compute several processes within one numerical program. We discuss the main principles of the numerical method for the loop integration at one-loop. In addition we give an outlook towards higher loops.

### 3.2 THE SUBTRACTION METHOD FOR THE LOOP INTEGRATION

The contributions to an infrared-safe $n$-jet observable observable $O$ at next-to-leading order are given by

$$
\begin{equation*}
\langle O\rangle^{N L O}=\int_{n+1} O_{n+1} d \sigma^{R}+\int_{n} O_{n} d \sigma^{V}+\int_{n} O_{n} d \sigma^{C} . \tag{16}
\end{equation*}
$$

[^119]Here a rather condensed notation is used. $d \sigma^{R}$ denotes the real emission contribution, whose matrix elements are given by the square of the Born amplitudes with $(n+3)$ partons $\left|A_{n+3}^{(0)}\right|^{2} . d \sigma^{V}$ denotes the virtual contribution, whose matrix elements are given by the interference term of the one-loop and Born amplitude $\operatorname{Re}\left(A_{n+2}^{(0)^{*}} A_{n+2}^{(1)}\right)$ and $d \sigma^{C}$ denotes a collinear subtraction term, which subtracts the initial state collinear singularities. Each term is separately divergent and only their sum is finite.

The subtraction method is widely used to render the real emission part of a NLO calculation suitable for a numerical Monte Carlo integration. One adds and subtracts a suitably chosen piece to be able to perform the phase-space integrations by Monte Carlo methods:

$$
\begin{equation*}
\langle O\rangle^{N L O}=\int_{n+1}\left(O_{n+1} d \sigma^{R}-O_{n} d \sigma^{A}\right)+\int_{n}\left(O_{n} d \sigma^{V}+O_{n} d \sigma^{C}+O_{n} \int_{1} d \sigma^{A}\right) . \tag{17}
\end{equation*}
$$

The first term $\left(O_{n+1} d \sigma^{R}-O_{n} d \sigma^{A}\right)$ is by construction integrable over the $(n+1)$-particle phase-space and can be evaluated numerically. The result of the integration of the subtraction term over the unresolved one-parton phase-space is written in a compact notation as

$$
\begin{equation*}
d \sigma^{C}+\int_{1} d \sigma^{A}=(\mathbf{I}+\mathbf{K}+\mathbf{P}) \otimes d \sigma^{B} \tag{18}
\end{equation*}
$$

The notation $\otimes$ indicates that colour correlations due to the colour charge operators $\mathbf{T}_{i}$ still remain. The terms with the insertion operators $\mathbf{K}$ and $\mathbf{P}$ pose no problem for a numerical evaluation. The term $\mathbf{I} \otimes d \sigma^{B}$ lives on the phase-space of the $n$-parton configuration and has the appropriate singularity structure to cancel the infrared divergences coming from the one-loop amplitude. Therefore $d \sigma^{V}+\mathbf{I} \otimes d \sigma^{B}$ is infrared finite.

We extend this subtraction method to the virtual part such that we can evaluate the one-loop integral of the one-loop amplitude numerically. The renormalised one-loop amplitude $\mathcal{A}^{(1)}$ is related to the bare amplitude $\mathcal{A}_{\text {bare }}^{(1)}$ by $\mathcal{A}^{(1)}=\mathcal{A}_{\mathrm{bare}}^{(1)}+\mathcal{A}_{\mathrm{CT}}^{(1)}$, where $\mathcal{A}_{\mathrm{CT}}^{(1)}$ denotes the ultraviolet counterterm from renormalisation. The bare amplitude involves the loop integration

$$
\begin{equation*}
\mathcal{A}_{\mathrm{bare}}^{(1)}=\int \frac{d^{D} k}{(2 \pi)^{D}} \mathcal{G}_{\mathrm{bare}}^{(1)} . \tag{19}
\end{equation*}
$$

where $\mathcal{G}_{\text {bare }}^{(1)}$ denotes the integrand of the bare one-loop amplitude. We introduce subtraction terms which match locally the singular behaviour of the bare integrand:

$$
\begin{equation*}
\mathcal{A}_{\text {bare }}^{(1)}+\mathcal{A}_{\mathrm{CT}}^{(1)}=\int \frac{d^{D} k}{(2 \pi)^{D}}\left(\mathcal{G}_{\text {bare }}^{(1)}-\mathcal{G}_{\mathrm{soft}}^{(1)}-\mathcal{G}_{\mathrm{coll}}^{(1)}-\mathcal{G}_{\mathrm{UV}}^{(1)}\right)+\left(\mathcal{A}_{\mathrm{CT}}^{(1)}+\mathcal{A}_{\mathrm{soft}}^{(1)}+\mathcal{A}_{\text {coll }}^{(1)}+\mathcal{A}_{\mathrm{UV}}^{(1)}\right) . \tag{20}
\end{equation*}
$$

Analogous to $\mathcal{G}_{\text {bare }}^{(1)}$, the integrands of the subtraction terms $\mathcal{A}_{x}^{(1)}$ are denoted by $\mathcal{G}_{x}^{(1)}$, where $x$ is equal to soft, coll or UV. The expression in the first bracket is finite and can therefore be integrated numerically in four dimensions. The integrated subtraction terms in the second bracket are easily calculated analytically in $D$ dimensions. The result can be written as

$$
\begin{equation*}
2 \operatorname{Re} \mathcal{A}^{(0)}\left(\mathcal{A}_{\mathrm{CT}}^{(1)}+\mathcal{A}_{\mathrm{soft}}^{(1)}+\mathcal{A}_{\mathrm{coll}}^{(1)}+\mathcal{A}_{\mathrm{UV}}^{(1)}\right)^{*} O_{n} d \phi_{n}=\mathbf{L} \otimes d \sigma^{B} . \tag{21}
\end{equation*}
$$

The insertion operator $\mathbf{L}$ contains the explicit poles in the dimensional regularisation parameter related to the infrared singularities of the one-loop amplitude. These poles cancel when combined with the insertion operator $\mathbf{I}$ :

$$
\begin{equation*}
(\mathbf{I}+\mathbf{L}) \otimes d \sigma^{B}=\text { finite } \tag{22}
\end{equation*}
$$

The operator $\mathbf{L}$ contains, as does the operator $\mathbf{I}$, colour correlations due to soft gluons. In analogy to the one-loop amplitude we can write $d \sigma^{V}=d \sigma_{\mathrm{CT}}+\int \frac{d^{D} k}{(2 \pi)^{D}} d \sigma_{\text {bare }}^{V}$ and then the NLO contributions reads

$$
\begin{align*}
& \langle O\rangle^{N L O}=  \tag{23}\\
& \quad \int_{n+1}\left(O_{n+1} d \sigma^{R}-O_{n} d \sigma^{A}\right)+\int_{n+\text { loop }} O_{n}\left(d \sigma_{\text {bare }}^{V}-d \sigma^{A^{\prime}}\right)+\int_{n} O_{n}(\mathbf{I}+\mathbf{L}+\mathbf{K}+\mathbf{P}) \otimes d \sigma^{B} .
\end{align*}
$$

In a condensed notation this reads

$$
\begin{equation*}
\langle O\rangle^{N L O}=\langle O\rangle_{\text {real }}^{N L O}+\langle O\rangle_{\text {virtual }}^{N L O}+\langle O\rangle_{\text {insertion }}^{N L O} . \tag{24}
\end{equation*}
$$

Every single term is finite and can be evaluated numerically.

### 3.3 THE SUBTRACTION TERMS

Amplitudes in QCD may be decomposed into group-theoretical factors (carrying the colour structures) multiplied by kinematic factors called partial amplitudes. At the loop level partial amplitudes may further be decomposed into primitive amplitudes. It is simpler to work with primitive one-loop amplitudes instead of a full one-loop amplitude. Our method exploits the fact that primitive one-loop amplitudes have a fixed cyclic ordering of the external legs and that they are gauge-invariant. The first point ensures that there are at maximum $n$ different loop propagators in the problem, where $n$ is the number of external legs, while the second property of gauge invariance is crucial for the proof of the method. We therefore consider in the following just a single primitive one-loop amplitude, which we denote by $A^{(1)}$, while keeping in mind that the full one-loop amplitude is just the sum of several primitive amplitudes multiplied by colour structures. We label the external momenta clockwise by $p_{1}, p_{2}, \ldots, p_{n}$ and define $q_{i}=p_{1}+$ $p_{2}+\ldots+p_{i}, k_{i}=k-q_{i}$. We can write the bare primitive one-loop amplitude in Feynman gauge as

$$
\begin{equation*}
A_{\text {bare }}^{(1)}=\int \frac{d^{D} k}{(2 \pi)^{D}} G_{\text {bare }}^{(1)}, \quad G_{\text {bare }}^{(1)}=P(k) \prod_{i=1}^{n} \frac{1}{k_{i}^{2}-m_{i}^{2}+i \delta} . \tag{25}
\end{equation*}
$$

$G_{b a r e}^{(1)}$ is the integrand of the bare one-loop amplitude. $P(k)$ is a polynomial in the loop momentum $k$. The $+i \delta$-prescription instructs us to deform - if possible - the integration contour into the complex plane to avoid the poles at $k_{i}^{2}=m_{i}^{2}$. If a deformation close to a pole is not possible, we say that the contour is pinched. If we restrict ourselves to non-exceptional external momenta, then the divergences of the one-loop amplitude related to a pinched contour are either due to soft or collinear partons in the loop. These divergences are regulated within dimensional regularisation by setting the number of space-time dimensions equal to $D=4-2 \varepsilon$. A primitive amplitude which has soft or collinear divergences must have at least one loop propagator which corresponds to a gluon. An amplitude which just consists of a closed fermion loop does not have any infrared divergences. We denote by $I_{g}$ the set of indices $i$, for which the propagator $i$ in the loop corresponds to a gluon. The soft and collinear subtraction terms for massless QCD read [169]

$$
\begin{align*}
G_{\mathrm{soft}}^{(1)} & =16 \pi \alpha_{s} i \sum_{j \in I_{g}} \frac{p_{j} \cdot p_{j+1}}{k_{j-1}^{2} k_{j}^{2} k_{j+1}^{2}} A_{j}^{(0)}, \\
G_{\mathrm{coll}}^{(1)} & =-8 \pi \alpha_{s} i \sum_{j \in I_{g}}\left[\frac{S_{j} g_{\mathrm{UV}}\left(k_{j-1}^{2}, k_{j}^{2}\right)}{k_{j-1}^{2} k_{j}^{2}}+\frac{S_{j+1} g_{\mathrm{UV}}\left(k_{j}^{2}, k_{j+1}^{2}\right)}{k_{j}^{2} k_{j+1}^{2}}\right] A_{j}^{(0)}, \tag{26}
\end{align*}
$$

where $S_{j}=1$ if the external line $j$ corresponds to a quark and $S_{j}=1 / 2$ if it corresponds to a gluon. The function $g_{\mathrm{UV}}$ ensures that the integration over the loop momentum is ultraviolet finite. Integrating
the soft and the collinear part we obtain

$$
\begin{align*}
& S_{\varepsilon}^{-1} \mu_{s}^{2 \varepsilon} \int \frac{d^{D} k}{(2 \pi)^{D}} G_{\mathrm{soft}}^{(1)}=-\frac{\alpha_{s}}{4 \pi} \frac{e^{\varepsilon \gamma_{E}}}{\Gamma(1-\varepsilon)} \sum_{j \in I_{g}} \frac{2}{\varepsilon^{2}}\left(\frac{-2 p_{j} p_{j+1}}{\mu_{s}^{2}}\right)^{-\varepsilon} A_{j}^{(0)}+\mathcal{O}(\varepsilon) \\
& S_{\varepsilon}^{-1} \mu_{s}^{2 \varepsilon} \int \frac{d^{D} k}{(2 \pi)^{D}} G_{\mathrm{coll}}^{(1)}=-\frac{\alpha_{s}}{4 \pi} \frac{e^{\varepsilon \gamma_{E}}}{\Gamma(1-\varepsilon)} \sum_{j \in I_{g}}\left(S_{j}+S_{j+1}\right) \frac{2}{\varepsilon}\left(\frac{\mu_{u v}^{2}}{\mu_{s}^{2}}\right)^{-\varepsilon} A_{j}^{(0)}+\mathcal{O}(\varepsilon) \tag{27}
\end{align*}
$$

$S_{\varepsilon}=(4 \pi)^{\varepsilon} e^{-\varepsilon \gamma_{E}}$ is the typical volume factor of dimensional regularisation, $\gamma_{E}$ is Euler's constant and $\mu$ is the renormalisation scale.

The ultraviolet subtraction terms correspond to propagator and vertex corrections. The subtraction terms are obtained by expanding the relevant loop propagators around a new ultraviolet propagator $\left(\bar{k}^{2}-\right.$ $\left.\mu_{\mathrm{UV}}^{2}\right)^{-1}$, where $\bar{k}=k-Q$ : For a single propagator we have

$$
\frac{1}{(k-p)^{2}}=\frac{1}{\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}}+\frac{2 \bar{k} \cdot(p-Q)}{\left(\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}\right)^{2}}-\frac{(p-Q)^{2}+\mu_{\mathrm{UV}}^{2}}{\left(\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}\right)^{2}}+\frac{[2 \bar{k} \cdot(p-Q)]^{2}}{\left(\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}\right)^{3}}+\mathcal{O}\left(\frac{1}{|\bar{k}|^{5}}\right)
$$

We can always add finite terms to the subtraction terms. For the ultraviolet subtraction terms we choose the finite terms such that the finite parts of the integrated ultraviolet subtraction terms are independent of $Q$ and proportional to the pole part, with the same constant of proportionality for all ultraviolet subtraction terms. This ensures that the sum of all integrated UV subtraction terms is again proportional to a tree-level amplitude [167].

### 3.4 CONTOUR DEFORMATION

Having a complete list of ultraviolet and infrared subtraction terms at hand, we can ensure that the integration over the loop momentum gives a finite result and can therefore be performed in four dimensions. However, this does not yet imply that we can safely integrate each of the four components of the loop momentum $k^{\mu}$ from minus infinity to plus infinity along the real axis. There is still the possibility that some of the loop propagators go on-shell for real values of the loop momentum. If the contour is not pinched this is harmless, as we may escape into the complex plane in a direction indicated by Feynman's $+i \delta$-prescription. However, it implies that the integration should be done over a region of real dimension 4 in the complex space $\mathbb{C}^{4}$. Let us consider an integral corresponding to a primitive one-loop amplitude with $n$ propagators minus the appropriate IR- and UV-subtraction terms:

$$
\begin{equation*}
\int \frac{d^{4} \tilde{k}}{(2 \pi)^{4}}\left(\mathcal{G}_{\mathrm{bare}}^{(1)}-\mathcal{G}_{\mathrm{soft}}^{(1)}-\mathcal{G}_{\mathrm{coll}}^{(1)}-\mathcal{G}_{\mathrm{UV}}^{(1)}\right)=\int \frac{d^{4} \tilde{k}}{(2 \pi)^{4}} P(\tilde{k}) \prod_{j=1}^{n} \frac{1}{\tilde{k}_{j}^{2}-m_{j}^{2}+i \delta} \tag{28}
\end{equation*}
$$

where $P(\tilde{k})$ is a polynomial of the loop momentum $\tilde{k}^{\mu}$ and the integration is over a complex contour in order to avoid whenever possible the poles of the propagators. We set $\tilde{k}^{\mu}=k^{\mu}+i \kappa^{\mu}(k)$, where $k^{\mu}$ is real [170]. After this deformation our integral equals

$$
\begin{equation*}
\int \frac{d^{4} k}{(2 \pi)^{4}}\left|\frac{\partial \tilde{k}^{\mu}}{\partial k^{\nu}}\right| P(\tilde{k}(k)) \prod_{j=1}^{n} \frac{1}{k_{j}^{2}-m_{j}^{2}-\kappa^{2}+2 i k_{j} \cdot \kappa} \tag{29}
\end{equation*}
$$

To match Feynman's $+i \delta$-prescription we have to construct the deformation vector $\kappa$ such that

$$
\begin{equation*}
k_{j}^{2}-m_{j}^{2}=0 \quad \rightarrow \quad k_{j} \cdot \kappa \geq 0 \tag{30}
\end{equation*}
$$

We remark that the numerical stability of the Monte Carlo integration depends strongly on the definition of the deformation vector $\kappa$.

### 3.5 NLO results for $\mathbf{n}$-jets in electron-positron annihilation

We have calculated results for jet observables in electron-positron annihilation, where the jets are defined by the Durham jet algorithm [166]. The cross section for $n$ jets normalised to the LO cross section for $e^{+} e^{-} \rightarrow$ hadrons reads

$$
\begin{equation*}
\frac{\sigma_{n-j e t}(\mu)}{\sigma_{0}(\mu)}=\left(\frac{\alpha_{s}(\mu)}{2 \pi}\right)^{n-2} A_{n}(\mu)+\left(\frac{\alpha_{s}(\mu)}{2 \pi}\right)^{n-1} B_{n}(\mu)+\mathcal{O}\left(\alpha_{s}^{n}\right) . \tag{31}
\end{equation*}
$$

One can expand the perturbative coefficient $A_{n}$ and $B_{n}$ in $1 / N_{c}$ :

$$
A_{n}=N_{c}\left(\frac{N_{c}}{2}\right)^{n-2}\left[A_{n, \mathrm{lc}}+\mathcal{O}\left(\frac{1}{N_{c}}\right)\right], \quad B_{n}=N_{c}\left(\frac{N_{c}}{2}\right)^{n-1}\left[B_{n, \mathrm{lc}}+\mathcal{O}\left(\frac{1}{N_{c}}\right)\right] .
$$

We calculate the leading order coefficient $A_{n, \text { lc }}$ and the next-to-leading order coefficient $B_{n, \text { lc }}$ for $n \leq 7$ at the renormalisation scale $\mu$ equal to the centre-of-mass energy. The centre-of-mass energy is taken to be equal to the mass of the $Z$-boson. The scale variation can be restored from the renormalisation group equation. The calculation is done with five massless quark flavours. Fig. 5 ]shows the comparison of our

Fig. 5: Comparison of the NLO corrections to the two-, three- and four-jet rate between the numerical calculation and an analytic calculation. The error bars from the Monte Carlo integration are shown and are almost invisible.
numerical approach with the well-known results for two, three and four jets [179, 180, 181]. We observe an excellent agreement. The results for five, six and seven jets for the jet parameter $y_{c u t}=0.0006$ are

$$
\begin{array}{ll}
\frac{N_{c}^{4}}{8} A_{5, \mathrm{lc}}=(2.4764 \pm 0.0002) \cdot 10^{4}, & \frac{N_{c}^{5}}{16} B_{5, \mathrm{lc}}=(1.84 \pm 0.15) \cdot 10^{6}, \\
\frac{N_{c}^{5}}{16} A_{6, \mathrm{lc}}=(2.874 \pm 0.002) \cdot 10^{5}, & \frac{N_{c}^{6}}{32} B_{6, \mathrm{lc}}=(3.88 \pm 0.18) \cdot 10^{7}, \\
\frac{N_{c}^{6}}{32} A_{7, \mathrm{lc}}=(2.49 \pm 0.08) \cdot 10^{6}, & \frac{N_{c}^{7}}{64} B_{7, \mathrm{lc}}=(5.4 \pm 0.3) \cdot 10^{8} . \tag{32}
\end{array}
$$

### 3.6 FIRST STEPS TOWARDS NNLO

An NNLO calculation requires among other things also the calculation of the one-loop amplitude squared. The expansion in the dimensional regularisation parameter $\varepsilon$ of the one-loop amplitude starts at order $(-2)$ one would naively expect that up to order $\varepsilon^{0}$ the $\mathcal{O}(\uparrow)$ - and $\mathcal{O}\left(\varepsilon^{2}\right)$-terms of the one-loop amplitude are needed for an NNLO calculation. However, it is by no means obvious how the approaches for one-loop amplitudes based on unitarity or the numerical method can be extended to include the higherorder terms in the $\varepsilon$-expansion. It turns out that the computation of these higher-order terms can be avoided, provided a method is known to compute the finite two-loop remainder function. The one- and two-loop amplitudes can be written as [182]

$$
\begin{align*}
\mathcal{A}^{(1)} & =\mathbf{Z}^{(1)} \mathcal{A}^{(0)}+\mathcal{F}_{\text {minimal }}^{(1)}, \\
\mathcal{A}^{(2)} & =\left(\mathbf{Z}^{(2)}-\mathbf{Z}^{(1)} \mathbf{Z}^{(1)}\right) \mathcal{A}^{(0)}+\mathbf{Z}^{(1)} \mathcal{A}^{(1)}+\mathcal{F}_{\text {minimal }}^{(2)}, \tag{33}
\end{align*}
$$

where the operators $\mathbf{Z}^{(1)}$ and $\mathbf{Z}^{(2)}$ contain all the infrared poles and $\mathcal{F}_{\text {minimal }}^{(1)}$ and $\mathcal{F}_{\text {minimal }}^{(2)}$ are finite remainders. Here we used the convention that the operators $\mathbf{Z}^{(1)}$ and $\mathbf{Z}^{(2)}$ contain only pole terms, but no terms of order $\varepsilon^{k}$ with $k \geq 0$. This corresponds to a minimal scheme. The operators $\mathbf{Z}^{(1)}$ and $\mathbf{Z}^{(2)}$ are well-known. At NNLO it is sufficient to know the $\varepsilon^{0}$-terms of $\mathcal{F}_{\text {minimal }}^{(1)}$ and $\mathcal{F}_{\text {minimal }}^{(2)}$, the $\varepsilon^{1}$ - or $\varepsilon^{2}$-terms of $\mathcal{A}^{(1)}$ or $\mathcal{F}_{\text {minimal }}^{(1)}$ are not required [183].

## ACKNOWLEDGEMENTS

I would like to thank Simon Plätzer for fruitful discussions during the workshop.

## 4. TOWARDS THE AUTOMATION OF ONE-LOOP AMPLITUDES ${ }^{6}$

#### Abstract

A program is presented that computes one-loop amplitudes automatically for processes with up to 6 external particles based on the Feynman-diagram approach. Additionally, universal one-loop building blocks, which can be used to compute several processes at NLO QCD are calculated.

### 4.1 INTRODUCTION

The calculation of processes with multi-particle final states beyond the leading order approximation has been an active field of research during the last years as a consequence of the demand of high accuracy for signal and background processes at the LHC. A next-to-leading (NLO) calculation consists of virtual and real radiation processes which are infrared divergent (IR) separately and can be computed numerically only after extracting the divergences of the real radiation contributions. The one-loop virtual calculation for multiple particles poseses a challenge of complexity not only due to the large number of contributing diagrams, but also concerning the stability of the numerical code to evaluate them. In the last years, an enormous progress has been achieved applying new techniques and using traditional Feynman-diagram approach, leading to new NLO predictions.

Due to the large number of processes of potential interest at the LHC, the scientific community has worked in the automation of the NLO calculations. The automation of the real contributions including their infrared subtraction terms has been successfully implemented in several packages and the automation of the virtual corrections, which is a harder problem, is currently being achieved in several programs (see [184] and references therein).

In Ref. [185], the early stage of a program, in the framework of Mathematica [186] and FeynCalc [187], to compute automatically one-loop amplitudes based on traditional Feynman-diagram techniques and involving up to $2 \rightarrow 4$ processes was presented. This program will become publicly available in the future. The method used is described in Section 4.2. In Section 4.3, we present a set of universal one-loop building blocks that has been used to compute recently several processes included in the VBFNLO package [42, 41].

### 4.2 TOWARDS AN AUTOMATIC ONE-LOOP AMPLITUDE GENERATOR

The program above mentioned automatically simplifies a set of amplitudes up to Hexagons of rank 5. The result is given in terms of scalar and tensor integrals following the Passarino-Veltman convention [112, 185], spinor chains, polarization vectors and model parameters. The simplified expression is written automatically to FORTRAN routines. For massless propagators, the amplitudes can be evaluated also in Mathematica with unlimited precision, which is used for testing purposes. To achieve that, the scalar integrals, the tensor reduction formalism to extract the tensor coefficient integrals, and also the helicity method described in Ref. [188, 189] to compute the spinor products have been implemented at

[^120]the FORTRAN and Mathematica level. For the determination of the tensor integrals up to the box level, the Passarino-Veltman tensor reduction formalism [112] is used applying the LU decomposition method to avoid the explicit calculation of inverse Gram matrices by solving a system of linear equations, which is a more stable procedure close to singular points. Finally, for singular Gram determinants, special tensor reduction routines following Ref. [115] have been implemented, however, the external momenta convention (Passarino-like) was used. The impact of these methods is discussed in detail in Ref. [185]. For pentagons, in addition to the Passarino-Veltman formalism, the method proposed by Denner and Dittmaier [115, 190], applied also to hexagons, has been implemented. For that, the recursion relations of Ref. [115] in terms of the Passarino-Veltman external momenta convention have been re-derived. This last method is used for the numerical implementation at the FORTRAN level.

The Mathematica function does several algebraic manipulations that are summarized as follows:

- Simultaneous extraction of rational terms based on Dirac algebra manipulations and cancelation of scalar products against propagators.
- Reduction to a minimal basis of tensor and scalar integrals.
- Reduction to a minimal basis of spinor chains.
- The use of Chisholm identities, which are only valid in 4 dimensions, for the contraction of Lorentz indices among different spinor chains is applied, if selected.
- Factorization of loop dependent and independent factors (Useful to perform gauge tests, Ward identities or the re-evaluation of the amplitudes for different helicity polarization of gluons and fermions at a lower CPU cost).
As an example of the notation used, the following Hexagon diagram is used. This is written as follows:

where $g_{0}$ is the strong unrenormalized coupling, $\mathcal{C}_{i j}^{V_{1} V_{2} V_{3} V_{4}}$ is a color diagram dependent factor, e.g, $\mathcal{C}_{i j}^{\gamma \gamma g \gamma}=\left(T_{a}\right)_{i j}\left(C_{F}-1 / 2 C_{A}\right) . g_{\tau}^{V_{i} f}$ are electroweak couplings and $\mathcal{M}_{\tau}^{i j}$ represents the amplitude considering generic off-shell vector bosons with color indices $i j$ for a given helicity $\tau$. The amplitude $\mathcal{M}_{\tau}^{i j}$, omitting color indices, is written in terms of

$$
\begin{equation*}
\mathcal{M}_{\tau}=\mathcal{M}_{\tau}^{D=4}+(D-4) \mathcal{M}_{\tau}^{D R} \tag{35}
\end{equation*}
$$

where $\mathcal{M}_{\tau}^{D=4}$ is the amplitude that one would obtain performing the Dirac algebra manipulation in four dimensions, $D=4$, and $\mathcal{M}_{\tau}^{D R}$ contains the rational terms and vanishes in Dimensional Reduction $(D R)$. These functions are decomposed in the form:

$$
\begin{equation*}
\mathcal{M}^{(D=4, D R)}=\sum_{i, j} \mathrm{SM}_{i, \tau} \mathrm{Fl}_{j}, \tag{36}
\end{equation*}
$$

where $\mathrm{SM}_{i, \tau}$ is a basis of Standard Matrix elements corresponding to spinor products describing the quark line of Eq. (34] which are computed following the helicity method [188, 189] with a defined helicity, $\tau . \mathrm{F1}_{j}$ are complex functions which are further decomposed into dependent and independent loop integral parts,

$$
\begin{equation*}
\mathrm{F}_{j}=\sum_{l, k} \mathrm{~F}_{l} T_{k}\left(\epsilon\left(p_{n}\right) \cdot p_{m} ; \epsilon\left(p_{i}\right) \cdot \epsilon\left(p_{r}\right)\right) \tag{37}
\end{equation*}
$$

$T_{k}$ is a monomial function at most for each polarization vector $\epsilon\left(p_{x}\right)$, i.e., $\epsilon\left(p_{x}\right)^{0}$ or $\epsilon\left(p_{x}\right)^{1}$. The first possibility, $\epsilon\left(p_{x}\right)^{0}$, implies that the polarization vector appears in the set of Standard Matrix elements
$\mathrm{SM}_{i, \tau} . F_{l}$ contains kinematic variables $\left(p_{i} \cdot p_{j}\right)$, the scalar integrals ( $B_{0}, C_{0}, D_{0}$ ), and the tensor integral coefficients $\left(B_{i j}, C_{i j}, D_{i j}, E_{i j}, F_{i j}\right)$. Then, the full result is obtained from $\mathcal{M}_{\tau}^{D=4}$ and $\mathcal{M}_{\tau}^{D R}$ using the finite and the coefficients of the $1 / \epsilon^{n}$ poles of the scalar and tensor coefficient integrals:

$$
\begin{equation*}
\mathcal{M}_{v}^{D=4}=\widetilde{\mathcal{M}}_{v}+\frac{\mathcal{M}_{v}^{1}}{\epsilon}+\frac{\mathcal{M}_{v}^{2}}{\epsilon^{2}}, \quad(D-4) \mathcal{M}_{v}^{D R}=\widetilde{\mathcal{N}}_{v}+\frac{\mathcal{N}_{v}^{1}}{\epsilon} \tag{38}
\end{equation*}
$$

where, e.g., $\widetilde{\mathcal{M}}_{v}$ is the finite contribution obtained using the finite pieces of the scalar and tensor coefficient integrals including the finite contributions from rational terms arising in ultraviolet tensor coefficient integrals.

### 4.3 UNIVERSAL BUILDING BLOCKS

Based on the observation that the same one-loop virtual amplitudes appear in many processes (Fig. 6), we are aiming to collect a basis of universal building blocks, which can be used to compute all of the $2 \rightarrow 4$ processes at LHC at the QCD one-loop level (Similar to the philosophy of older versions of MADGRAPH [191] calling the HELAS [192] routines). This methodology of collecting topologies in groups has been proved very successful in the program VBFNLO, where for example a boxline routine, first line of Fig. 6, is computed and applied to $p p \rightarrow V V, p p \rightarrow V V V, p p \rightarrow V V j$ and EW production of $p p \rightarrow V j j$ and $p p \rightarrow H V j j$.

Fig. 6: Boxline contributions appearing in different processes.

To do that, we use the effective current approach described and applied in Refs. [39, 47, 31, 193, 21]. As illustration, the first diagram of the second raw of Fig. 6is used. This can be written as,

$$
\begin{equation*}
A_{V_{1} V_{2} V_{3} V_{4}, \tau}=J_{V_{1}^{*}}^{\mu_{1}} J_{V_{2}^{*}}^{\mu_{2}} \mathcal{M}_{\mu_{1} \mu_{2}, \tau} \equiv \mathcal{M}_{V_{1}^{*} V_{2}^{*}, \tau} \tag{39}
\end{equation*}
$$

where the color indices have been omitted. Here, $J_{V_{1}^{*}}^{\mu_{1}}$ and $J_{V_{2}^{*}}^{\mu_{2}}$ represent effective polarization vectors in the unitarity gauge for the EW sector including finite width effects in the scheme of Refs. [194, 195] and propagator factors, e.g.,

$$
\begin{equation*}
J_{V_{1}^{*}}^{\mu_{1}}\left(q_{1}\right)=\frac{-i}{q_{1}^{2}-M_{V_{1}^{*}}^{2}-i M_{V_{1}^{*}} \Gamma_{V_{1}^{*}}}\left(g_{\mu}^{\mu_{1}}-\frac{q_{1}^{\mu_{1}} q_{1 \mu}}{q_{1}^{2}-M_{V_{1}^{*}}^{2}-i M_{V_{1}^{*}} \Gamma_{V_{1}^{*}}}\right) \Gamma_{V_{1}^{*} V_{1} V_{3}}^{\mu} \tag{40}
\end{equation*}
$$

with $\Gamma_{V_{1}^{*}}$, the width of the $V_{1}^{*}$ vector boson, and $\Gamma_{V_{1}^{*} V_{1} V_{3}}^{\mu}$, the triple vertex, which can also contain the leptonic decay of the EW vector bosons including all off-shell effects or BSM physics. In this manner, we can then concentrate in computing, instead of $A_{V_{1} V_{2} V_{3} V_{4}, \tau}$, the virtual correction to two massive vector bosons attached to the quark line, $\mathcal{M}_{V_{1}^{*} V_{2}^{*}, \tau}$, or equivalently $\mathcal{M}_{\mu_{1} \mu_{2}, \tau}$, where the polarization vectors or effective currents have been factored out. In our approach, this basic building block is the so-called Boxline, which is computed only once and re-used in different processes.

We plan to do a classification of all the topologies that appear at 1 loop level for up to $2 \rightarrow 4$ processes and install a library with all the basic one-loop building blocks already computed and simplified. This would be an advantage since, for example for $q q \rightarrow V V V V$ production, up to 24 hexagons for a single subprocess would appear, corresponding to the permutations of the vector bosons on the hexagon of Eq. 34. In this approach, the amplitude is obtained by calling the same one-loop amplitude 24 times with the corresponding ordering of momenta and polarization vectors. We aim towards an automation of this procedure, which will result into a faster and shorter final FORTRAN code generation. The specific building blocks are collected into groups with specific gauge and IR factorization properties, e.g, factorization of the IR divergences against the corresponding born, known behavior under Ward identity checks.

In Fig. 7. we present the topologies that have been computed and tested. In the first line, corrections to a quark line with the emission of $\mathrm{V}_{n}$ vector bosons in a fixed order are represented for 4 different topologies. (The first 2 were explained in detail in Ref. [185], including their stability behavior). We have only depicted the virtual amplitude with the higher complexity for a giving building block, e.g. the boxline of Fig.6is obtained from the first diagram with two vector bosons attached, i.e., $n=2$ in $V_{n}$. The first two topologies of the second line are collected by putting together all possible Feynman-diagrams with a fixed order of the vector bosons and attaching it to the quark lines in all possible ways. The crossing of the fermion lines are treated as independent building blocks and are not depicted. Finally, the fermion-loop corrections for a fixed order of vector bosons, $V_{n}$, are computed in the last diagram of the second line

The use of modular structure routines, as the above presented, has been proved to be an advantage in the program VBFNLO [42, 41] since once a structure is computed and checked it can be re-used for different processes. For example, using the building blocks of the first and second topology together with the fermion-loop diagrams, results at NLO QCD for all $V V V$ [39, 47, 46, 45, 43, 44], several $V V j$ [31, 32, 196, 197], $H \gamma j j$ [198] and $W \gamma \gamma j$ [21] production channels have been computed recently. The last one representing the first calculation at this accuracy falling in the category of $V V V+j$ production. Up to the pentagon level, these building blocks are publicly available as part of the VBFNLO [42, 41] package together with the tensor reduction routines, excluding the routines for small Gram determinants which will become available in the future, in addition to the other building blocks.

### 4.4 CONCLUSIONS

A program which automatically evaluates one-loop amplitudes for up to $2 \rightarrow 4$ processes has been presented based on the traditional Feynman-diagram approach. The program has been developed in the framework of Mathematica and FeynCalc and writes down automatically the simplified expression to FORTRAN. Up to the pentagon level and for massless propagators, the code can be evaluated numerically inside Mathematica with unlimited precision which can be used for testing purposes. For the reduction of tensor integrals, we have developed a library that includes expansion for small Gram determinants. Using the leptonic tensor formalism, we are building a library of universal one-loop building blocks, which can be used to compute several processes at NLO QCD. Recently, following this strategy, we have reported results for all $V V V$ [39, 47, 46, 45, 43, 44], several $V V j$ [31, 32, 196, 197], $H \gamma j j$ [198] and $W \gamma \gamma j$ [21] production channels inside the VBFNLO collaboration. The ultimate goal is to generalize the library to compute all of the $2 \rightarrow 4$ processes at LHC at the QCD one-loop level, similar to the philosophy of older versions of MADGRAPH [191] calling the HELAS [192] routines,

Fig. 7: Topologies of universal building one-loop blocks. Only the most complicated diagram of each topology is depicted, e.g, the boxline of Fig 6 is obtained from the first diagram with two vector bosons attached, i.e., $V_{n}, n=2$.
and deliver a Mathematica package compatible with FeynArts [132], which can be used to compute full one-loop amplitudes automatically using the universal building blocks, resulting into a faster and shorter code generation.

## ACKNOWLEDGEMENTS

F.C acknowledges fruitful discussions with the members of the VBFNLO collaboration and partial support of a postdoctoral fellowship of the Generalitat Valenciana, Spain (Beca Postdoctoral d'Excel•lència), by the European FEDER and Spanish MICINN under the grant FPA2008-02878 and by the Deutsche Forschungsgemeinschaft via the Sonderforschungsbereich/Transregio SFB/TR-9 "Computational Particle Physics". The Feynman diagrams in this paper were drawn using Axodraw [139].

## 5. THE TWO-LOOP QCD VIRTUAL AMPLITUDE FOR W PAIR PRODUCTION WITH FULL MASS DEPENDENCE 7

### 5.1 INTRODUCTION

One of the main aims in the Large Hadron Collider (LHC) physics program is undoubtedly the discovery (or the exclusion) of the Higgs boson which is responsible for the fermion and gauge boson masses and also part of the mechanism of dynamical breaking of the Electroweak (EW) symmetry. Another important goal for the LHC is the precise measurement of the hadronic production of gauge boson pairs, $W W, W Z, Z Z, W \gamma, Z \gamma$, this in connection to the investigation of the non-Abelian gauge structure of the SM . W pair production,

$$
\begin{equation*}
q \bar{q} \rightarrow W^{+} W^{-}, \tag{41}
\end{equation*}
$$

[^121]plays an essential role as it serves as a signal process in the search for New Physics and also is the dominant irreducible background to the Higgs discovery channel $p p \rightarrow H \rightarrow W^{*} W^{*} \rightarrow l \bar{\nu} \bar{l}^{\prime} \nu^{\prime}$, in the intermediate Higgs mass range [199]. Both ATLAS and CMS collaborations have released first values for the $W W$ cross section [200, 201].

The process (41) is currently known at next-to-leading order (NLO) accuracy [202, 203, 204, 205, 206, 157, ?]. The NLO corrections were proven to be large enhancing the tree-level result by almost $70 \%$ which falls to a (still) large $30 \%$ after imposing a jet veto. Therefore, if a theoretical estimate for the W pair production is to be compared against experimental measurements at the LHC, one is bound to go one order higher in the perturbative expansion, namely, to the next-to-next-to-leading order (NNLO). This would allow, in principle, an accuracy of around $10 \%$.

High accuracy for the W pair production is also needed when the process is studied as background to Higgs production in order to match accuracies between signal and background. The signal process for the Higgs discovery via gluon fusion, $g g \rightarrow H$, as well as the process $H \rightarrow W W \rightarrow l \bar{\nu} \bar{l}^{\prime} \nu^{\prime}$ are known at NNLO [207, 208, 209, 210, 211, 212, 213, 214, 215, 216], whereas the EW corrections are known beyond NLO [217]. Another process that needs to be included in the background is the W pair production in the loop induced gluon fusion channel,

$$
\begin{equation*}
g g \rightarrow W^{+} W^{-} \tag{42}
\end{equation*}
$$

The latter contributes at $\mathcal{O}\left(\alpha_{s}^{2}\right)$ relative to the quark-anti-quark-annihilation channel but is nevertheless enhanced due to the large gluon flux at the LHC [218, 219].

The first main difficulty in studying the NNLO QCD corrections for W pair production is the calculation of the two-loop virtual amplitude since it is a $2 \rightarrow 2$ process with massive external particles. We have already computed the virtual corrections at the high energy limit [220, 97, 221]. However, this is not enough as it cannot cover the kinematical region close to threshold. Therefore, in order to cover all kinematical regions we proceed as follows. We perform a deep expansion in the W mass around the high energy limit which in combination with the method of numerical integration of differential equations [222, 223, 224] allows us the numerical computation of the two-loop amplitude with full mass dependence over the whole phase space.

### 5.2 THE HIGH ENERGY LIMIT

The methodology for obtaining the massive amplitude in the high energy limit, namely the limit where all the invariants are much larger than the W mass, is similar to the one followed in Refs. [225, 226]. The amplitude is reduced to an expression that only contains a small number of integrals (master integrals) with the help of the Laporta algorithm [227]. In the calculation for the two-loop amplitude there are 71 master integrals. Next step is the construction, in a fully automatised way, of the Mellin-Barnes (MB) representations [228, 229] of all the master integrals by using the MBrepresentation package [230]. The representations are then analytically continued in the number of space-time dimensions by means of the MB package [231], thus revealing the full singularity structure. An asymptotic expansion in the mass parameter ( W mass) is performed by closing contours and the integrals are finally resummed, either with the help of XSummer [232] or the PSLQ algorithm [233]. The result is expressed in terms of harmonic polylogarithms.

### 5.3 POWER CORRECTIONS AND NUMERICAL EVALUATION

The high energy limit by itself is not enough, as was mentioned before. The next step, following the methods applied in Ref. [234], is to compute power corrections in the W mass. Power corrections are good enough to cover most of the phase space, apart from the region near threshold as well as the regions corresponding to small angle scattering.

We recapitulate here some of the notation of Ref. [221] for completeness. The charged vectorboson production in the leading partonic scattering process corresponds to

$$
\begin{equation*}
q\left(p_{1}\right)+\bar{q}\left(p_{2}\right) \rightarrow W^{-}\left(p_{3}, m\right)+W^{+}\left(p_{4}, m\right) \tag{43}
\end{equation*}
$$

where $p_{i}$ denote the quark and W momenta and $m$ is the mass of the W boson.
We have chosen to express the amplitude in terms of the kinematic variables $x$ and $m_{s}$ which are defined to be

$$
\begin{equation*}
x=-\frac{t}{s}, \quad m_{s}=\frac{m^{2}}{s} \tag{44}
\end{equation*}
$$

where

$$
\begin{equation*}
s=\left(p_{1}+p_{2}\right)^{2} \text { and } t=\left(p_{1}-p_{3}\right)^{2}-m^{2} \tag{45}
\end{equation*}
$$

The variation then of $x$ within the range $[1 / 2(1-\beta), 1 / 2(1+\beta)]$, where $\beta=\sqrt{1-4 m^{2} / s}$ is the velocity, corresponds to angular variation between the forward and backward scattering.

It should be evident that any master integral $M_{i}$ can be written then as

$$
\begin{equation*}
M_{i}=M_{i}\left(m_{s}, x, \epsilon\right)=\sum_{j=k}^{l} \epsilon^{j} I_{i j}\left(m_{s}, x\right) \tag{46}
\end{equation*}
$$

where $\epsilon$ is the usual regulator in dimensional regularization $(d=4-2 \epsilon)$ and the lowest power of $\epsilon$ in the sum can be -4 .

The crucial point now is that the derivative of any Feynman integral with respect to any kinematical variable is again a Feynman integral with possibly higher powers of denominators or numerators which can also be reduced anew in terms of the initial set of master integrals. This means that one can construct a partially triangular system of differential equations in the mass, which can subsequently be solved in the form of a power series expansion, with the expansion parameter in our case being $m_{s}$ following the conventions above.

Let us differentiate with respect to $m_{s}$ and $x$, we will then have respectively

$$
\begin{equation*}
m_{s} \frac{d}{d m_{s}} M_{i}\left(m_{s}, x, \epsilon\right)=\sum_{j} C_{i j}\left(m_{s}, x, \epsilon\right) M_{j}\left(m_{s}, x, \epsilon\right) \tag{47}
\end{equation*}
$$

and

$$
\begin{equation*}
x \frac{d}{d x} M_{i}\left(m_{s}, x, \epsilon\right)=\sum_{j} C_{i j}^{\prime}\left(m_{s}, x, \epsilon\right) M_{j}\left(m_{s}, x, \epsilon\right) \tag{48}
\end{equation*}
$$

We use Eq. 47) to obtain the mass corrections for the master integrals calculating the power series expansion up to order $m_{s}^{11}$ (see also Ref. [234] for more details). This deep expansion in $m_{s}$ should be sufficient for most of the phase space but still not enough to cover the whole allowed kinematical region. The way to proceed from this point is to numerically integrate the system of differential equations.

In particular, we choose to work with the master integrals in the form of Eq. 46, where the $\epsilon$ dependence is explicit. We can then work with the coefficients of the $\epsilon$ terms and accordingly have

$$
\begin{equation*}
m_{s} \frac{d}{d m_{s}} I_{i}\left(m_{s}, x\right)=\sum_{j} J_{i j}^{M}\left(m_{s}, x\right) I_{j}\left(m_{s}, x\right) \tag{49}
\end{equation*}
$$

and

$$
\begin{equation*}
x \frac{d}{d x} I_{i}\left(m_{s}, x\right)=\sum_{j} J_{i j}^{X}\left(m_{s}, x\right) I_{j}\left(m_{s}, x\right) \tag{50}
\end{equation*}
$$

where the Jacobian matrices $J^{M}$ and $J^{X}$ have rational function elements.

By using this last system of differential equations, one can obtain a full numerical solution to the problem. What we are essentially dealing now with is an initial value problem and the main requirement is to have the initial conditions to proper accuracy. The initial conditions, namely the values of the master integrals at a proper kinematical point which we call initial point, are provided by the power series expansion. The initial point has to be chosen somewhere in the high energy limit region, where $m_{s}$ is small and therefore, the values obtained by the power series are very accurate. Starting from there, one can evolve to any other point of the phase space by numerically integrating the system of differential equations Eq. (49) and Eq. (50).

We parametrise with a suitable grid of points the region close to threshold and then we calculate the master integrals for all points of the grid by evolving as described previously. Given that the master integrals have to be very smooth (we remain above all thresholds) one can use, after having the values for the grid points, interpolation to get the values at any point of the region. We use 1600 points for the grid and take as initial conditions the values of the master integrals at the point $m_{s}=5 \times 10^{-3}, x=1 / 4$. The relative errors at that point were estimated not to exceed $10^{-18}$.

The numerical integration is performed by using one of the most advanced software packages implementing the variable coefficient multistep method (ODEPACK) [235]. We use quadruple precision to maximise accuracy. The values at any single grid point can be obtained in about 15 minutes in average (with a typical 2 GHz Intel Core 2 Duo system) after compilation with the Intel Fortran compiler. The accuracy is around 10 digits for most of the points of the grid. It is also worth noting that in order to perform the numerical integration one needs to deform the contour in the complex plane away from the real axis. This is due to the fact that along the real axis there are spurious singularities. We use an elliptic contour and we achieve a better estimate of the final global error by calculating more than once for each point of the grid, using each time different eccentricities. Grids of solutions can actually be constructed, which will be subsequently interpolated when implemented as part of a Monte Carlo program.

One very stringent test we use to cross-check the correctness and also the accuracy of our calculation is to compare the infrared pole structure of our two-loop result against the one predicted by Catani [182] (see also Refs. [236, 237, 238]). According to Catani, the infrared poles of the interference of the tree and the two-loop amplitudes follow a generic formula which in our case, since we work with the rescaled variables $m_{s}$ and $x$, can be cast into the following form:

$$
\begin{equation*}
\mathcal{C}_{\text {atani }}^{(0 \times 2)}\left(m_{s}, x, \frac{s}{\mu}\right)=2 \operatorname{Re}\left\{\mathrm{I}^{(1)}(\mathrm{ffl})\left\langle\mathrm{M}^{(0)} \mid \mathrm{M}^{(1)}\right\rangle+\mathrm{I}^{(2)}(\mathrm{ff})\left\langle\mathrm{M}^{(0)} \mid \mathrm{M}^{(0)}\right\rangle\right\} \tag{51}
\end{equation*}
$$

where $\mathrm{M}^{(0)}$ and $\mathrm{M}^{(1)}$ are the tree level and one-loop amplitudes respectively and $\mu$ is the renormalization scale. The operators $\mathrm{I}^{(1)}(\mathrm{ffl})$ and $\mathrm{I}^{(2)}(\mathrm{ffl})$ encode the information for the infrared pole structure and their exact expressions can be found in Ref. [97].

The way to perform the test is straightforward. For each point of the grid with coordinates $\left(m_{s(i)}, x_{(i)}\right)$, we compute the numerical value of the two-loop amplitude $\left(\mathrm{M}^{(2)}\right)$ interfered with the tree level amplitude

$$
\begin{equation*}
\mathcal{A}^{(0 \times 2)}\left(m_{s(i)}, x_{i}, \frac{s}{\mu}\right)=\left\langle\mathrm{M}^{(0)} \mid \mathrm{M}^{(2)}\right\rangle+\left\langle\mathrm{M}^{(2)} \mid \mathrm{M}^{(0)}\right\rangle \tag{52}
\end{equation*}
$$

by numerically integrating the differential equations as described previously and we also calculate the numerical value of the quantity $\mathcal{C}_{\text {atani }}^{(0 \times 2)}\left(m_{s(i)}, x_{(i)}, \frac{s}{\mu}\right)$ by using Eq. 51). Then, all we need to make sure is that the infrared singularities of the quantity $\left\{\mathcal{A}^{(0 \times 2)}\left(m_{s(i)}, x_{i}, \frac{s}{\mu}\right)-\mathcal{C}_{\text {atani }}^{(0 \times 2)}\left(m_{s(i)}, x_{i}, \frac{s}{\mu}\right)\right\}$ cancel numerically for every point $\left(m_{s(i)}, x_{(i)}\right)$ of the grid (ultraviolet divergencies have been removed by renormalization). We will not present here any numbers since the aim was to describe the general methods. The details and the results of the study will be presented in a future publication [239].

### 5.4 CONCLUSIONS

W pair production via quark-anti-quark-annihilation is an important signal process in the search for New Physics as well as the dominant irreducible background for one of the main Higgs discovery channels: $H \rightarrow W W \rightarrow 4$ leptons. Therefore, the accurate knowledge of this process is essential for the LHC. After having calculated the two-loop and the one-loop-squared virtual QCD corrections to the W boson pair production in the high energy limit we proceed to the next step. Namely, we use a combination of a deep expansion in the W mass around the high energy limit and of numerical integration of differential equations to compute the two-loop amplitude with full mass dependence over the whole phase space. A strigent cross-check of our calculation is to verify that the infrared structure of our result agrees with the prediction of the Catani formalism for the infrared structure of QCD amplitudes.

## 6. COMPUTATION OF INTEGRATED SUBTRACTION TERMS NUMERICALLY ${ }^{8}$

#### Abstract

We report on a numerical representation of the integrated subtraction terms of the NNLO subtraction scheme defined in Refs. [240, 241, 242, 243]. The integrated approximate cross sections themselves can be written as products of insertion operators (in colour space) times the Born, or the one-loop cross section. The insertion operator is constructed from the numerical representation of the integrated subtraction terms. We give selected results for the integrated doubly-collinear subtraction term.

### 6.1 INTRODUCTION

We consider the NNLO correction to a generic $m$-jet observable,

$$
\begin{equation*}
\sigma^{\mathrm{NNLO}}=\int_{m+2} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}} J_{m+2}+\int_{m+1} \mathrm{~d} \sigma_{m+1}^{\mathrm{RV}} J_{m+1}+\int_{m} \mathrm{~d} \sigma_{m}^{\mathrm{VV}} J_{m} . \tag{53}
\end{equation*}
$$

The three contributions on the right hand side are separately divergent in $d=4$ dimensions, but their sum is finite for IR safe observables. To obtain the finite NNLO correction, we first continue analytically all integrals to $d=4-2 \epsilon$ dimensions and then rewrite Eqn. (53) as

$$
\begin{equation*}
\sigma^{\mathrm{NNLO}}=\int_{m+2} \mathrm{~d} \sigma_{m+2}^{\mathrm{NNLO}}+\int_{m+1} \mathrm{~d} \sigma_{m+1}^{\mathrm{NNLO}}+\int_{m} \mathrm{~d} \sigma_{m}^{\mathrm{NNLO}} \tag{54}
\end{equation*}
$$

that is a sum of three integrals where the integrands,

$$
\begin{gather*}
\mathrm{d} \sigma_{m+2}^{\mathrm{NNLO}}=\left\{\mathrm{d} \sigma_{m+2}^{\mathrm{RR}} J_{m+2}-\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{2}} J_{m}-\left[\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}} J_{m+1}-\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{12}} J_{m}\right]\right\}_{\epsilon=0},  \tag{55}\\
\mathrm{~d} \sigma_{m+1}^{\mathrm{NNLO}}=\left\{\left[\mathrm{d} \sigma_{m+1}^{\mathrm{RV}}+\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}}\right] J_{m+1}-\left[\mathrm{d} \sigma_{m+1}^{\mathrm{RV}, \mathrm{~A}_{1}}+\left(\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}}\right)^{\mathrm{A}_{1}}\right] J_{m}\right\}_{\epsilon=0}, \tag{56}
\end{gather*}
$$

and

$$
\begin{equation*}
\mathrm{d} \sigma_{m}^{\mathrm{NNLO}}=\left\{\mathrm{d} \sigma_{m}^{\mathrm{VV}}+\int_{2}\left[\mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{2}}-\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{12}}\right]+\int_{1}\left[\mathrm{~d} \sigma_{m+1}^{\mathrm{RV}, \mathrm{~A}_{1}}+\left(\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}}\right)^{\mathrm{A}_{1}}\right]\right\}_{\epsilon=0} J_{m}, \tag{57}
\end{equation*}
$$

[^122]are integrable in four dimensions by construction. The approximate cross sections $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{2}}$ and $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}$ regularise the doubly- and singly-unresolved limits of the real-emission contribution, $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}}$ respectively. The double subtraction due to the overlap of these two terms is compensated by $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{12}}$. These terms are given explicitly in Ref. [242]. Finally, $\mathrm{d} \sigma_{m+1}^{\mathrm{RV}, \mathrm{A}_{1}}$ and $\left(\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}\right)^{\mathrm{A}_{1}}$ regularise the singly-unresolved limits of $\mathrm{d} \sigma_{m+1}^{\mathrm{RV}}$ and $\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}$ respectively. They are given explicitly in Ref. [243].

The construction of each approximate cross section in Eqns. (55-57) is based on the known and universal IR limits of tree level and one-loop squared matrix elements, and proceeds in two steps. First, the IR factorisation formulae are written in such a way that their complicated overlap structure can be disentangled ("matching of limits") [240, 244]. Second, we define "extensions" of the formulae, so that they are unambiguously defined away from the strict IR limits [241, 242, 243]. These extensions are defined by the use of various momentum mappings that map a set of $m+1$ or $m+2$ momenta into a set of $m$ momenta,

$$
\begin{equation*}
\{p\}_{m+1} \longrightarrow\{\tilde{p}\}_{m} \quad \text { and } \quad\{p\}_{m+2} \longrightarrow\{\tilde{p}\}_{m} \tag{58}
\end{equation*}
$$

such that (i) the delicate structure of cancellations among the matched limit formulae in various limits is respected (ii) exact momentum conservation is implemented, and (iii) the original $m+1$ or $m+2$ particle phase space factorises exactly into the product of an $m$ particle phase space and a one- or two-particle phase space measure,

$$
\begin{equation*}
\mathrm{d} \phi_{m+r}\left(\{p\}_{m+r} ; Q\right)=\mathrm{d} \phi_{m}\left(\{\tilde{p}\}_{m} ; Q\right)\left[\mathrm{d} p_{r, m}\right], \quad r=1,2 . \tag{59}
\end{equation*}
$$

To finish the definition of the scheme, one must compute once and for all the one- and two-particle integrals, denoted formally as $\int_{1}$ and $\int_{2}$, appearing in Eqns. 5657 .

In general the integrated subtraction terms are integrals of extensions over the whole phase space of combinations of the QCD splitting functions and squared soft currents. In this proceedings we discuss two examples: (i) the singly-collinear subtractions $\mathcal{C}_{i r}^{(\ell, 0)}$ and (ii) the doubly-collinear subtractions $\mathcal{C}_{i r, j s}^{(0,0)}$, which are part of $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}$ and $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{2}}$ in Eqn. 55 , respectively. The precise definitions of these terms can be found in Ref. [242]. The meaning of the superscript is irrelevant for our present purpose (also explained in Ref. [242]).

Denoting a generic subtraction term by $\mathcal{X}^{(\ell, k)}$ (such as $\mathcal{C}_{i r}^{(\ell, 0)}$ ) the integrated counterterms can be written in the following general form:

$$
\begin{equation*}
\int_{r} \mathcal{X}^{(\ell, k)}=\left[\frac{\alpha_{\mathrm{s}}}{2 \pi} S_{\epsilon}\left(\frac{\mu^{2}}{Q^{2}}\right)^{\epsilon}\right]^{r+\ell} N_{X}(\epsilon) X^{(\ell)}(x, \ldots) \operatorname{Re}\left\langle\mathcal{M}_{m}^{(0)}(\{\tilde{p}\})\right| \boldsymbol{T}_{i} \cdot \boldsymbol{T}_{j} \ldots\left|\mathcal{M}_{m}^{(k)}(\{\tilde{p}\})\right\rangle, \tag{60}
\end{equation*}
$$

where $S_{\epsilon}=(4 \pi)^{\epsilon} / \Gamma(1-\epsilon)$, and $X^{(\ell)}(x, \ldots)$ represents a function that depends on kinematical invariants of the factorized $m$-parton phase space. It results in the integration of the subtraction term $\mathcal{X}^{(\ell, k)}$ over the factorized phase spaces [ $\mathrm{d} p_{r, m}$ ] in Eqn. 59). In a NNLO computation the possible cases are $r+\ell+k=1$ with $\ell+k=0$ or 1 , and $r=2$ with $\ell+k=0$. We use the colour- and spin-state notation of Ref. [236], when the amplitude for a scattering process involving $m$ final-state momenta, $\left|\mathcal{M}_{m}^{(k)}\right\rangle$, is an abstract vector in colour and spin space; $k$ denotes the number of loops. Colour interactions at QCD vertices are represented by associating colour charges $\boldsymbol{T}_{i}$ with the emission of a gluon from each parton $i$. There are $2 r$ such colour charges. Then the functions $X^{(\ell)}$ are dimensionless in colour-space. For certain subtraction terms, universal, possibly $\epsilon$-dependent numerical factors, $N_{X}(\epsilon)$ appear naturally, which can be factored out. Our purpose is to compute all functions $X^{(\ell)}$, which we discuss next.

### 6.2 INTEGRATING THE COUNTERTERMS

The actual computation of the integrated counterterms leads to a large number of multi-dimensional integrals. The ultimate goal is to find the analytical form of the coefficients of a Laurent expansion (in
$\epsilon$ ) of these integrals, which turns out to be a rather tedious job. In order to compute these coefficients as efficiently as possible, we have explored several methods.

First, it is possible to extend the method of integration-by-parts identities and solving of differential equations, developed for computing multi-loop Feynman integrals [245, 246], to the relevant phase space integrations [247]. This method yields $\epsilon$-expansions with fully analytical coefficients, with the final results being expressed in terms of two-dimensional harmonic polylogarithms (after a suitable basis extension, see Ref. [247] for details). This approach was used successfully to compute a class of singlyunresolved integrals [247].

Second, the phase space integrals that arise can be computed via the method of Mellin-Barnes (MB) representations [228, 229, 248]. Here we obtain the $\epsilon$-expansion coefficients in terms of complex contour integrals over $\Gamma$-functions. Performing these integrals by the use of the residue theorem, a representation in terms of harmonic sums is obtained. In many cases, the sums can be evaluated in a closed form, yielding an analytical result. In some instances however, we find multi-dimensional MB integrals that are very difficult to compute fully analytically. Nevertheless, in these situations a direct numerical evaluation of the appropriate MB representations provides a fast and reliable way to obtain final results with small numerical uncertainties. We stress that for phenomenological applications, this is all that is required, since the numerical uncertainty of the complete computation is dominated by the phase space integrations. We have used the MB method to compute all singly-unresolved integrals [249], and all two-particle integrals appearing in $\int_{2} \mathrm{~d} \sigma_{m+2}^{R R, A_{12}}$ as well [91].

Finally, the method of iterated sector decomposition [250] can also be used to calculate the integrals we encounter [251]. Sector decomposition produces a representation of the $\epsilon$-expansion where the coefficients are given in terms of (mostly quite cumbersome) finite integrals over the unit hypercube. The analytical evaluation of these integrals is not feasible except for the simplest cases. Nevertheless, this method is simple to implement and can be automated to a large extent. In fact there are several computer programs that use various implementations of sector decomposition to provide numerical values of coefficients of the powers of $\epsilon$ in the Laurent expansion of dimensionally regulated integrals [252, 253, 254]. We found the program $\operatorname{SecDec}$ powerful and flexible to generate sufficiently precise values of our integrated subtraction terms.

Choosing the Cuhre integrator implemented in SecDec, we can easily reach $10^{-7}$ relative precision for the integration. Such precision is sufficient for our purposes: (i) to demonstrate the cancellation of the $\epsilon$ poles numerically, and (ii) to compute the finite integrals in Eqns. (56) and (57). As the numerical uncertainty of the second item is limited more by the Monte Carlo integration over the $m+1$ and $m$ particle phase spaces, for item (ii) much lower (not better than $10^{-3}$ ) precision is sufficient. This looser requirement on the precision for the $\mathrm{O}(1)$ terms and the fact that the integrated subtraction terms are smooth functions of their parameters, with logarithmic behaviour for asymptotically small values of the parameters, makes possible that we find sufficient approximations to the integrated subtraction terms.

### 6.3 APPROXIMATE INTEGRATED SUBTRACTION TERMS

The computation of the integrated subtraction terms at any given values of the kinematical parameters, as required in the Monte Carlo integration over the phase space, is not feasible. In order to demonstrate the cancellation of the $\epsilon$ poles numerically we can choose several randomly selected phase space points and evaluate the necessary integrals with high precision. The cancellation cannot depend on the particular phase space point. In the case of the finite remainders, in order to compute the phase space integrals in Eqns. 56 ) and (57), we are able to find sufficiently precise approximations to the integrated subtraction terms using a procedure that can be automated to high degree. The latter point is also important as there are several hundred integrals to compute. In the following, we outline our procedure for two cases: (i) an example with integrals depending on one kinematical parameter, $\left(\int_{1} \mathcal{X}^{(\ell, k)}=\int_{1} \mathcal{C}_{i r}^{(\ell, 0)}\right)$ and (ii) another example with integrals depending on two kinematical parameters, $\left(\int_{2} \mathcal{X}^{(\ell, k)}=\int_{2} \mathcal{C}_{i r, j s}^{(0,0)}\right)$.

In order to compute $\int_{1} \mathcal{C}_{i r}^{(\ell, 0)}$, we have to integrate the azimuthally averaged Altarelli-Parisi splitting functions $P_{f_{i} f_{r}}^{(\ell)}\left(z_{i, r}, z_{r, i} ; \epsilon\right)$ in $4-2 \epsilon$ dimensions for the splitting process $f_{i r} \rightarrow f_{i}+f_{r}$, with $z_{i}$ being the momentum fraction of parton $f_{i}$. It was discussed in Ref. [249] that the corresponding functions $C_{i r}^{(\ell)}$ can be expressed as combinations of the integrals (we changed the notation from $\mathcal{I}$ to $\mathcal{I}_{C}$ )

$$
\begin{equation*}
\mathcal{I}_{C}\left(x ; \epsilon, \alpha_{0}, d_{0}, \kappa, k, \delta, g_{I}^{( \pm)}\right)=\frac{16 \pi^{2}}{S_{\epsilon}} Q^{2 \epsilon} \int_{1}\left[\mathrm{~d} p_{1, m+1}^{(i r)}\right] \frac{z_{r}^{k+\delta \epsilon}}{s_{i r}^{1+\kappa \epsilon}} g_{I}^{( \pm)}\left(z_{r}\right) f\left(\alpha_{0}, \alpha_{i r}, d(m, \epsilon)\right) . \tag{61}
\end{equation*}
$$

In terms of explicit integration variables these collinear integrals have the general form [249]

$$
\begin{align*}
& \mathcal{I}_{C}\left(x ; \epsilon, \alpha_{0}, d_{0} ; \kappa, k, \delta, g_{I}^{( \pm)}\right)=x \int_{0}^{\alpha_{0}} \mathrm{~d} \alpha \alpha^{-1-(1+\kappa) \epsilon}(1-\alpha)^{2 d_{0}-1}[\alpha+(1-\alpha) x]^{-1-(1+\kappa) \epsilon} \\
& \quad \times \int_{0}^{1} \mathrm{~d} v[v(1-v)]^{-\epsilon}\left(\frac{\alpha+(1-\alpha) x v}{2 \alpha+(1-\alpha) x}\right)^{k+\delta \epsilon} g_{I}^{( \pm)}\left(\frac{\alpha+(1-\alpha) x v}{2 \alpha+(1-\alpha) x}\right) . \tag{62}
\end{align*}
$$

The necessary functions $g_{I}^{( \pm)}$are listed in Ref. [249], where analytic results of these integrals for $\alpha_{0}=1$ and $d_{0}=3$ are also presented.

Our present goal is to provide sufficiently precise numerical approximations to the functions $\mathcal{I}_{C}(x)$ in a simple way. The motivation is that often it is difficult to perform the analytic computation with arbitrary values of the parameters. For instance, the derivation with $\alpha_{0}=1$ is rather different from a derivation with $\alpha_{0}<1$. Also, the choice for $d_{0}$ is to some extent arbitrary, and a new choice requires a completely new analytic computation. Thus, for the sake of flexibility we propose a fully numerical approach here.

First we used the program SecDec, modified such that it can compute the value of the integral at multiple values of the parameter $x$ in a single run. For simplicity, we call the $\mathrm{O}(1)$ terms of the integral 'measurements'. Then, inspired by the analytic results in Ref. [249], we fitted these measurements by combinations of logarithms and polynomials in $x$ of the form

$$
\begin{equation*}
\mathcal{F}_{C}\left(x ; \kappa=0, k, \delta=0, g_{I}^{( \pm)}=1\right)=\sum_{n=0}^{n_{\max }} P_{n}^{(m)}(x, k) \log ^{n}(x), \quad P_{n}^{(m)}(x, k)=\sum_{n=0}^{m} a_{n}^{(k)} x^{n} \tag{63}
\end{equation*}
$$

where the upper limit $n_{\max }$ is determined by the power $-n_{\text {max }}$ of the leading pole in the Laurentexpansion (in $\epsilon$ ) of the integral. As for the degree of the polynomials we tried several simple choices ( $m=1,2,3$ ). We found that splitting the region of the parameter space into an asymptotic ( $0<x \leq$ $10^{-4}$ ) and a non-asymptotic ( $10^{-4}<x \leq 1$ ) region, we could provide a fit with $m=2$ that approximates the analytic result within relative difference few times $10^{-4}$. The loss of relative precision is associated with phase space points where the function changes sign, and its numerical value is close to zero (around $x=0.2$ ).

In Fig. 8 we show the approximate function $\mathcal{F}_{C}\left(x ; \alpha_{0}, d_{0}, 0,-1,0,1\right)$ together with the 'measurements', which coincide with the known exact analytic result to at least six digit accuracy. We find very good agreement, which is characterized by the ratio of the two values in the lower panels. In Fig. 8 b we show the approximate function for $\alpha_{0}=0.1$ and $d_{0}=3-3 \epsilon$ together with the corresponding 'measurements'. In this case the analytic results are not available.

Building on the experience gained in studying the one-parameter case, we worked out a similar strategy for the integrated subtraction term $\int_{2} \mathcal{C}_{i r, j s}^{(0,0)}$. The corresponding functions $C_{i r, j s}^{(0,0)}$ can be ex-

Fig. 8: The fitted function $\mathcal{F}_{C}(x ; 0,-1,0,1)$ compared to the integral $\mathcal{I}(x ; 0,-1,0,1)$ at a) $\alpha_{0}=1$ and $d_{0}=3$, b) $\alpha_{0}=0.1$ and $d_{0}=3-3 \epsilon$.
pressed as combination of the integrals

$$
\begin{align*}
& \mathcal{I}_{2 C}\left(x_{i}, x_{j} ; \epsilon, \alpha_{0}, d_{0} ; k, l\right)=x_{i} x_{j} \int_{0}^{1} \mathrm{~d} \alpha \int_{0}^{1} \mathrm{~d} \beta \Theta\left(\alpha_{0}-\alpha-\beta\right) \\
& \quad \times(1-\alpha-\beta)^{2 d_{0}-2(1-\epsilon)} \alpha^{-1-\epsilon} \beta^{-1-\epsilon}\left(\alpha+(1-\alpha-\beta) x_{i}\right)^{-1-\epsilon}\left(\beta+(1-\alpha-\beta) x_{j}\right)^{-1-\epsilon} \\
& \quad \times \int_{0}^{1} \mathrm{~d} v v^{-\epsilon}(1-v)^{-\epsilon} \int_{0}^{1} \mathrm{~d} u u^{-\epsilon}(1-u)^{-\epsilon}\left(\frac{\alpha+(1-\alpha-\beta) x_{i} v}{2 \alpha+(1-\alpha-\beta) x_{i}}\right)^{k}\left(\frac{\beta+(1-\alpha-\beta) x_{j} u}{2 \beta+(1-\alpha-\beta) x_{j}}\right)^{l} . \tag{64}
\end{align*}
$$

We again run SecDec with $\alpha_{0}=0.1$ and $d_{0}=3-3 \epsilon$ at several hundred different values of the kinematic parameters to obtain the 'measurements'. To reach $10^{-7}$ relative precision for all such 'measurements' takes several hours on a single CPU. Then we fitted these 'measurements' with the function

$$
\begin{equation*}
\mathcal{F}_{2 C}\left(x_{i}, x_{j} ; k, l\right)=\sum_{n_{i}=0}^{n_{\max }} \sum_{n_{j}=0}^{n_{\max }-n_{i}} P_{n_{i}}^{(m)}\left(x_{i}, k, l\right) P_{n_{j}}^{(m)}\left(x_{j}, k, l\right) \log ^{n_{i}}\left(x_{i}\right) \log ^{n_{j}}\left(x_{j}\right) . \tag{65}
\end{equation*}
$$

We divide the parameter space $0<x_{i}, x_{j} \leq 1$ into four regions: (i) $0<x_{i}, x_{j} \leq 10^{-4}$, (ii) $0<x_{i} \leq$ $10^{-2}$ and $10^{-4}<x_{j} \leq 1$, (iii) $0<x_{j} \leq 10^{-2}$ and $10^{-4}<x_{i} \leq 1$, (iv) $10^{-2}<x_{i}, x_{j} \leq 1$. Using $m=2$, we are able to fit the original function $\mathcal{I}_{2 C}$ to per mille precision almost everywhere. The ratio of the fitted function $\mathcal{F}_{2 C}$ to the numerical evaluation of $\mathcal{I}_{2 C}$ is shown in Fig. 9 together whith the fitted function $\mathcal{F}_{2 C}$ itself.

## CONCLUSIONS

We have worked out a numerical procedure for providing simple approximations of the integrated subtraction terms of the NNLO subtraction scheme defined in Refs. [240, 241, 242, 243]. We use the publicly available program SecDec to compute the coefficients of the Laurent expansion of the necessary integrals to high numerical precision. We found that the integrals that depend on one or two kinematical invariants can be approximated with simple combinations of polynomials and logarithms. The precision of these approximations is usually at per mille or better.

## PARTON DISTRIBUTION FUNCTIONS

## 7. WHICH EXPERIMENTS CONSTRAIN THE GLUON PDF IN A GLOBAL QCD FIT? 9

#### Abstract

Based on computation of PDF-induced correlations, we identify the experiments in CTEQ and MSTW global QCD analyses that are sensitive to the gluon parton density in the proton. The Tevatron inclusive jet production at large momentum fractions $x$ and DIS charm quark production at moderately small $x$ show the strongest correlation with the gluon PDF. The strength of the PDF-induced correlation between the gluon PDF and inclusive (di)jet production data is different in the CTEQ and MSTW analyses.

### 7.1 Introduction

The parton distribution function (PDF) of gluons in a proton, $g(x, \mu)$, plays an important role in hadron collider phenomenology. It arises in cross sections for production of hadronic final states, massive scalar

[^123]

Fig. 10: CT10 and CTEQ 6.6 PDF uncertainty bands at $\mu=2 \mathrm{GeV}$ (left) and 100 GeV (right), taken from Ref. [255]. The CTEQ 6.6 best-fit PDFs and uncertainties are indicated by solid curves and hatched bands, while those of CT10 are indicated by dashed curves and dotted bands.
bosons, and hypothetical elementary particles, often in a combination with an overall normalization prefactor proportional to $\alpha_{s}$. The gluon distributions from CT10 [255] and CTEQ 6.6 [256] PDF sets are shown in Fig 10. The figure shows that the gluon PDF is constrained well by fitted experiments at the intermediate momentum fractions $x$, but the uncertainty grows in the region $x>0.1$. We may ask which experiments in the global fit impose the most significant constraints on the the gluon PDF. It is often said that the precise neutral-current DIS data provides the tightest constraints on the gluon PDF at $x$ of order $10^{-3}$, while inclusive jet production at the Tevatron plays the key role in constraining the gluon at $x>0.1$. However, the net PDF uncertainty reflects subtle interplay of numerous constraints imposed by QCD theory and multiple experiments, as well as various correlated uncertainties in experimental measurements. In this contribution, we identify the experiments with the strongest sensitivity to the gluon PDF by using a method of PDF-induced correlations that was developed in Refs. [256, 257, 258]. The analysis of correlations provides a systematic way to identify such experiments and also to establish specific ranges of $x$ and $Q$ where the correlations of the experimental data sets with the gluon PDF are the most pronounced.

### 7.2 Log-likelihood $\chi^{2}$ and PDF-induced correlations

The quality of theory description of an experimental data set can be quantified by the log-likelihood function $\chi^{2}$. Many high-energy physics experiments publish three kinds of measurement errors for each data point $i$ : the statistical error $\sigma_{i}$, uncorrelated systematic error $u_{i}$, and correlated systematic errors $\left\{\beta_{1 i}, \beta_{2 i}, \beta_{3 i} \ldots . \beta_{K i}\right\}$ of $K$ different types. To compare a theory prediction $T_{i}$ to the data value $D_{i}$ for a data point $i$, while accounting for all types of errors, the $\chi^{2}$ function can be constructed as [259, 260]

$$
\begin{equation*}
\chi^{2}=\sum_{\text {expt. }}\left[\sum_{i=1}^{N_{e}}\left(\frac{D_{i}-T_{i}(a)-\sum_{k=1}^{K} r_{k} \beta_{k i}}{\alpha_{i}^{2}}\right)^{2}+\sum_{k=1}^{K} r_{k}^{2}\right] \tag{66}
\end{equation*}
$$

where $\alpha_{i}^{2}=\sigma_{i}^{2}+u_{i}^{2}$ is the combined uncorrelated error; $r_{k}$ are random parameters describing each of $K$ correlated errors (each distributed according to the standard normal distribution); $N_{e}$ is the number of
the data points; and $K$ is the number of the sources of the correlated systematic errors.
Analytic minimization of the function (66) with respect to the correlated systematic parameters $r_{k}$ renders the following result [257, 259]:

$$
\begin{equation*}
\left.r_{k}\right|_{\text {best fit }}=\sum_{k^{\prime}=1}^{K} A_{k k^{\prime}}^{-1} B_{k^{\prime}}, \tag{67}
\end{equation*}
$$

where $A_{k k^{\prime}}$ and $B_{k}$ are given by

$$
\begin{equation*}
A_{k k^{\prime}}=\delta_{k k^{\prime}}+\sum_{i=1}^{N_{e}} \frac{\beta_{k i} \beta_{k^{\prime} i}}{\alpha_{i}^{2}}, \quad \text { and } \quad B_{k}=\sum_{i=1}^{N_{e}} \frac{\beta_{k i}\left(D_{i}-T_{i}\right)}{\alpha_{i}^{2}} . \tag{68}
\end{equation*}
$$

Substituting Eq. 67] into Eq. (66], we obtain a reduced $\chi^{2}$ function [257, 259],

$$
\begin{equation*}
\chi^{2}=\sum_{\text {expt. }}\left[\sum_{i=1}^{N_{e}} \frac{\left(D_{i}-T_{i}\right)^{2}}{\alpha_{i}^{2}}-\sum_{k, k^{\prime}=1}^{K} B_{k} A_{k k^{\prime}}^{-1} B_{k^{\prime}}\right] . \tag{69}
\end{equation*}
$$

In this function, the information about the systematic shifts in $r_{k}$ is included implicitly. Often, the influence of the correlated shifts on the PDFs is substantial.

Next, we wish to discuss correlations between PDF uncertainties of two variables, $X(\vec{a})$ and $Y(\vec{a})$, where $\vec{a}=\left\{a_{1}, a_{2}, \ldots, a_{N}\right\}$ is the vector of $N$ PDF parameters. The correlations can be computed either in the Hessian [256, 257, 258] or Monte-Carlo [261] approaches. In this note we will adopt the Hessian approach.

A symmetric PDF uncertainty $\Delta X$ corresponds to the maximal variation of $X$ for all combinations of PDF parameters that lie within the tolerance hypersphere $\Delta \chi^{2} \leq T^{2}$. This uncertainty is given by

$$
\begin{equation*}
\Delta X=\frac{1}{2} \sqrt{\sum_{i=1}^{N}\left[X_{i}^{+}-X_{i}^{-}\right]^{2}} \tag{70}
\end{equation*}
$$

in terms of the value $X_{0}$ of $X$ obtained with the central PDF set, and values $X_{i}^{+}$and $X_{i}^{-}$of $X$ obtained for maximal positive and negative displacements of each orthonormal PDF parameter $a_{i}$ within the tolerance hypersphere. The same "master equation" defines $\Delta Y$, the PDF uncertainty of the variable $Y$.

In the linear approximation, the pairs of values of $X$ and $Y$ that are allowed within the PDF uncertainty correspond to the points inside an ellipse in the $X-Y$ plane. The boundary of the ellipse is parametrically described by

$$
\begin{align*}
& X=X_{0}+\Delta X \cos \theta  \tag{71}\\
& Y=Y_{0}+\Delta Y \cos (\theta+\varphi) \tag{72}
\end{align*}
$$

where the parameter $\theta$ varies between 0 and $2 \pi$, and the relative phase angle $\varphi$ is a function of $X_{i}^{ \pm}$and $Y_{i}^{ \pm}$. The PDF uncertainties $\Delta X$ and $\Delta Y$ are calculated according to Eq. 70). The angle $\varphi$ is included between the gradients $\vec{\nabla} X$ and $\vec{\nabla} Y$ of $X$ and $Y$ in the PDF parameter space. Its cosine,

$$
\begin{equation*}
\cos \varphi=\frac{\vec{\nabla} X \cdot \vec{\nabla} Y}{\Delta X \Delta Y}=\frac{1}{4 \Delta X \Delta Y} \sum_{i=1}^{N}\left(X_{i}^{(+)}-X_{i}^{(-)}\right)\left(Y_{i}^{(+)}-Y_{i}^{(-)}\right) \tag{73}
\end{equation*}
$$

quantifies the degree of similarity in the PDF dependence of $X$ and $Y$. If $X$ and $Y$ are strongly correlated (corresponding to $\cos \varphi \rightarrow 1$ ) or anti-correlated $(\cos \varphi \rightarrow-1)$, the PDF uncertainties of $X$ and $Y$ are driven by essentially the same combinations of PDF parameters. Conversely, the PDF dependence of $X$ is independent from the PDF dependence of $Y$ if $\cos \varphi \approx 0$.

### 7.3 Which experiments are sensitive to the gluon PDF?

If an experimental cross section $\sigma$ strongly constrains a PDF $f_{a}(x, Q)$ for some combination of $x$ and $Q$, we expect that Eq. $\sqrt{73} \mid$ returns $|\cos \varphi|$ close to unity when using $X=f_{a / A}(x, Q)$ and $Y=\sigma$. If the experimental data set includes several data points, we can use $Y=\chi^{2}$. The strength of the constraint on the PDF from this experiment is determined by $|\cos \varphi|$ and the magnitude of $\chi^{2}$. In the majority of the fitted experiments, $\chi^{2} / N_{e}$ is close to 1 , so that $|\cos \varphi|$ tends to be more important for distinguishing between the sensitivities of the experiments than the magnitude of $\chi^{2}$.

Following this approach, we compute $\cos \varphi$ between the NLO gluon PDF $g(x, Q)$ in various $x$ ranges (for $Q^{2}=10 \mathrm{GeV}^{2}$ ), and $\chi^{2}$ for typical experimental data sets that are used in the PDF analysis. In this study, we compute $\cos \varphi$ for the experiments from the CT10 analysis that are listed in Table 4 . In the figures, we refer to each experiment by its numerical ID that is shown in the left column of Table 4 .

The $\cos \varphi$ values between the gluon PDF at a given $x$ value and $\chi^{2}$ for each experiment are plotted as two-dimensional contour plots for CT10 NLO PDFs [255] in the left panel of Fig. [11, and for MSTW' 08 NLO PDFs [262] in the right panel. The horizontal axis indicates the range of $x$ in $g(x, Q)$. The vertical axis indicates the ID of the experiment. At the bottom of the figure, we show the color legend adopted to draw the contour plots. The color legend is chosen so as to emphasize only cells with large correlation ( $\cos \varphi>0.5$, dark yellow-red colors) or large anticorrelation ( $\cos \varphi<-0.5$, blue colors). The regions with $|\cos \varphi|<0.5$ are filled with a light-yellow color. The $\chi^{2}$ values for each data set are computed according to Eqs. (66) and (69) using the CTEQ fitting code for both CT10 and MSTW PDF sets.

Visual inspection of two panels of Fig. 11 reveals both similarities and differences in the pattern of correlations of the gluon PDF in the CT10 and MSTW PDF sets. In the case of the CT10 PDF (left panel), the gluon PDF has a pronounced anti-correlation (blue spots) with HERA charm and bottom SIDIS production data sets (experiments $140,143,145,156,157$ ) at $x<0.1$, as well as with Tevatron inclusive jet production data sets (experiments $504,505,514$, and 515) at $x>0.05$. Some correlations (brown and red spots) are also observed, but they are not as pronounced as the anti-correlations. Weaker (anti-)correlations can be noticed with the NMC $F_{2}^{p}$, CDHSW $F_{2}^{p}$, and E605 pp Drell-Yan process data, corresponding to experiments 103, 108, and 201.

While the gluon PDF of the MSTW'08 set (right panel of Fig. 11) also shows an (anti-)correlation with the heavy-quark DIS and jet production data, the overall pattern of the correlations is somewhat different from the CT10 case. Here, the gluon PDF is mostly correlated with high- $x$ jet production (experiments 504, 505,514, and 515), while it is either correlated or anti-correlated with heavy-quark DIS experiments (experiments 140, 143, 145, 156, 157). In addition, we observe significant (anti-)correlations with the combined HERA DIS data set ( $\mathrm{ID}=159$ ) and fixed-target DIS experiments ( $\mathrm{ID}=101-124$ ) that are not seen in the CT10 panel.

We now turn to the correlations of the gluon and $u$-quark PDFs with $\chi^{2}$ values in individual bins of Tevatron inclusive jet and dijet production data. For this purpose, we represent $\chi^{2}$ for one experimental data set in Eq. 69 as a sum of contributions $\chi_{i}^{2}$ from individual data points $i$ :

$$
\begin{equation*}
\chi^{2}=\sum_{i=1}^{N_{e}} \chi_{i}^{2}, \tag{74}
\end{equation*}
$$

where

$$
\begin{equation*}
\chi_{i}^{2}=\frac{D_{i}-T_{i}}{\alpha_{i}} \sum_{j=1}^{N_{e}}\left\{\delta_{i j}-\frac{D_{j}-T_{j}}{\alpha_{j}} \sum_{k, k^{\prime}=1}^{K} \frac{\beta_{k i}}{\alpha_{i}} A_{k k^{\prime}}^{-1} \frac{\beta_{k^{\prime} j}}{\alpha_{j}}\right\} . \tag{75}
\end{equation*}
$$

Each contribution $\chi_{i}^{2}$ accounts for the effect of correlated systematic shifts through the term that includes $A_{k k^{\prime}}^{-1}$ on the right-hand side of Eq. 75 . Again, the constraining power of each point is determined both

Table 4: Experimental data sets examined in this analysis.

Fig. 12: Correlation cosine between $\chi_{i}^{2}$ in each $p_{T}$ bin from D $\emptyset$ Run- 2 inclusive jet production and gluon and $u$ quark distributions from CT10 and MSTW 2008 NLO sets. The horizontal axis refers to the $x$ value in the PDF. The vertical axis indicates the numerical ID of the experimental bin for which $\chi^{2}$ is computed. The ID for each bin is indicated as $100 i_{y}+i_{p_{T}}$, where $i_{y}=1, \ldots 6$ and $i_{p_{T}}$ are the ID's of the corresponding rapidity interval and the $p_{T}$ interval, respectively.

Fig. 13: Correlation cosine between $\chi_{i}^{2}$ in each $m_{j j}$ bin from D $\emptyset$ Run-2 dijet production and gluon and $u$ quark distributions from CT10 and MSTW 2008 NLO sets. The horizontal axis refers to the $x$ value in the PDF. The vertical axis indicates the numerical ID of the experimental bin for which $\chi^{2}$ is computed. The ID for each bin is indicated as $100 i_{y_{\max }}+i_{m_{j j}}$, where $i_{y_{\max }}=1, . ., 6$ and $i_{m_{j j}}$ are the ID's of the corresponding intervals in $y_{\max }$ and $m_{j j}$, respectively.
by the value of $|\cos \varphi|$ and the magnitude of $\chi_{i}^{2}$, with the latter being comparable to unity for the majority of the data points.

For D $\emptyset$ Run-2 single-inclusive jet cross sections [287], we plot the $\cos \varphi$ values for the gluon and $u$-quark PDFs, with $\chi_{i}^{2}$ computed for each bin of the jet's transverse momentum $p_{T}$ and rapidity $y$. The resulting contour plots are shown in Fig. 12. Similarly, for DØ Run-2 dijet cross sections [289], Fig. 13 shows the contour plots of $\cos \varphi$ for $\chi_{i}^{2}$ in the bins of of dijet invariant mass $m_{j j}$ and maximal absolute rapidity $|y|=\max \left(\left|y_{1}\right|,\left|y_{2}\right|\right)$ of the dijets. In both figures, theory cross sections are computed at NLO (without threshold resummation corrections) with the FASTNLO code [290, 291], using the settings described in Section 13. The same color legend as in Fig. 11 is used. Similar patterns of correlations were found with the CDF Run-2 inclusive jet data (not shown).

The upper panels in both figures show $\cos \varphi$ for CT 10 NLO and MSTW' 08 NLO gluon PDFs. The correlated experimental errors modify the correlations by smearing the $\cos \varphi$ distribution. The pattern of $\cos \varphi$ indicates clearly that the (di)jet data are very sensitive to the gluon at $x$ above 0.01 . However, the correlation is weaker for the CT10 gluon PDF (left panel) then for MSTW'08 PDF (right panel), suggesting that the importance of the constraints on the gluon PDF from the jet data is not the same in two fits. In addition, the MSTW'08 $u$-quark PDF shows mild (anti-)correlation with both single-inclusive jet data and dijet data, as can be observed in the right lower panels in Figs. 12 and 13 . No pronounced (anti-)correlations with the $u$-quark PDF or other quark PDFs of physical flavors are observed for the CT10 set, shown in the lower left panels.

The contour plots confirm the expectation that the inclusive jet data play an important role in constraining the gluon PDF. While the constraints are strongest at $x>0.1$, they extend down to $x$ as low as 0.05 for both CT10 and MSTW sets, as can be observed in Figs. 12 and 13 . The gluon PDF is sensitive to constraints from heavy-quark semi-inclusive DIS production at even lower $x$ values, cf. Fig. 11. As the HERA data on heavy-quark DIS production continue to improve, it will play an increasingly important role in constraining the low- $x$ gluon density.

While the patterns of PDF-induced correlations are visually similar for the CT10 and MSTW'08 sets, they are not completely identical. Constraints on the gluon PDF from Tevatron jet production may not be as strong in the CT10 fit as in the MSTW'08 fit, according to Figs. 12 and 13 It remains to be investigated what causes the observed differences between CT10 and MSTW sets in the correlations involving the gluon PDF. Several features are different in these fits, including different heavy-quark DIS schemes, choice of experimental data sets, PDF parametrizations, and radiative contributions in theoretical cross sections. A combination of these effects may indirectly affect the strength of the constraints imposed on the gluon density by the collider jet data.

## 8. PDF CONSTRAINTS FROM ELECTROWEAK VECTOR BOSON PRODUCTION AT THE LHC ${ }^{10}$

#### Abstract

We present a study of the impact of the recent $W$ and $Z$ measurements from ATLAS, CMS and LHCb on parton distribution functions. We show that the NNPDF2.1 NNLO predictions are consistent with all the new data, but that these provide significant further constraints on the light quarks and antiquarks

[^124]at medium and small- $x$. We conclude that these data already have the potential to play a useful role in future global PDF analyses.

### 8.1 LHC measurements sensitive to PDFs

The LHC has already provided an impressive set of measurements which are sensitive to parton distributions: inclusive jet and dijet data [292, 293, 294], electroweak vector boson production [295, 296, 297, 298, 299, 300] (both inclusive and in association with heavy quarks [301]) and direct photon production [302, 303]. The purpose of this contribution is to quantify the impact on PDFs of a subset of these data, the $W$ and $Z$ inclusive production measurements. In this first section we will review the status of LHC data relevant for PDF determination and then in the next section we will study how the $W, Z$ data impact on the NNPDF analysis.

Let's begin this short review of LHC data with electroweak vector boson production. ATLAS has measured the $W$ lepton and $Z$ rapidity distributions using the 2010 data ( $36 \mathrm{pb}^{-1}$ ) and determined the full covariance matrix of correlated experimental uncertainties [295]. This measurement supersedes the original muon asymmetry measurement from $W$ decays [296], for which the covariance matrix was not available. The CMS collaboration has presented a preliminary measurement of the muon asymmetry with 2011 data ( $234 \mathrm{pb}^{-1}$ ) [297] which supersedes the 2010 data [298]. In addition it has presented a measurement of the normalized $Z$ rapidity distribution using 2010 data [299]. In neither of these two measurements has the full covariance matrix been made available. Finally, the LHCb Collaboration has presented preliminary results for the $Z$ rapidity distribution, $W$ lepton asymmetry and W lepton charge ratio using 2010 data [300].

| Data Set | Ref. | $N_{\text {dat }}$ | $\left[\eta_{\text {min }}, \eta_{\text {max }}\right]$ | $\left\langle\sigma_{\text {stat }}\right\rangle(\%)$ | $\left\langle\sigma_{\text {sys }}\right\rangle$ (\%) | $\left\langle\sigma_{\text {norm }}\right\rangle$ (\%) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| ATLAS W,Z $36 \mathrm{pb}^{-1}$ | [295] | 30 | [0, 3.2] | 1.9 | 1.7 | 3.4 |
| ATLAS $W^{+} 36 \mathrm{pb}^{-1}$ | [295] | 11 | [0, 2.4] | 1.4 | 1.3 | 3.4 |
| ATLAS $W^{-} 36 \mathrm{pb}^{-1}$ | [295] | 11 | [0, 2.4] | 1.6 | 1.4 | 3.4 |
| ATLAS $Z 36 \mathrm{pb}^{-1}$ | [295] | 8 | [0, 3.2] | 2.8 | 2.4 | 3.4 |
| CMS $Z$ rapidity $36 \mathrm{pb}^{-1}$ | [299] | 35 | [0, 3.6] | 12.3 | - | 0 |
| CMS muon asymmetry $234 \mathrm{pb}^{-1}$ | [297] | 11 | [0, 2.4] | 1.7 | 3.1 | 0 |
| LHCb $Z$ rapidity $36 \mathrm{pb}^{-1}$ | [300] | 5 | [2, 4.5] | 20 | 5 | 3.4 |
| LHCb $W$ lepton asymmetry $36 \mathrm{pb}^{-1}$ | [300] | 5 | [2, 4.5] | 16 | 21 | 0 |

Table 5: The number of data points, kinematical coverage and average statistical, systematic and normalization percentage uncertainties for each of the experimental LHC $W$ and $Z$ datasets considered in the present analysis. For the CMS $Z$ rapidity data, the systematic uncertainty is included in the statistical uncertainty: there is no normalization uncertainty because these data are normalised to the total cross-section.

The kinematical coverage of each of the various LHC $W$ and $Z$ dataset with the corresponding average experimental uncertainties for each dataset are summarized in Table5. As we can see the LHC electroweak data span a large range in rapidity up to $\eta=4.5$. Each of the three processes considered, $W^{+}, W^{-}$and $Z$ is sensitive to different partonic subprocesses.

There are other LHC datasets potentially sensitive to PDFs. Jet production from the Tevatron has been a very important measurement not only to constrain the gluon at high $x$, but in determining the strong coupling from a global PDF analysis [304, 305]. Similar constraints are expected from the LHC jet data, extended into a wider kinematical range. From the $2010\left(36 \mathrm{pb}^{-1}\right)$ dataset inclusive jet and dijet production has been measured by both CMS [292, 293] and ATLAS [294], however only for ATLAS is the full experimental covariance matrix available. The LHC inclusive jet data can be treated within a global analysis framework using tools like FastNLO or APPLgrid [306]. Since the full NNLO corrections to the inclusive jet production are unknown, jet data in a NNLO analysis can be included only within some approximation: for example with NNLO PDF evolution and coupling running but with NLO matrix elements, or else with NLO matrix elements supplemented with Sudakov estimates of the

NNLO corrections. Another LHC measurement that has the potential to constrain the gluon PDFs is prompt photon production from ATLAS [302] and CMS [303]: its consistency with NLO QCD and their impact on the NNPDF2.1 PDFs will be discussed in detail in Ref. [307].

### 8.2 PDF constraints from LHC $W$ and $Z$

Until recently all available NNPDF sets [308, 309, 261, 310, 311, 312, 313] were based on non-LHC data. NNPDF2.2 [314] was the first set to include LHC data, the $W$ lepton asymmetry from ATLAS and CMS [298, 296]. However now these two datasets are outdated, the first because now the full correlation matrix of the $W$ and $Z$ lepton distributions is available, and the second because data from higher luminosities is also available. So we have chosen to continue to use as our baseline the NNPDF2.1 NNLO set.

We now study the impact of the latest LHC $W$ and $Z$ data on the NNPDF parton distributions. All our theoretical NNLO predictions will be computed with DYNNLO [315] with the same cuts and settings as in the respective measurements. The impact of the new data will be quantified using the reweighting method of Refs. [316, 314] applied to the $N_{\text {rep }}=1000$ replicas of the NNPDF2.1 NNLO set.

To begin with, we have computed the $\chi^{2}$ for each of the datasets in Table 5 for the most recent NNLO PDF sets currently available on LHAPDF: NNPDF2.1, MSTW08 [262], ABKM09 [317], HERAPDF1.5 [318] and JR09 [319]. When available, we use the full experimental covariance matrix. Normalization uncertainties are included using the $t_{0}$ method [320]. This is important specially for the treatment of the ATLAS differential distributions where normalization uncertainties are comparable to the statistical and systematic uncertainties (See Table 5).

The results are summarized in Table 6. For the ATLAS $W$ and $Z$ lepton distributions we show the results both for the total dataset and the individual subsets, where in the latter case cross-correlations between subsets have been neglected. In all cases the theoretical NNLO predictions have been obtained with DYNNLO as discussed above. We can see that none of these PDF sets describes the ATLAS and CMS data perfectly, although NNPDF2.1 and HERAPDF1.5 give probably the best description, while ABKM09 and JR09 are significantly worse. All five sets give a reasonable description of the LHCb data within their large uncertainties.

| Dataset | $\chi^{2}$ NNPDF2.1 | $\chi^{2}$ MSTW08 | $\chi^{2}$ ABKM09 | $\chi^{2}$ JR09 | $\chi^{2}$ HERAPDF1.5 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| ATLAS | 2.7 | 3.6 | 3.6 | 5.0 | 2.0 |
| ATLAS $W^{+} 36 \mathrm{pb}^{-1}$ | 5.7 | 6.5 | 11.4 | 5.4 | 5.3 |
| ATLAS $W^{-} 36 \mathrm{pb}^{-1}$ | 2.5 | 4.1 | 5.4 | 8.0 | 6.4 |
| ATLAS $Z 36 \mathrm{pb}^{-1}$ | 1.8 | 3.7 | 4.2 | 6.5 | 2.9 |
| CMS | 2.0 | 3.0 | 2.8 | 3.6 | 2.8 |
| CMS $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.9 | 2.9 | 2.7 | 2.0 | 3.0 |
| CMS muon asymmetry $234 \mathrm{pb}^{-1}$ | 2.0 | 3.4 | 3.0 | 8.7 | 2.1 |
| LHCb | 0.8 | 0.7 | 1.2 | 0.4 | 0.6 |
| LHCb $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.1 | 0.7 | 0.8 | 0.6 | 0.8 |
| LHCb $W$ lepton asymmetry $36 \mathrm{pb}^{-1}$ | 0.5 | 0.6 | 1.6 | 0.2 | 0.5 |

Table 6: Comparison between LHC $W$ and $Z$ data and the most recent NNLO PDFs. For each PDF set we provide the $\chi^{2} / d o f$ between data and theory predictions, computed using the $t_{0}$-method.

For the ATLAS data, we would like to emphasize the importance of properly taking into account the correlations between datasets, specially the normalization: the description of the individual $W^{+}$, $W^{-}$and $Z$ datasets is always worse than the overall description because of these cross-correlations. For the CMS $Z$ rapidity distribution we find that the fixed order NNLO description seems rather worse than the NLO+LL prediction implemented in POWHEG [299]: the origin of this difference should be investigated in future studies.

We now discuss the impact of these LHC EW data into the NNPDF2.1 NNLO PDFs [313]. In Table 7 we summarize the initial $\chi^{2}$ for each dataset, the $\chi^{2}$ after reweighting, $\chi_{\mathrm{rw}}^{2}$. We find excellent agreement with all the LHC electroweak measurements after reweighting. Some comparisons between data and theory for a selected observables are shown in Fig. 14. From top to bottom we show the comparison with ATLAS, CMS and LHCb data. In each case we have included all the most updated electroweak datasets from each collaboration.

In Table 7 we also show the effective number of replicas left after the reweighting, defined as in Ref. [316] using the Shannon entropy,

$$
\begin{equation*}
N_{\text {eff }} \equiv \exp \left\{\frac{1}{N_{\text {rep }}} \sum_{k=1}^{N_{\text {rep }}} w_{k} \ln \left(N_{\text {rep }} / w_{k}\right)\right\} \tag{76}
\end{equation*}
$$

In each case we have performed the reweighting separately for each of the experimental datasets individually, for the combined datasets from each experiment, and finally with all three combined together.

| Dataset | $\chi^{2}$ | $\chi_{\mathrm{rw}}^{2}$ | $N_{\text {eff }}$ |
| :---: | :---: | :---: | :---: |
| ATLAS | 2.7 | 1.2 | 16 |
| ATLAS $W^{+} 36 \mathrm{pb}^{-1}$ | 5.7 | 1.5 | 17 |
| ATLAS $W^{-} 36 \mathrm{pb}^{-1}$ | 2.5 | 1.0 | 205 |
| ATLAS $Z 36 \mathrm{pb}^{-1}$ | 1.8 | 1.1 | 581 |
| CMS | 2.0 | 1.2 | 56 |
| CMS $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.9 | 1.4 | 223 |
| CMS muon asymmetry $234 \mathrm{pb}^{-1}$ | 2.0 | 0.4 | 200 |
| LHCb | 0.8 | 0.8 | 972 |
| LHCb $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.1 | 1.0 | 962 |
| LHCb $W$ lepton asymmetry $36 \mathrm{pb}^{-1}$ | 0.8 | 0.5 | 961 |
| All data combined | 2.1 | 1.2 | 4 |

Table 7: The impact of LHC electroweak measurements on the NNPDF2.1 NNLO PDFs. For each dataset we show the initial $\chi^{2}$, the $\chi^{2}$ after reweighting these particular dataset and the effective number of replicas $N_{\text {eff }}$ in this case. We show both the results for individual datasets as well as for the combined impact of all datasets within the same experiment. All the results have been computed starting with $N_{\text {rep }}=1000$ replicas.

When all the datasets are taken together, the initial $\chi^{2}=2.1$, already quite reasonable is reduced down to $\chi_{\mathrm{rw}}^{2}=1.2$, thus obtaining a very good overall description of all the most recent LHC electroweak data. The effective number of replicas for all combined datasets is only $N_{\text {eff }}=4$ however: from this we conclude that to determine the combined impact of these data on PDFs would require many more replicas (around 25,000 in fact, to obtain reasonable statistical accuracy), or, more practically, a new fit. Note that the fact that the total effective number of replicas for the whole dataset is rather smaller than that of any individual subset confirms their mutual compatibility and the lack of any appreciable tension. Comparing the effective number of replicas for the individual datasets, the most constraining data are the ATLAS $W$ and $Z$ distributions, specially the very precise $W^{+}$data. On the other hand the LHCb data have a rather small impact.

Let us now examine how various PDFs change when new experiments are added. In particular we show in Fig. 15 the NNPDF2.1 NNLO $d\left(x, Q^{2}\right)$ and $\bar{u}\left(x, Q^{2}\right)$ PDFs at $Q^{2}=M_{W}^{2}$ as ratios to the central value before including the new data. As described above, we put together all the data from a given experiment. As can be seen, the ATLAS data give a moderate reduction in PDF uncertainties, and a somewhat softer small- $x$ sea quarks, although the old and new PDFs agree at the 1 -sigma level. For CMS the central values for the old and new PDFs are unchanged with a moderate error reduction at medium- $x$. Finally, for LHCb the PDF uncertainties are almost unaffected, due to the low constraining power of these datasets.

Fig. 14: Comparison between data and theory before and after reweighting for NNPDF2.1 NNLO compared to the various LHC EW datasets considered. From top to bottom we show comparisons with ATLAS ( $W^{+}$lepton $Z$ rapidity distributions), CMS ( $W$ lepton asymmetry and $Z$ rapidity distribution) and LHCb data (same as CMS). For the ATLAS data the error bars include statistical and systematic uncertaintes, but not the normalization uncertainties.

### 8.3 Conclusions

In this contribution we have quantified the impact of the most updated LHC electroweak data on the NNPDF2.1 NNLO parton distributions. NNPDF2.1 provides a reasonable description of all these datasets even before their impact on the PDFs is included. We find that all the datasets are mutually consistent, with no obvious tensions. The PDF uncertainties for the light quarks and antiquarks at medium and small- $x$ are moderately reduced. The ATLAS $W, Z$ data seem to prefer a softer small- $x$ sea. It is clear from our results that the LHC $W$ and $Z$ data should play an important part in any future PDF global fit.

## 9. HEAVY QUARK PRODUCTION IN THE ACOT SCHEME AT NNLO AND $\mathbf{N}^{3} \mathbf{L O}^{11}$

#### Abstract

We extend the ACOT scheme for heavy quark production to NNLO and $\mathrm{N}^{3} \mathrm{LO}$ for the structure functions $F_{2}$ and $F_{L}$ in deep-inelastic scattering (DIS). We use the fully massive ACOT scheme up to NLO, and estimate the dominant heavy quark mass effects at the higher orders using the massless Wilson coefficients together with a generalized slow-rescaling prescription. We present results for $F_{2}$ and $F_{L}$ showing the effect of the higher orders and the contributions from the heavy flavors.

### 9.1 INTRODUCTION

The production of heavy quarks in high energy processes has become an increasingly important subject of study both theoretically and experimentally. The theory of heavy quark production in perturbative Quantum Chromodynamics ( pQCD ) is more challenging than that of light parton (jet) production because of the additional heavy quark mass scale. The correct theory must properly take into account the changing role of the heavy quark over the full kinematic range of the relevant process from the threshold region (where the quark behaves like a typical "heavy particle") to the asymptotic region (where the same quark behaves effectively like a parton, similar to the well known light quarks $\{u, d, s\}$ ).

With the ever-increasing precision of experimental data and the progression of theoretical calculations and parton distribution function (PDF) evolution to next-to-next-to-leading order (NNLO) of QCD, there is a clear need to implement the heavy quark schemes at this order and beyond. The most important case is arguably the heavy quark treatment in inclusive deep-inelastic scattering (DIS) since the very precise HERA data for DIS structure functions and cross sections form the backbone of any modern global analysis of PDFs. Here, the heavy quark structure functions contribute up to $30 \%$ or $40 \%$ to the inclusive structure functions at small momentum fractions $x$. Extending the heavy quark schemes to higher orders is relevant for extracting precision PDFs, and hence for accurate predictions of observables at the LHC.

An example where higher order corrections are particularly important is the longitudinal structure function $F_{L}$ in DIS. The leading order $\mathcal{O}\left(\alpha_{s}^{0}\right)$ contributions to this structure function vanishes for massless quarks due to helicity conservation (Callan-Gross relation). Since the first unsuppressed contribution to $F_{L}$ is at next-to-leading order, the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ corrections are more important than for $F_{2}$. In Fig. 16 we show the preliminary results for the $F_{L}$ measurement from the H1 and ZEUS experiments [321]. In Fig. 17 displays sample Feynman diagrams at the various orders. Producing an accurate

[^125]

Fig. 17: Example Feynman diagrams contributing to DIS heavy quark production (from left): LO $\mathcal{O}\left(\alpha_{S}^{0}\right)$ quark-boson scattering $Q V \rightarrow Q$, NLO $\mathcal{O}\left(\alpha_{S}^{1}\right)$ boson-gluon scattering $g V \rightarrow Q \bar{Q}$, NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ boson-gluon scattering $g V \rightarrow g Q \bar{Q}$ and $\mathrm{N}^{3} \mathrm{LO} \mathcal{O}\left(\alpha_{S}^{3}\right)$ boson-gluon scattering $g V \rightarrow g g Q \bar{Q}$.
prediction for $F_{L}$ is a challenge, particularly in the region of low $Q^{2}$ and small $x$.
In this paper, we will briefly outline the method we used to incorporate the higher order terms, the key elements of the ACOT scheme, and the treatment of the heavy quark masses. We then present results for the $F_{2}$ and $F_{L}$ neutral current DIS structure functions.

### 9.2 THE ACOT SCHEME AND ITS EXTENSION BEYOND NLO

Fig. 18: Comparison of schemes for $F_{2}^{c}$ at $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical.

The ACOT scheme [322, 323] is based upon the factorization theorem for heavy quarks[324]; hence, it is valid at any order of perturbation theory. The factorization proof ensures that the ACOT scheme can be applied throughout the full kinematic regime, and that there is a smooth transition from a massless result $(m=0)$ to the heavy-mass decoupling limit $(m \rightarrow \infty)$.

In the limit where the quark $Q$ of mass $m$ is relatively heavy compared to the characteristic energy scale ( $\mu \lesssim m$ ), the ACOT result naturally reduces to the Fixed-Flavor-Number-Scheme (FFNS). In the FFNS, the heavy quark is treated as being extrinsic to the hadron, and there is no corresponding heavy quark PDF, $f_{Q}(x, \mu)=0$. Conversely, in the limit where the quark mass is relatively light $(\mu \gtrsim m)$, the ACOT result reduces to the $\overline{M S}$ Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS) exactlywithout any finite renormalizations. In this limit, the quark mass $m$ no longer plays any dynamical role; it serves purely as a regulator. This feature is presented in Fig. 18 where we can see that the ACOT scheme precisely matches the results of the FFNS and ZM-VFNS schemes in their respective limits.

Additionally Fig. 18 shows the results obtained within the Simplified-ACOT scheme (SACOT) [325]. The S-ACOT scheme drops the heavy quark mass dependence for the hard-scattering

Fig. 17: Example Feynman diagrams contributing to DIS heavy quark production (from left): LO $\mathcal{O}\left(\alpha_{S}^{0}\right)$ quark-boson scattering $Q V \rightarrow Q$, NLO $\mathcal{O}\left(\alpha_{S}^{1}\right)$ boson-gluon scattering $g V \rightarrow Q \bar{Q}$, NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ boson-gluon scattering $g V \rightarrow g Q \bar{Q}$ and $\mathrm{N}^{3} \mathrm{LO} \mathcal{O}\left(\alpha_{S}^{3}\right)$ boson-gluon scattering $g V \rightarrow g g Q \bar{Q}$.
prediction for $F_{L}$ is a challenge, particularly in the region of low $Q^{2}$ and small $x$.
In this paper, we will briefly outline the method we used to incorporate the higher order terms, the key elements of the ACOT scheme, and the treatment of the heavy quark masses. We then present results for the $F_{2}$ and $F_{L}$ neutral current DIS structure functions.

### 9.2 THE ACOT SCHEME AND ITS EXTENSION BEYOND NLO

Fig. 18: Comparison of schemes for $F_{2}^{c}$ at $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical.

The ACOT scheme [322, 323] is based upon the factorization theorem for heavy quarks[324]; hence, it is valid at any order of perturbation theory. The factorization proof ensures that the ACOT scheme can be applied throughout the full kinematic regime, and that there is a smooth transition from a massless result $(m=0)$ to the heavy-mass decoupling limit $(m \rightarrow \infty)$.

In the limit where the quark $Q$ of mass $m$ is relatively heavy compared to the characteristic energy scale ( $\mu \lesssim m$ ), the ACOT result naturally reduces to the Fixed-Flavor-Number-Scheme (FFNS). In the FFNS, the heavy quark is treated as being extrinsic to the hadron, and there is no corresponding heavy quark PDF, $f_{Q}(x, \mu)=0$. Conversely, in the limit where the quark mass is relatively light $(\mu \gtrsim m)$, the ACOT result reduces to the $\overline{M S}$ Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS) exactlywithout any finite renormalizations. In this limit, the quark mass $m$ no longer plays any dynamical role; it serves purely as a regulator. This feature is presented in Fig. 18 where we can see that the ACOT scheme precisely matches the results of the FFNS and ZM-VFNS schemes in their respective limits.

Additionally Fig. 18 shows the results obtained within the Simplified-ACOT scheme (SACOT) [325]. The S-ACOT scheme drops the heavy quark mass dependence for the hard-scattering

Fig. 19: $F_{L}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$, (left to right). The three lines show the mass effects via the scaling variable: $n=\{0,1,2\}$, (Red, Green, Blue). We observe the effect of the $n$-scaling is negligible except for small $x$ and $Q$ values.
processes with incoming heavy quarks or with internal on-shell cuts on a heavy quark line. The S-ACOT scheme is not an approximation; it is an exact renormalization scheme, extensible to all orders. Note, the ACOT and S-ACOT results agree throughout the kinematic region.

### 9.21 Beyond NLO

While there is no conceptual difficulty with extending the ACOT scheme beyond NLO, the fully massive Wilson coefficients have yet to be computed ${ }^{[12}$ However massless calculations of NNLO and even $\mathrm{N}^{3} \mathrm{LO}$ for $F_{2}$ and $F_{L}$ structure functions are available $\sqrt{13}$

The question is: can we use these results, together with the knowledge that ACOT reduces to the massless $\overline{M S}$ (ZM-VFNS) for $m \rightarrow 0$, to estimate mass effects at NNLO and $\mathrm{N}^{3} \mathrm{LO}$ ? Obviously we cannot restore the fully massive ACOT result from the massless limit, but we can try to extract the dominant higher order contributions. There are two ways in which mass effects enter the calculation. The first is "dynamically" through the mass dependent Wilson coefficients. The second is "kinematically" via the restricted phase space. Comparisons using the fully massive results at NLO suggest that the kinematic mass effects are dominant, and that much of this dependence can be obtained with a rescaling of the Bjorken $x$ variable. We introduce a generalized rescaling $x \rightarrow x\left[1+(n m / Q)^{2}\right]$ where $n=0$ is the massless result, $n=1$ is the original Barnett[329] rescaling, and $n=2$ is the $\chi$-rescaling [330].

Thus, our strategy is as follows. We use the fully massive ACOT result to NLO [331], and add to this the massless NNLO and $\mathrm{N}^{3} \mathrm{LO}$ contributions using the generalized rescaling prescription. By varying $n$, we can investigate the influence of the kinematic mass in our results. We argue that the massless Wilson coefficients at NNLO and $\mathrm{N}^{3} \mathrm{LO}$, together with the generalized rescaling prescription provide a good approximation of the exact result. At worst, the error is of order $\alpha \alpha_{S}^{2} \times\left[m^{2} / Q^{2}\right]$, and comparative studies at NLO suggest the error is less. ${ }^{[14}$ For example, in Fig. 19 we display the results of $F_{L}$ for $n=\{0,1,2\}$. The effects of the detailed mass dependence is most noticeable for low $Q^{2}$ and small $x$. While the massless scaling result $(n=0)$ does deviate from the other curves, comparing the $n=1$ and $n=2$ curves we observe the details of the mass rescaling are relatively small. While this is not a proof ${ }_{[15}^{15}$ this result does give us confidence that the mass effects are under control.

Fig. 20: Fractional contribution for each quark structure function $F_{2, L}^{i}$ for each flavor $i=\{u, d, s, c, b\}$ for (a) $F_{2}^{i}$ and (b) $F_{L}^{i}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for the ACOT- $\chi$ scheme.

### 9.3 RESULTS

In Fig. 20 we display the fractional contributions to the structure functions $F_{2}$ and $F_{L}$. At larger values of $x$ and low $Q$, we observe that the heavy flavor contributions are minimal. For example, for $x=10^{-1}$, we see that the $u$-quark structure function $F^{u}$ comprises $\sim 80 \%$ of the total structure function. In contrast, at $x=10^{-5}$ and large $Q$ we see that the contributions of the $u$ and $c$ quarks are comparable (as they couple with a factor 4/9), and the $d$ and $s$ quarks contributions are comparable (as they couple with a factor $1 / 9$ ).

Figure 20 also shows how the $\chi$-rescaling introduces a damping of the heavy quark contributions as we move from large $Q^{2}$ values to smaller values. The $\chi$-rescaling ensures the heavy quarks $(c, b)$ are appropriately suppressed for low $Q^{2}$ scales.

In Fig. 21a we display the results for $F_{2}$ vs. $Q$ computed at various orders; the ratio to the $\mathrm{N}^{3} \mathrm{LO}$ result is displayed in Fig. 21b For large $x$ (c.f. $x=0.1$ ) we find the perturbative calculations are particularly stable. We see that the LO result is within $20 \%$ of the others at small $Q$, and within $5 \%$ at large $Q$. The NLO is within $2 \%$ at small $Q$, and indistinguishable from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ for $Q$ values above $\sim 10 \mathrm{GeV}$. The NNLO and $\mathrm{N}^{3} \mathrm{LO}$ results are essentially identical throughout the kinematic range. For smaller $x$ values $\left(10^{-3}, 10^{-5}\right)$, the contributions of the higher order terms are slightly larger. Here, the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ coincide for $Q$ values above $\sim 5 \mathrm{GeV}$, but the NLO result can differ by $\sim 5 \%$ for low $Q^{2}$ scales.

In Fig. 22 we display the results for $F_{L}$ vs. $Q$ computed at various orders. In contrast to $F_{2}$, we find that NLO corrections are large; this is expected because the LO corrections to $F_{L}$ (which violate

[^126]
(a) $F_{2}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$ (red, green, blue, cyan) for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$, (left to right) for ACOT- $\chi$ scheme.

(b) Ratio of $F_{2}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$ (red, green, blue, cyan) compared to $F_{2}$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=$ $\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$, (left to right) for ACOT- $\chi$ scheme.

Fig. 21: $F_{2}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$.
the Callan-Gross relation) are suppressed by $\left(m^{2} / Q^{2}\right)$ compared to the dominant gluon contributions which enter at NLO. Consequently, we observe that the LO result for $F_{L}$ receives large contributions from the higher order terms. Essentially, NLO is the first non-trivial order for $F_{L}$, and the subsequent contributions then converge. For example, at large $x$ (c.f. $x=0.1$ ) for $Q \sim 10 \mathrm{GeV}$ we find the NLO results yields $\sim 70 \%$ of the total, the NNLO is a $\sim 20 \%$ correction, and the $\mathrm{N}^{3} \mathrm{LO}$ is a $\sim 10 \%$ correction. For lower $x$ values $\left(10^{-3}, 10^{-5}\right.$ ) the convergence of the perturbative series improves, and the NLO results is within $\sim 10 \%$ of the $\mathrm{N}^{3} \mathrm{LO}$ result. Curiously, for $x=10^{-5}$ the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ roughly compensate each other so that the NLO and the $\mathrm{N}^{3} \mathrm{LO}$ match quite closely for $Q \gtrsim 2 \mathrm{GeV}$.

### 9.4 CONCLUSIONS

We have computed the $F_{2}$ and $F_{L}$ structure functions in the ACOT scheme at NNLO and $\mathrm{N}^{3} \mathrm{LO}$. The full mass dependence is computed to NLO, and the dominant mass effects for the higher orders are approximated using a generalized rescaling; the details of this rescaling are demonstrated to be small. This allows us to make detailed predictions throughout the kinematic range investigated by HERA, and we obtain a reasonable estimate of the uncertainty due to the higher order mass effects. Together with the precise HERA data, these calculations facilitate accurate determination of the PDFs which are the foundation of the LHC calculations.

## 10. FINITE-WIDTH EFFECTS IN TOP-QUARK PAIR PRODUCTION AND DECAY AT THE LHC ${ }^{16}$

#### Abstract

We investigate finite-top-width effects in top-quark pair production by comparing NLO QCD predictions for $\mathrm{pp} \rightarrow$ WWb $\overline{\mathrm{b}}$ to corresponding $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow$ WWb $\bar{b}$ results in the narrow-top-width limit. Finite-top-width effects, which result from non-resonant and off-shell contributions, are discussed in detail for the case of the inclusive cross section (with experimental cuts) and for selected differential observables in the di-lepton channel.

### 10.1 INTRODUCTION

Top-quark pair production at hadron colliders allows for key tests of the Standard Model and represents an omnipresent background to Higgs-boson and new-physics searches. The very large t $\bar{t}$ samples from the Tevatron and the LHC, and the steadily increasing systematic precision call for a continu-

[^127]ous improvement of theory predictions ${ }^{17}$ In this context, a reliable theoretical description of experimental cuts and exclusive $t \bar{t}$ observables, which depend on details of the $\mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ final state, requires higher-order calculations for top-pair production and decay. The first NLO QCD predictions for $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}+X[335,336$, 337] have been obtained in the narrow-top-width limit, an approximation where the $2 \rightarrow 4$ particle process is factorised into on-shell $t \bar{t}$ production and (anti)top decays, taking into account spin correlations. In this framework, it was shown that NLO QCD effects in top-quark decays have a significant impact on the kinematic properties of final-state leptons and b-jets [335, 336, 337], and play an important role for top-mass measurements at the LHC [338]. More recently, NLO QCD predictions for the complete $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}+X$ process became available [25, 23], which include all effects related to the finite top-quark width, i.e. on- and off-shell intermediate top quarks, non-resonant contributions, and their interference with resonant t $\bar{t}$ production. Besides new evidence for the importance of NLO corrections to $t \bar{t}$ production and decay, these studies provided a first quantitative assessment of finite-width effects in the inclusive cross section. Applying a numerical $\Gamma_{\mathrm{t}} \rightarrow 0$ extrapolation to the $\mathrm{NLO} \mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ predictions, it was found that finite-topwidth contributions to the WWbb cross section at the Tevatron and the LHC ( 7 TeV ) range from 0.2 to 1 percent [25, 23], which is perfectly consistent with the expected order of magnitude ( $\Gamma_{\mathrm{t}} / m_{\mathrm{t}} \simeq 0.9 \%$ ) of finite-top-width effects in inclusive observables.

In this study, we pursue the investigation of finite-top-width effects by means of a tuned comparison of the $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ NLO calculation of Ref. [25] against the narrow-top-width approximation of Ref. [336]. This permits us, for the first time, to investigate $\Gamma_{\mathrm{t}}$-effects in different phenomenologically interesting regions of the $\mathrm{WWb} \overline{\mathrm{b}}$ phase space, where large off-shell and non-resonant contributions cannot be excluded a priori as in the case of inclusive observables.

### 10.2 NARROW-TOP-WIDTH APPROXIMATION AND FINITE-WIDTH EFFECTS

Let us start by recalling the main features of the NLO QCD calculations of $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ in narrow-top-width approximation [336] and $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ with finite-top-width effects [25]. For brevity, we denote them as $t \bar{t}$ and WWbb calculations, respectively. Both calculations implement leptonic W-boson decays in spin-correlated narrow-W-width approximation.

In the narrow-top-width limit of Ref. [336], top-quark resonances are approximated by

$$
\begin{equation*}
\lim _{\Gamma_{\mathrm{t}} / m_{\mathrm{t}} \rightarrow 0} \frac{1}{\left(p_{\mathrm{t}}^{2}-m_{\mathrm{t}}^{2}\right)^{2}+m_{\mathrm{t}}^{2} \Gamma_{\mathrm{t}}^{2}}=\frac{\pi}{m_{\mathrm{t}} \Gamma_{\mathrm{t}}} \delta\left(p_{\mathrm{t}}^{2}-m_{\mathrm{t}}^{2}\right), \tag{77}
\end{equation*}
$$

with delta functions that enforce the on-shell conditions, $p_{\mathrm{t}}^{2}=m_{\mathrm{t}}^{2}$, and are accompanied by $1 / \Gamma_{\mathrm{t}}$ factors. Contributions of $\mathcal{O}\left(\Gamma_{\mathrm{t}} / m_{\mathrm{t}}\right)$, i.e. terms that do not involve two resonant top propagators, are systematically neglected. The differential $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$ cross section is factorised into the $\mathrm{pp} \rightarrow \mathrm{t} \mathrm{\bar{t}}$ cross section times $\mathrm{t} \rightarrow \mathrm{Wb}$ partial decay widths, $\mathrm{d} \sigma=\left(\mathrm{d} \sigma_{\mathrm{t} \overline{\mathrm{t}}} \mathrm{d} \Gamma_{\mathrm{t}} \mathrm{d} \Gamma_{\overline{\mathrm{t}}}\right) / \Gamma_{\mathrm{t}}^{2}$, taking into account top-quark spin correlations. The LO and NLO predictions can be schematically expressed as

$$
\begin{align*}
\mathrm{d} \sigma_{\mathrm{LO}} & =\Gamma_{\mathrm{t}, \mathrm{LO}}^{-2}\left(\mathrm{~d} \sigma_{\mathrm{tt}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{0}\right), \\
\mathrm{d} \sigma_{\mathrm{NLO}} & =\Gamma_{\mathrm{t}, \mathrm{NLO}}^{-2}\left[\left(\mathrm{~d} \sigma_{\mathrm{tt}}^{0}+\mathrm{d} \sigma_{\mathrm{t} \mathfrak{t}}^{1}\right) \mathrm{d} \Gamma_{\mathrm{t}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{0}+\mathrm{d} \sigma_{\mathrm{tt}}^{0}\left(\mathrm{~d} \Gamma_{\mathrm{t}}^{1} \mathrm{~d} \Gamma_{\mathrm{t}}^{0}+\mathrm{d} \Gamma_{\mathrm{t}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{1}\right)\right], \tag{78}
\end{align*}
$$

where the superscripts 0 and 1 indicate tree-level quantities and NLO corrections, respectively. The NLO prediction involves three terms, where the corrections are applied either to $\mathrm{d} \sigma_{\mathrm{tt}}$ or to one of the decays. All ingredients of $\mathrm{d} \sigma_{\mathrm{LO}}$ and $\mathrm{d} \sigma_{\mathrm{NLO}}$ have to be evaluated with input parameters at the corresponding perturbative order. In particular, LO and NLO predictions must be computed using $\Gamma_{\mathrm{t}, \mathrm{LO}}$ and $\Gamma_{\mathrm{t}, \mathrm{NLO}}$ decay widths, as indicated in $\left.\boxed{78}\right|^{18}$ This guarantees that-up to higher-order corrections-the integration over

[^128]the phase space of each top decay in (78) is consistent with the branching fraction
\[

$$
\begin{equation*}
\frac{\int \mathrm{d} \Gamma_{\mathrm{t} \rightarrow \mathrm{~b} l \nu}}{\Gamma_{\mathrm{t}}}=\frac{\Gamma_{\mathrm{t} \rightarrow \mathrm{~b} l \nu}}{\Gamma_{\mathrm{t}}}=\mathrm{BR}(\mathrm{t} \rightarrow \mathrm{~b} l \nu) . \tag{79}
\end{equation*}
$$

\]

In this context, let us point out that a consistent inclusion of finite-W-width corrections-both in the scattering amplitudes and the $\Gamma_{\mathrm{t}}$ input parameters-is expected to lead to doubly-suppressed effects. This is due to the fact that, in the $\Gamma_{\mathrm{t}} \rightarrow 0$ limit, $\mathcal{O}\left(\Gamma_{\mathrm{W}}\right)$ corrections to the numerator and denominator of the branching fraction (79) cancel. Finite-W-width corrections are thus expected to produce very small effects of $\mathcal{O}\left(\frac{\Gamma_{\mathrm{W}} \Gamma_{\mathrm{t}}}{M_{\mathrm{w}} m_{\mathrm{t}}}\right)$ in inclusive observables. This justifies the use of the narrow-W-width approximation in combination with finite-top-width contributions, which is the approach adopted in Ref. [25], although in kinematic regions where finite- $\Gamma_{\mathrm{t}}$ effects become large also finite-W-width corrections [23] might become non-negligible.

The calculation of Ref. [25] provides a full description of $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ at order $\mathcal{O}\left(\alpha_{\mathrm{S}}^{3} \alpha^{2}\right)$. The top-quark width is incorporated into the complex top mass, $\mu_{\mathrm{t}}^{2}=m_{\mathrm{t}}^{2}-\mathrm{i} m_{\mathrm{t}} \Gamma_{\mathrm{t}}$, in the complex-mass scheme [339]. In this way, off-shell-top contributions are consistently described by Breit-Wigner distributions. Besides contributions with two intermediate top resonances, also singly- and non-resonant diagrams are taken into account, including interferences. A few representative tree diagrams are shown in Fig 23. The NLO WWbb̄ predictions involve factorisable corrections to doubly-resonant diagrams, which provide the off-shell extension of NLO corrections in $t \bar{t}$ approximation (78). In addition, there are non-factorisable corrections, where $t \bar{t}$ production and decay parts of the process are connected via exchange of QCD partons, and NLO corrections to singly- and non-resonant topologies. Further technical aspects are discussed in the original publications [336, 25].

Fig. 23: Representative LO diagrams of doubly-resonant (upper line), singly-resonant (first diagram in lower line), and non-resonant type (last two diagrams in lower line).

### 10.3 NUMERICAL RESULTS

### 10.31 Input parameters and setup

In the following we compare $\mathrm{t} \overline{\mathrm{t}}$ and $\mathrm{WWb} \overline{\mathrm{b}}$ predictions for $\mathrm{W}^{+}\left(\rightarrow \nu_{\mathrm{e}} \mathrm{e}^{+}\right) \mathrm{W}^{-}\left(\rightarrow \mu^{-} \bar{\nu}_{\mu}\right) \mathrm{b} \overline{\mathrm{b}}$ production at the Tevatron ( $\mathrm{p} \overline{\mathrm{p}}$ collisions at 1.96 TeV ) and the LHC ( pp collisions at 7 and 14 TeV ). These results are based on the same input parameters and cuts as in Ref. [25]. In NLO (LO) QCD we employ MSTW2008NLO (LO) parton distributions [262] and describe the running of the strong coupling constant $\alpha_{\mathrm{S}}$ with two-loop (one-loop) accuracy, including five active flavours. Contributions induced by the strongly suppressed bottom-quark density are neglected. For the gauge-boson and top-quark masses we use $m_{\mathrm{t}}=172 \mathrm{GeV}, M_{\mathrm{W}}=80.399 \mathrm{GeV}$, and $M_{\mathrm{Z}}=91.1876 \mathrm{GeV}$. The masses of all other quarks, including b-quarks, are neglected. In view of the negligibly small Higgs-mass dependence we adopt the $M_{\mathrm{H}} \rightarrow \infty$ limit, i.e. we omit diagrams involving Higgs bosons. The electroweak couplings are derived

Table 8: Integrated $\nu_{\mathrm{e}} \mathrm{e}^{+} \mu^{-} \bar{\nu}_{\mu} \mathrm{b} \overline{\mathrm{b}}$ cross section in narrow-with approximation $\left(\sigma_{\mathrm{t} \overline{\mathrm{t}}}\right)$ and including finite-top-width effects $\left(\sigma_{\mathrm{WWb}} \overline{\mathrm{b}}\right)$. The relative error of the narrow-width approximation (sixth column) is compared to the prediction of Ref. [25] (seventh column). Factor-two scale variations in $\sigma_{\mathrm{tt}}$ and $\sigma_{\mathrm{Wwb} \overline{\mathrm{b}}}$ are shown as sub- and super-scripts, while statistical errors are given in parenthesis.
from the Fermi constant $G_{\mu}=1.16637 \times 10^{-5} \mathrm{GeV}^{-2}$ in the $G_{\mu}$-scheme, where the sine of the mixing angle and the electromagnetic coupling read $s_{\mathrm{w}}^{2}=1-M_{\mathrm{W}}^{2} / M_{\mathrm{Z}}^{2}$ and $\alpha=\sqrt{2} G_{\mu} M_{\mathrm{W}}^{2} s_{\mathrm{w}}^{2} / \pi$. For consistency, we perform the LO and NLO calculations using the top-quark widths $\Gamma_{\mathrm{t}, \mathrm{LO}}=1.4655 \mathrm{GeV}$ and $\Gamma_{\mathrm{t}, \mathrm{NLO}}=1.3376 \mathrm{GeV}$ [340], respectively. Since the leptonic W-boson decay does not receive NLO QCD corrections we employ the NLO W-boson width $\Gamma_{\mathrm{W}}=2.0997 \mathrm{GeV}$ everywhere.

Final-state quarks and gluons with pseudo-rapidity $|\eta|<5$ are converted into infrared-safe jets using the anti- $k_{\mathrm{T}}$ algorithm [341]. For the Tevatron (LHC) we set the jet-algorithm parameter $R=0.4$ (0.5) and apply the transverse-momentum and pseudo-rapidity cuts $p_{\mathrm{T}, \mathrm{b}-\mathrm{jet}}>20(30) \mathrm{GeV},\left|\eta_{\mathrm{b}-\mathrm{jet}}\right|<2.5$. Moreover, we require a missing transverse momentum of $p_{\mathrm{T}, \mathrm{miss}}>25(20) \mathrm{GeV}$ and charged leptons with $p_{\mathrm{T}, l}>20 \mathrm{GeV}$ and $\left|\eta_{l}\right|<2.5$.

For the renormalisation and factorisation scales we adopt the central value $\mu=m_{\mathrm{t}}$ and study factor-two variations of $\mu=\mu_{\mathrm{ren}}=\mu_{\mathrm{fact}}$, i.e. we compare predictions at $\mu / m_{\mathrm{t}}=0.5,1,2$. The scale variations are applied also to $\Gamma_{\mathrm{t}, \mathrm{NLO}}$, but not to $\Gamma_{\mathrm{W}}$.

### 10.32 Integrated cross section

Results for the integrated $\nu_{\mathrm{e}} \mathrm{e}^{+} \mu^{-} \bar{\nu}_{\mu} \mathrm{b} \overline{\mathrm{b}}$ cross sections and scale uncertainties at the Tevatron and the LHC are reported in Table 8. While the $\sigma_{\text {Wwb币 }}$ results for Tevatron and LHC at 7 TeV correspond to those of Ref. [25] ${ }^{19}$, the ones for LHC at 14 TeV as well as all $\sigma_{\mathrm{t} \bar{\epsilon}}$ predictions are new. Comparing all $\mathrm{WWb} \overline{\mathrm{b}}$ and $t \bar{t}$ predictions we find that finite-top-width effects never exceed one percent, both in LO and NLO. The statistical precision of the calculations permits us to assess the error of the NWA, $\sigma_{\mathrm{t} \overline{\mathrm{t}}} / \sigma_{\mathrm{WWbb}}-1$, with an accuracy of $1-3$ permille. At the Tevatron, the NWA overestimates the WWb $\bar{b}$ cross section by an amount very close to $\Gamma_{\mathrm{t}} / m_{\mathrm{t}} \simeq 0.9 \%$, both in LO and NLO. The error of the NWA at the 7 (14) TeV LHC ranges between 4 and 8 permille. As shown in the last column of Table 8 these finite-width effects are in very good agreement with the results of the $\Gamma_{\mathrm{t}} \rightarrow 0$ extrapolation in Ref. [25]. Similar results can be found also in Ref. [23].

[^129]
### 10.33 Differential distributions

The small finite-width corrections to the integrated cross section demonstrate that-in presence of standard LHC and Tevatron cuts-the NWA provides a fairly accurate description of inclusive WWb̄ production. It is thus interesting to investigate to which extent this conclusion applies to the various phenomenologically important regions of the WWb $\overline{\mathrm{b}}$ phase space. To this end we have compared $\mathrm{t} \overline{\mathrm{t}}$ and WWbb predictions for a few differential observables that are relevant for top-pair production, either as signal or as background to Higgs production or new physics. Note that we refrain from selecting kinematic variables like the top-quark invariant mass or imposing cuts of type $M_{\mathrm{Wb}}>200 \mathrm{GeV}$, which would lead to obvious enhancements of non-resonant contributions.

In Figs. 2427 we present predictions for some invariant-mass and transverse-momentum distributions, restricting ourselves to the case of the 7 TeV LHC. For each observable we display $t \bar{t}$ (dashed curves) and $\mathrm{WWb} \overline{\mathrm{b}}$ (solid curves) results in LO (blue) and NLO (red) approximation. Absolute predictions (left plots) are complemented by the ratios $\left(\mathrm{d} \sigma_{\mathrm{LO}}-\mathrm{d} \sigma_{\mathrm{NLO}}\right) / \mathrm{d} \sigma_{\mathrm{NLO}}$ (upper right plots) and $\left(\mathrm{d} \sigma_{\mathrm{t} \bar{t}}-\mathrm{d} \sigma_{\mathrm{WWb} \overline{\mathrm{b}}}\right) / \mathrm{d} \sigma_{\mathrm{WWb}}$ (lower right plots), which indicate the relative error of LO and narrow-width approximations w.r.t. the best predictions, i.e. NLO and WWb $\overline{\mathrm{b}}$.

Fig. 24: Distribution in the transverse momentum of the harder b-jet at the 7 TeV LHC: LO (blue) and NLO (red) predictions in narrow-width approximation ( $\mathrm{t} \overline{\mathrm{t}}$, dashed) and including finite-top-width effects (WWb $\overline{\mathrm{b}}$, solid). Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrow-width (lower-right) approximations w.r.t. NLO and WWb̄ predictions, respectively.

The transverse-momentum distribution of the harder b-jet is shown in Fig. 24 In the range below 200 GeV , which contains the bulk of the cross section, the NLO and finite-width corrections behave similarly as for the integrated cross section: LO predictions deviate from NLO ones by about $-20 \%$, and the error of the NWA ranges between +1 and $-4 \%$. Finite-width effects tend to increase with $p_{\mathrm{T}}$ and reach the $10 \%$ level around 300 GeV . Within the entire $p_{\mathrm{T}}$ range the LO/NLO ratios resulting from the $t \bar{t}$ and WWbb̄ calculations are almost equal. Equivalently, we find the same $\mathrm{d} \sigma_{\mathrm{tt}} / \mathrm{d} \sigma_{\mathrm{WWbb}}$ ratios in LO and NLO.

Fig. 25: Distribution in the transverse momentum of the b̄ di-jet system at the 7 TeV LHC: LO (blue) and NLO (red) predictions in narrow-width approximation ( $\mathrm{t} \overline{\mathrm{t}}$, dashed) and including finite-top-width effects (WWb百, solid). Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrow-width (lower-right) approximations w.r.t. NLO and WWb̄ predictions, respectively.

In Fig. 25 we show the transverse-momentum distribution of the $b \bar{b}$ di-jet system. This kinematic variable plays an important role in boosted-Higgs searches with a large t $\bar{t}$ background. In particular, the strategy proposed in Ref. [342] to extract a pp $\rightarrow \mathrm{H}(\rightarrow \mathrm{b} \overline{\mathrm{b}}) \mathrm{W}$ signal at the LHC is based on the selection of boosted $\mathrm{H} \rightarrow \mathrm{b} \overline{\mathrm{b}}$ candidates with $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}}>200 \mathrm{GeV}$, which permits to reduce $\mathrm{t} \overline{\mathrm{t}}$ contamination (and other backgrounds) in a very efficient way. As can be seen from Fig. 25, the suppression of $t \bar{t}$ production is indeed particularly strong at $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}} \gtrsim 150 \mathrm{GeV}$. This is due to kinematic constraints that characterise the LO and narrow-width approximations: in order to acquire $p_{\mathrm{T}, \mathrm{b}}>\left(m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2}\right) /\left(2 m_{\mathrm{t}}\right) \simeq 65 \mathrm{GeV}$ b-quarks need to be boosted via the $p_{\mathrm{T}}$ of their parent (anti)top quarks, and the fact that top and antitop quarks have opposite transverse momenta (at LO) makes it difficult to generate a b $\bar{b}$ system with high $p_{\mathrm{T}}$. The NLO and finite-width corrections undergo less stringent kinematic restrictions, resulting into a significant enhancement of $W W b \overline{\mathrm{~b}}$ events at large $p_{\mathrm{T}, \mathrm{b}}$. This is clearly reflected in the differences between the various curves in the left plot of Fig. 25. The most pronounced effect comes from the NLO corrections, where the $t \bar{t}$ system can acquire large transverse momentum by recoiling against extra jet radiation. As indicated by the right-upper plot, the NLO correction represents $50-80 \%$ of the cross section at high $p_{\mathrm{T}}$, corresponding to a huge $K$-factor of $2-5$. Finite-width effects (lower-right plot) lead to a further significant, although less dramatic, enhancement; for example, non-resonant topologies can lead to direct b $\overline{\mathrm{b}}$ production via high- $p_{\mathrm{T}}$ gluons that recoil against $\mathrm{W}^{+} \mathrm{W}^{-}$pairs. For $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}}>200 \mathrm{GeV}$, we find that $20-40 \%$ of the LO WWbb cross section is due to finite-width contributions, while this fraction decreases to $7-15 \%$ at NLO. This reduction is related to the dominance of the jet-emission contribution, which we expect to be rather well described by the NWA. On the other hand, an optimal suppression of the $t \bar{t}$ background will require a very tight jet-veto [342], and in this case we expect finite-width corrections to the NLO t̄ predictions to be as large as in LO.

The distribution in the missing transverse momentum, i.e. the vector sum of the $\nu_{e}$ and $\bar{\nu}_{\mu}$ trans-

Fig. 26: Distribution in the missing transverse momentum at the 7 TeV LHC: LO (blue) and NLO (red) predictions in narrow-width approximation ( $\mathrm{t} \overline{\mathrm{t}}$, dashed) and including finite-top-width effects (WWb $\overline{\mathrm{b}}$, solid). Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrowwidth (lower-right) approximations w.r.t. NLO and WWb̄̄ predictions, respectively.
verse momenta, is displayed in Fig. 26. This distribution is relevant for new-physics searches based on missing transverse energy plus jets and leptons. Its tail features a qualitatively similar behaviour as in the case of $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}}$, due to analogous kinematic constraints. However, in the case of $p_{\mathrm{T}, \mathrm{miss}}$ the corrections are less pronounced: the NLO correction does not exceed $40-50 \%$ of the full prediction, and finite-width contributions stay below roughly $10 \%$.

Figure 27 displays the distribution in the invariant mass of the positron and a b-jet, i.e. the visible products of a top-quark decay. More precisely, assuming that the charge of the b-jet is not known, the $\mathrm{e}^{+} \mathrm{b}$ pair is built by selecting the b-jet that yields the smallest invariant mass ${ }^{20}$ In narrow-width and LO approximation this kinematic quantity is characterised by a sharp upper bound, $M_{\mathrm{e}^{+} \mathrm{b}}^{2}<m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2} \simeq$ $(152 \mathrm{GeV})^{2}$, which renders it very sensitive to the top-quark mass. The value of $m_{\mathrm{t}}$ can be extracted with high precision using, for instance, the invariant-mass distribution of a positron and a $J / \psi$ from a $B$ meson decay [343, 338], an observable that is closely related to $M_{\mathrm{e}^{+} \mathrm{b}}$. In the region below the kinematic bound, the NLO corrections to $M_{\mathrm{e}^{+} \mathrm{b}}$ vary between $5-30 \%$, and the impact of the NLO shape distortion on a precision $m_{\mathrm{t}}$-measurement is certainly significant. For $M_{\mathrm{e}^{+} \mathrm{b}}<150 \mathrm{GeV}$, the NWA agrees with the WWb $\bar{b}$ predictions at the $1 \%$ level or better. In contrast, in the vicinity of the kinematic bound the impact of finite-width (and NLO) corrections becomes clearly more important, giving rise to a tail that extends above $M_{\mathrm{e}^{+} \mathrm{b}}^{2}=m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2}$. The resulting contribution to the total cross section is fairly small, but the impact of such finite-width effects on the top-mass measurement might be non-negligible, given the high $m_{\mathrm{t}}$-sensitivity of the $M_{\mathrm{e}^{+} \mathrm{b}}^{2} \simeq m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2}$ region.

Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrow-width (lower-right) approximations w.r.t. NLO and WWb $\bar{b}$ predictions, respectively.

### 10.4 CONCLUSIONS

Based on recent NLO QCD calculations, we have presented a systematic comparison of top-pair production and decay in narrow-top-width approximation, $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$, against the complete $\mathrm{pp} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$ process, which involves finite-top-width effects of non-resonant and off-shell type.

At the Tevatron and the LHC ( 7 and 14 TeV ), finite-top-width contributions to the integrated cross section (in the di-lepton channel) turn out not to exceed one percent. This confirms previous estimates based on the $\Gamma_{\mathrm{t}} \rightarrow 0$ extrapolation of $\mathrm{pp} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$ predictions. At the 7 TeV LHC, we also investigated differential observables that are relevant either for top-pair production as a signal or as a background in Higgs or new-physics searches. In the case of the b-jet transverse momentum and $p_{\mathrm{T}, \mathrm{miss}}$ distributions, finite-width effects remain very small over a large kinematic range and reach the $10 \%$ level only around 300 GeV . In contrast, the $p_{\mathrm{T}}$-distribution of the b $\overline{\mathrm{b}}$ di-jet system receives $\Gamma_{\mathrm{t}}$-corrections beyond 20-30\% for $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}} \gtrsim 200 \mathrm{GeV}$, a kinematic region that plays an important role in $\mathrm{pp} \rightarrow \mathrm{H}(\rightarrow \mathrm{b} \overline{\mathrm{b}}) \mathrm{W}$ searches based on boosted $\mathrm{H} \rightarrow \mathrm{b} \overline{\mathrm{b}}$ candidates. For the lepton-b-jet invariant-mass distribution-an observable that provides high sensitivity to the top-quark mass-finite-width corrections do not exceed one percent in the range that contains the bulk of the cross section, but become more sizable in the region of highest $m_{\mathrm{t}}$-sensitivity. This motivates more detailed studies of finite-width effects in the context of high-precision $m_{\mathrm{t}}$-measurements at the LHC. The results of this investigation of finite-width effects in t̄̄ production give also useful insights into possible limitations of treating associated top-pair production processes in the narrow-width approximation, since NLO calculations for $\mathrm{pp} \rightarrow \mathrm{WWb} \mathrm{\bar{b}}$ and similar reactions will not be available too soon.

[336] were performed on the Homewood High Performance Cluster of Johns Hopkins University supported by grant NSF-OCI-108849.

## 11. Strong and Smooth Ordering in Antenna Showers ${ }^{21}$

#### Abstract

We comment on strong and smooth ordering in antenna showers, and extend the definition of smooth ordering to include the case of $g \rightarrow q \bar{q}$ splittings. We define three observables in hadronic $Z$ decays that can be used to probe the subleading properties of shower models.

### 11.1 INTRODUCTION

Traditional parton showers are based on collinear factorization, and the shower evolution proceeds via $1 \rightarrow 2$ branchings, on which additional constraints have to be imposed to ensure momentum conservation and QCD coherence (see [344]). Antenna showers are instead based on momentum-conserving and intrinsically coherent $2 \rightarrow 3$ branchings, as pioneered by Ariadne [345, 346]. This note concerns the antenna shower implementation in the Vincia code [347], a plug-in to Pythia 8 [348], though we emphasize that the notion of smooth ordering could be applied to other shower types as well.

In leading-logarithmic (LL) antenna showers, the fundamental step is a Lorentz-invariant $2 \rightarrow 3$ branching process by which two on-shell "parent" partons are replaced by three on-shell "daughter" partons. This $2 \rightarrow 3$ process makes use of three ingredients [349]:

1. An antenna function that captures the leading tree-level singularities of QCD matrix elements.
2. An antenna phase space - an exact, momentum-conserving and Lorentz-invariant factorization of the pre- and post-branching phase spaces.
3. A kinematics map, specifying how the global orientation of the post-branching momenta are related to the pre-branching ones.
Antenna showers come in two varieties: global and sector. The two kinds differ in how the collinear singularities of gluons are partitioned among neighboring antennae, see [350, 351]. Here, we shall only be concerned with the global type [345, 352, 347, 349], in which the gluon-collinear singularity is partitioned such that two neigbouring antennae each contain "half" of it; their sum reproduces the full singularity.

If each antenna in a global shower is allowed to emit in its full phase space, the resulting shower evolution amounts to an incoherent addition of independently radiating dipoles. This tends to overcount regions in which several dipole terms contribute at the same level, i.e., in regions where dipole-dipole interference effects (or, equivalently, multipole effects) are important [353, 351]. The situation is analogous to, though less severe than, the case of traditional parton showers with virtuality-ordering [354], which represent an incoherent addition of independent monopoles. In parton/monopole showers, multiparton interference effects for soft radiation can be taken into account by the requirement of angular ordering [355], while in dipole/antenna showers, typically a measure of transverse momentum is used, such as

$$
\begin{equation*}
p_{\perp A}^{2}=\frac{s_{i j} s_{j k}}{s_{I K}} \tag{80}
\end{equation*}
$$

for a branching $I K \rightarrow i j k$, with $s_{a b} \equiv 2 p_{a} \cdot p_{b}=\left(p_{a}+p_{b}\right)^{2}$ for massless partons. Some alternative possibilities are compared in [349].

[^131]
### 11.2 STRONG AND SMOOTH ORDERING

In a strongly-ordered shower, each consecutive branching is required to occur at a lower scale in the evolution variable than that of the previous one: $Q_{n+1}<Q_{n}$. This can be represented as a step function in the evolution variable, multiplying the branching kernels. In a smoothly-ordered shower [349], the step function is replaced by a smooth dampening factor designed to leave the soft and collinear limits unchanged while suppressing radiation at scales above $\sim Q_{n}$. Specifically, for evolution in $p_{\perp}$, we replace the strong-ordering condition as follows,

$$
\begin{equation*}
\Theta\left(\hat{p}_{\perp}-p_{\perp}\right) P_{L L} \rightarrow P_{i m p} P_{L L} \equiv \frac{\hat{p}_{\perp}^{2}}{\hat{p}_{\perp}^{2}+p_{\perp}^{2}} P_{L L} \tag{81}
\end{equation*}
$$

where $\hat{p}_{\perp}$ characterizes the scale of the previous branching ${ }^{22}, p_{\perp}$ is the scale of the emission under consideration, and $P_{L L}$ is an ordinary LL shower kernel, which in our case is represented by a gluonemission antenna function. (We return to the case of $g \rightarrow q \bar{q}$ below.)

Thus, for $p_{\perp} \ll \hat{p}_{\perp}$ (the strongly-ordered limit) the smooth-ordering factor $P_{\text {imp }}$ tends to unity, while for $p_{\perp} \sim \hat{p}_{\perp}$ (the ordering threshold) it tends to $1 / 2$, and finally for $p_{\perp} \gg \hat{p}_{\perp}$ (highly unordered), it tends to zero $\propto \hat{p}_{\perp}^{2} / p_{\perp}^{2}$. Note that, since $P_{L L}$ is likewise $\propto 1 / p_{\perp}^{2}$, the net effect of the suppression factor is to modify the behavior of the splitting kernel from $1 / p_{\perp}^{2}$ in the strongly-ordered limits to $1 / p_{\perp}^{4}$ for highly unordered branchings, similar to what has been studied for initial-state parton showers in [356]; above the strong-ordering threshold, the branching probability is explicitly suppressed beyond LL.

For a rigourous interpretation of the $P_{\text {imp }}$ factor one would have to analyze the $2 \rightarrow 4$ antennae [79] and check that the combination of two $2 \rightarrow 3$ antennae times this factor does indeed reproduce subleading aspects of the full $2 \rightarrow 4$ function. In the absence of such a study, one may still physically interpret its purpose in the following way: the LL antenna functions are derived assuming the outgoing partons/jets to be massless. This is a good approximation if the virtuality that they can acquire (through further showering) is restricted by the strong-ordering threshold. When allowing unordered branchings, however, the corresponding Feynman diagrams contain highly off-shell propagators, which the $P_{\text {imp }}$ factor attempts to mimic by introducing an "effective mass" in the denominator of eq. 81.

For gluon emissions, it was shown in [349] that the smooth-ordering condition does lead to a systematic improvement in the shower. Since it simultaneously guarantees a complete phase-space coverage (contrary to the case for strong ordering [357, 349]), it is the default option in Vincia.

Antenna showers including $g \rightarrow q \bar{q}$ splittings were studied in [358], in which evolution in $m_{q \bar{q}}^{2}$ was introduced for such branchings. This is based on the observation [359] that the scale controlling the divergences of $g \rightarrow q \bar{q}$ splittings is the invariant mass of the pair, not its $p_{\perp}$. By analogy with the physical interpretation given to the $P_{\text {imp }}$ factor for gluon emissions above, it therefore seems well-motivated to study a "generalized" $P_{\text {imp }}$ factor where each scale depends on whether we are dealing with a gluon or a quark:

$$
\begin{equation*}
P_{i m p}=\frac{\hat{Q}_{E}^{2}}{\hat{Q}_{E}^{2}+Q_{E}^{2}}, \tag{82}
\end{equation*}
$$

where $Q_{E}$ is the evolution variable: $p_{\perp}$ for gluons and invariant mass for quark-antiquark pairs.
We can assess the improvement that this produces in the shower by plotting the ratio of the shower approximation vs. the LO matrix element for $Z \rightarrow q \bar{q}^{\prime} q^{\prime} \bar{q}$ and $Z \rightarrow q \bar{q}^{\prime} q^{\prime} g \bar{q}$. This is shown in fig. 28, where the histograms represent the distribution of $\log _{10}(\mathrm{PS} / \mathrm{ME})$ in a flat phase-space scan, normalized to unity (i.e., the same type of distributions that were shown in [349, 358, 351]). Points to the left of zero are undercounted by the shower approximation, while points to the right are overcounted. Although the agreement is by no means perfect, we do observe a slight improvement in the shower approximation

[^132]

Fig. 28: Comparison between generalized $\tilde{P}_{i m p}$ and "old" $P_{i m p}$ factor in the global shower approximations to LO matrix elements, for processes involving a $g \rightarrow q \bar{q}$ splitting. Left: $Z \rightarrow q \bar{q}^{\prime} q^{\prime} \bar{q}$. Right: $Z \rightarrow q \bar{q}^{\prime} q^{\prime} q \bar{q}$. In both cases, GKS matching to the LO matrix element for the preceding multiplicity ( $Z \rightarrow 3$ and $Z \rightarrow 4$, respectively) has been included, and the Ariadne factor was applied to $g \rightarrow q \bar{q}$ splittings.
when the $P_{i m p}$ factor is defined in terms of $Q_{E}$ (solid black histogram), as compared to the definition used previously (dashed histogram). Note that we used the so-called Ariadne factor in the shower approximation for all cases, see [358], and that the distributions were made including GKS matching to the preceding multiplicities [349].

### 11.3 SENSITIVE OBSERVABLES IN HADRONIC Z DECAYS

The properties of shower and matrix-element matching algorithms are coming under increasing scrutiny, not least due to the desire of achieving reliable descriptions of jet production and jet properties, such as jet substructure, for signal and background estimates at the LHC.

For final-state radiation, i.e., jet broadening and jet splitting, hadronic $Z$ decays are the main reference, with a large set of events shapes and jet resolutions/rates being used to constrain and tune shower algorithms (see, e.g., [360, 344]). However, in the logarithmically dominated regions, these observables are typically dominated by leading logs, and are well described by all coherent and reasonably well-tuned shower algorithms on the market. In order to probe the subleading properties in a more dedicated way, we have found the following three simple observables useful, each designed to isolate a specific aspect.

We consider hadronic $Z$ events (photon ISR is switched off, and matching beyond 3 jets is switched off for the strongly-ordered showers) and use the $k_{T}$ clustering algorithm [361] to cluster all events back to two jets. The $3 \rightarrow 2$ clustering scale is denoted $y_{23}=k_{T 3}^{2} / m_{Z}^{2}$, and so on for higher jet numbers. We require all $y_{i j}$ entering in the observables below to be greater than 0.005 , to remove contamination from $B$ decays and lower scales. Since the original topology contains two jets, we also keep track of which "side" each clustering happens on. Strong ordering corresponds to $y_{23} \gg y_{34} \gg \ldots$, while events with, e.g., $y_{34} \sim y_{23}$ should be more sensitive to the ordering condition and to the effective $1 \rightarrow 3$ spliting kernels.

The first observable is thus simply the ratio $y_{34} / y_{23}$, in events where the $4 \rightarrow 3$ and $3 \rightarrow 2$ clusterings happen in the same jet. This distribution is illustrated in the left-hand pane of fig. 29, with logarithmic axes. Vertical error bars indicate the expected $1 \sigma$ statistical error with 400 k hadronic $Z$ decays. Since the $k_{T}$ algorithm allows for unordered clustering scales, the distribution extends beyond $\xi_{24}=\ln \left(y_{34} / y_{24}\right)=0$. Default Pythia (thick solid line) is compared to three different Vincia settings: smooth (thin solid) and strong (dashed) ordering in $p_{\perp}$ and strong ordering in dipole virtuality, $m_{D}$ (dotted). Note here that ordering in the variables $p_{\perp}$ or $m_{D}$ does not directly imply ordering in $k_{T}$.

Fig. 29: Left: $\xi_{24}=\ln \left(y_{34} / y_{23}\right)$ in "same-side" 4-jet events. Right: Ratio of jet masses, $m_{L}^{2} / m_{H}^{2}$, in "compressed" 4-jet events. Error bars indicate expected $1 \sigma$ statistical errors with 400 k hadronic $Z$ decays.

The fact that the $P_{\text {imp }}$ factor also suppresses branchings slightly below the strong-ordering threshold is manifest in the thin solid line lying below the other ones in the region just below zero, which should be statistically significant with a sample size of $\sim 0.5 \mathrm{M}$ events. Note as well that these distributions become indistinguishable if one does not make the requirement of sameside clustering (not shown), presumably since opposite-side collinear splittings then dominate.

A related observable is shown in the right-hand pane of fig. 29. To force a "compressed" scale hierarchy, we impose the cut $y_{34}>0.5 y_{23}$, and plot the ratio $M_{L}^{2} / M_{H}^{2}$ of the masses of the jets at the end of the clustering. With four partons at LO, the light jet mass is zero if both the $4 \rightarrow 3$ and $3 \rightarrow 2$ clusterings happen in the same jet, while it is non-zero otherwise. Thus, the region close to zero isolates events with a $1 \rightarrow 3$ splitting occurring in one of the jets, while the region above $\sim 0.25$ is dominated by opposite-side $1 \rightarrow 2$ splittings. In Pythia and in mass-ordered Vincia, the peak at zero is stronger than in the $p_{\perp}$-ordered Vincia cases, while there is no difference between strong and smooth ordering in this variable. It thus serves as a useful complement to $\xi_{24}$.

Finally, in fig. 30, we consider 4-jet events in which the second and third jets (ordered in energy) are nearly collinear and back-to-back to the hardest jet. Specifically, we impose the cuts $\theta_{12}>120^{\circ}$, $\theta_{13}>120^{\circ}$, and $\theta_{23}<30^{\circ}$. We then plot the angle of the fourth (softest) jet with respect to the hardest one. Again the strong and smooth ordering options are indistinguishable, but interesting differences with respect to both Pythia and mass-ordered Vincia are visible. Mass-ordering tends to produce a broader distribution, with more radiation at right angles to the hardest jet (consistent with mass-ordering prioritizing wide-angle emissions over collinear ones), and the $p_{\perp}$-ordered Vincia showers exhibit a stronger collinear peak than the Pythia one. A similar observable was proposed in [362].

We conclude that, if all three observables could be measured with an accuracy of $\sim 5-10 \%$ or better, a useful and multi-dimensional constraint on the subleading shower aspects would be obtained, including sensitivity both to the type and shape of the ordering condition, and to the form of the effective $1 \rightarrow 3$ probabilities produced by the shower. We emphasize that we have here restricted our attention to shower models that are virtually indistinguishable on all other observables we have considered.

## ACKNOWLEDGEMENTS

## 12. PERTURBATIVE UNCERTAINTIES AND RESUMMATION FOR EXCLUSIVE JET CROSS SECTIONS ${ }^{23}$

### 12.1 Introduction

In this writeup we discuss predictions for exclusive jet cross sections, which have a particular number of jets in the final state. There are several motivations for analyzing events by dividing the data into exclusive jet bins, in particular when the relevant backgrounds strongly depend on the number of jets, or when the sensitivity can be increased by optimizing the analysis for the individual jet bins. As our primary example we will consider the Higgs analysis in the $H \rightarrow W W$ channel, which is performed separately in exclusive 0 -jet, 1 -jet, and 2 -jet bins [363, 364, 365]. Other examples are vector-boson fusion analyses, which are typically performed in the exclusive 2-jet channel, boosted $H \rightarrow b \bar{b}$ analyses that include a veto on additional jets, as well as $H \rightarrow \tau \tau$ and $H \rightarrow \gamma \gamma$ which benefit from improved sensitivity when the Higgs recoils against a jet. The importance of the Higgs +1 jet channel in $H \rightarrow \tau \tau$ and $H \rightarrow W W^{*}$ was demonstrated explicitly in Refs. [366, 367]. Another motivation for studying exclusive jet bins are the $W+$ jets channels, which are important backgrounds for new physics searches. We will use the notation $\sigma_{N}$ for an exclusive $N$-jet cross section (with exactly $N$ jets), and the notation $\sigma_{\geq N}$ for an inclusive $N$-jet cross section (with $N$ or more jets).

To explore the implications of the jet bin restrictions, consider a simple example where we divide the total cross section, $\sigma_{\text {total }}$, into an exclusive 0 -jet bin, $\sigma_{0}\left(p^{\mathrm{cut}}\right)$, and the remaining inclusive $(\geq 1)$-jet bin, $\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right)$,

$$
\begin{equation*}
\sigma_{\mathrm{total}}=\int_{0}^{p^{\mathrm{cut}}} d p \frac{d \sigma}{d p}+\int_{p^{\mathrm{cut}}} d p \frac{d \sigma}{d p} \equiv \sigma_{0}\left(p^{\mathrm{cut}}\right)+\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right) . \tag{83}
\end{equation*}
$$

Here $p$ denotes the kinematic variable which is used to divide up the cross section into jet bins. A typical choice is $p \equiv p_{T}^{\text {jet }}$, defined by the largest $p_{T}$ of any jet in the event, such that $\sigma_{0}\left(p_{T}^{\text {cut }}\right)$ only contains events with jets having $p_{T} \leq p_{T}^{\mathrm{cut}}$, and $\sigma_{\geq 1}\left(p_{T}^{\mathrm{cut}}\right)$ contains events with at least one jet with $p_{T} \geq p_{T}^{\text {cut }}$. By defining $\sigma_{0}\left(p_{T}^{\text {cut }}\right)$ and $\sigma_{\geq 1}\left(p_{T}^{\text {cut }}\right)$ one has divided up initial-state radiation from the

[^133]colliding hard partons and soft radiation in the event. This restriction on additional emissions changes the coefficients appearing in the $\alpha_{s}$ expansion and leads to the appearance of double and single logarithms of the form $\alpha_{s} \ln ^{2}\left(p^{\text {cut }} / Q\right)$ and $\alpha_{s} \ln \left(p^{\text {cut }} / Q\right)$ (with higher powers $\alpha_{s}^{n} \ln ^{m \leq 2 n}\left(p^{\text {cut }} / Q\right)$ appearing at higher orders in perturbation theory). Here $Q$ is the hard scale of the process, such as $Q=m_{H}$ for Higgs production, and most often we have $p^{\text {cut }} \ll Q$. These changes to the perturbation series can modify the convergence of fixed-order results and make it prudent to consider resummed cross section predictions that include an all-orders resummation of the large logarithms. For $N$ jets the analog of Eq. 833) is $\sigma_{\geq N}=\sigma_{N}\left(p_{N+1}^{\mathrm{cut}}\right)+\sigma_{\geq N+1}\left(p_{N+1}^{\mathrm{cut}}\right)$ and the same discussion applies regarding the large logarithms of $p_{N}^{\text {cut }}$ that are not present in $\sigma_{\geq N}$, but are present in each of $\sigma_{N}$ and $\sigma_{\geq N+1}$.

The definition of $\sigma_{0}\left(p^{\mathrm{cut}}\right)$ may include dependence on rapidity and on the grouping of particles. For a jet-based variable like $p_{T}^{\text {jet }}$ the former is induced by only considering jets within the rapidity range $\left|\eta^{\text {jet }}\right| \leq \eta^{\text {cut }}$, and the latter enters through the choice of jet algorithm. These dependencies make theoretical predictions more difficult. In Higgs production via gluon fusion the cross section is known to next-to-next-to-leading order (NNLO) [208, 368, 207, 209, 210, 211, 369, 370], and NNLO results including full kinematic information are available through FeHiP [214, 371] and HNNLO [90, 216] (as well as by combining the total NNLO cross section with MCFM [157, 372] for some distributions). When the measurements are performed in exclusive jet bins, the perturbative uncertainties in the theoretical predictions must also be evaluated separately for each individual jet bin [373]. When combining channels with different jet multiplicities, the correlations between the theoretical uncertainties can be significant and must be taken into account [26]. The perturbative predictions can be made more precise by including a resummation of large $p^{\text {cut }}$ dependent logarithms on top of the fixed-order predictions. At the leading logarithmic level this can be achieved with standard parton shower Monte Carlo programs, regardless of the precise definition of $p^{\mathrm{cut}}$. So far a next-to-next-to-leading logarithmic (NNLL) resummed result for a jet-veto variable only exists for beam thrust [374], $\mathcal{T}_{\mathrm{cm}}$, which is a rapidity weighted $E_{T}$-like inclusive variable. The definitions of the jet-veto variables we will use are

$$
\begin{equation*}
p_{T}^{\text {jet }}=\left|\sum_{k \in \mathrm{jet}} \vec{p}_{T k}\right|, \quad \quad \mathcal{T}_{\mathrm{cm}}=\sum_{k}\left|\vec{p}_{T k}\right| e^{-\left|\eta_{k}\right|}=\sum_{k}\left(E_{k}-\left|p_{k}^{z}\right|\right) . \tag{84}
\end{equation*}
$$

For $p_{T}^{\text {jet }}$ our jets are defined using anti- $k_{T}$ [341] with $R=0.5$, and we consider jets that satisfy a rapidity cut $|\eta| \leq \eta^{\text {cut }}$. For $\mathcal{T}_{\text {cm }}$ the sum is over all objects in the final state except the Higgs decay products, and can in principle be considered over particles, topo-clusters, or jets with a small $R$ parameter. In all our results we consistently use MSTW2008 NNLO PDFs [262].

In this writeup we will explore fixed NNLO and resummed NNLL+NNLO predictions for $H+$ 0 -jet cross sections and compare various methods for evaluating the uncertainty as a function of cuts on $p_{T}^{\text {jet }}$ and $\mathcal{T}_{\mathrm{cm}}$. The three methods we will discuss for evaluating the uncertainties in exclusive jet cross sections are
A) "Direct Exclusive Scale Variation". Here the uncertainties are evaluated by directly varying the renormalization and factorization scales in the fixed-order predictions for each exclusive jet cross section $\sigma_{N}$. This implies that the uncertainties are $100 \%$ correlated for different $N$ s.
B) "Combined Inclusive Scale Variation", as proposed in Ref. [26] and utilized in Refs. [363, 364 365]. Here, the perturbative uncertainties in the inclusive $N$-jet cross sections, $\sigma_{\geq N}$, are treated as the primary uncertainties that can be evaluated by scale variations in fixed-order perturbation theory. These uncertainties are treated as uncorrelated for different $N$. The exclusive $N$-jet cross sections are obtained using $\sigma_{N}=\sigma_{\geq N}-\sigma_{\geq N+1}$. The uncertainties and correlations follow from standard error propagation, including the appropriate anticorrelations between $\sigma_{N}$ and $\sigma_{N \pm 1}$ related to the division into jet bins.
C) "Uncertainties from Resummation." Resummed calculations for exclusive jet cross sections can provide uncertainty estimates that allow one to simultaneously include both types of correlated
and anticorrelated uncertainties as in methods A and B. The magnitude of the uncertainties may also be reduced from the resummation of large logarithms.
In all three methods, adding the exclusive jet cross sections yields the expected scale variation in the total cross section. Method B avoids a potential underestimate of the uncertainties in individual jet bins due to strong cancellations that can potentially take place in method A. Method B produces realistic perturbative uncertainties for exclusive jet cross sections when using fixed-order predictions for various processes, since it accounts for the presence of large logarithms at higher orders caused by the jet binning. In Method C one utilizes higher-order resummed predictions for the exclusive jet cross sections, which allow one to obtain improved central values and further refined uncertainty estimates.

The basic structure of the large logarithms in the perturbative series is discussed in Sec. 12.2. In Sec. 12.3 we discuss and compare the above three methods to determine the perturbative uncertainties. The work discussed here regarding methods A, B, and C builds on work done in Refs. [375, 26], was initiated at Les Houches, and has also been incorporated in the second Higgs Yellow Book report [376] (Secs. 5.2 and 5.5.) We also review recent work by others that can be found in [376](Sec. 5.3).

Note that here we are only discussing the theoretical uncertainties due to unknown higher-order perturbative corrections, which are commonly estimated using scale variation. Parametric uncertainties, such as PDF choices and $\alpha_{s}\left(m_{Z}\right)$ uncertainties, must be treated appropriately as common sources for all investigated channels.

### 12.2 Theoretical Motivation

### 12.21 Structure of the Perturbative Series

We begin by discussing the structure of the large logarithms in exclusive jet cross sections. For Higgs production from gluon fusion with $p_{T}^{\text {jet }} \leq p_{T}^{\text {cut }}$ the leading double logarithms appearing at $\mathcal{O}\left(\alpha_{s}\right)$ are

$$
\begin{equation*}
\sigma_{0}\left(p_{T}^{\mathrm{cut}}\right)=\sigma_{B}\left(1-\frac{3 \alpha_{s}}{\pi} 2 \ln ^{2} \frac{p_{T}^{\mathrm{cut}}}{m_{H}}+\cdots\right), \tag{85}
\end{equation*}
$$

where $\sigma_{B}$ is the Born (tree-level) cross section.
The total cross section only depends on the hard scale $Q=m_{H}$, which means by choosing the factorization and renormalization scales $\mu_{f} \simeq \mu_{r} \simeq m_{H}$, the fixed-order expansion does not contain large logarithms and has the structure

$$
\begin{equation*}
\sigma_{\text {total }} \simeq \sigma_{B}\left[1+\alpha_{s}+\alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] . \tag{86}
\end{equation*}
$$

Our expressions for perturbative series such as this one are schematic, showing the scaling of the terms without the coefficient functions. The convolution with the parton distribution functions (PDFs) are also not displayed. For $g g \rightarrow H$, the coefficients of this series can be large, corresponding to the well-known large K factors. As usual, varying the scale in $\alpha_{s}(\mu)$ (and the PDFs) one obtains an estimate of the size of the missing higher-order terms in this series, which we denote by $\Delta_{\text {total }}$.

The inclusive 1 -jet cross section has the perturbative structure

$$
\begin{equation*}
\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right) \simeq \sigma_{B}\left[\alpha_{s}\left(L^{2}+L+1\right)+\alpha_{s}^{2}\left(L^{4}+L^{3}+L^{2}+L+1\right)+\mathcal{O}\left(\alpha_{s}^{3} L^{6}\right)\right], \tag{87}
\end{equation*}
$$

where the logarithms $L=\ln \left(p^{\text {cut }} / m_{H}\right)$. For $p^{\text {cut }} \ll m_{H}$ these logarithms can get large enough to overcome the $\alpha_{s}$ suppression. In the limit $\alpha_{s} L^{2} \simeq 1$, the fixed-order perturbative expansion breaks down and the logarithmic terms must be resummed to all orders in $\alpha_{s}$ to obtain a meaningful result. For typical experimental values of $p^{\text {cut }}$ fixed-order perturbation theory can still be considered, but the logarithms cause large corrections at each order and dominate the series.

The exclusive 0 -jet cross section is equal to the difference between Eqs. (86) and (87), and so has the schematic structure
$\sigma_{0}\left(p^{\mathrm{cut}}\right)=\sigma_{\text {total }}-\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right)$

$$
\begin{equation*}
\simeq \sigma_{B}\left\{\left[1+\alpha_{s}+\alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right]-\left[\alpha_{s}\left(L^{2}+L+1\right)+\alpha_{s}^{2}\left(L^{4}+L^{3}+L^{2}+L+1\right)+\mathcal{O}\left(\alpha_{s}^{3} L^{6}\right)\right]\right\} \tag{88}
\end{equation*}
$$

In this difference, the large positive corrections in $\sigma_{\text {total }}$ partly cancel against the large negative logarithmic corrections in $\sigma_{\geq 1}$. For example, at $\mathcal{O}\left(\alpha_{s}\right)$ there is a value of $L$ for which the $\alpha_{s}$ terms in Eq. (88) cancel exactly. At this $p^{\text {cut }}$ the NLO 0 -jet cross section has vanishing scale dependence and is equal to the LO cross section, $\sigma_{0}\left(p^{\mathrm{cut}}\right)=\sigma_{B}$. Due to this cancellation, a standard use of scale variation in $\sigma_{0}\left(p^{\mathrm{cut}}\right)$ does not actually probe the size of the large logarithms, and does not provide an estimate of $\Delta_{\text {cut }}$. This issue impacts the uncertainties in the experimentally relevant region for $p^{\text {cut }}$.

For example, for $g g \rightarrow H$ (with $\sqrt{s}=7 \mathrm{TeV}, m_{H}=165 \mathrm{GeV}, \mu_{f}=\mu_{r}=m_{H} / 2$ ), one finds [214, 371, 90, 216]

$$
\begin{align*}
\sigma_{\text {total }} & =(3.32 \mathrm{pb})\left[1+9.5 \alpha_{s}+35 \alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] \\
\sigma_{\geq 1}\left(p_{T}^{\mathrm{jet}} \geq 30 \mathrm{GeV},\left|\eta^{\mathrm{jet}}\right| \leq 3.0\right) & =(3.32 \mathrm{pb})\left[4.7 \alpha_{s}+26 \alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] \tag{89}
\end{align*}
$$

In $\sigma_{\text {total }}$ one can see the impact of the well-known large $K$ factors. (Using instead $\mu_{f}=\mu_{r}=m_{H}$ the $9.5 \alpha_{s}$ and $35 \alpha_{s}^{2}$ coefficients in $\sigma_{\text {total }}$ increase to $11 \alpha_{s}$ and $65 \alpha_{s}^{2}$.) In $\sigma \geq 1$, one can see the impact of the large logarithms on the perturbative series. Taking their difference to get $\sigma_{0}$, one observes a sizeable numerical cancellation between the two series at each order in $\alpha_{s}$.

### 12.22 Perturbative Series for the Event Fraction

Experimentally the desired quantity which incorporates the jet-veto cut is the exclusive 0-jet event fraction

$$
\begin{equation*}
f_{0}\left(p^{\mathrm{cut}}\right)=\frac{\sigma_{0}\left(p^{\mathrm{cut}}\right)}{\sigma_{\mathrm{total}}}=1-\frac{\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right)}{\sigma_{\mathrm{total}}} . \tag{90}
\end{equation*}
$$

One option for treating $f_{0}\left(p^{\mathrm{cut}}\right)$ is to consider it as a derived quantity, given the basic observables $\left\{\sigma_{0}, \sigma_{\text {total }}\right\}$ or $\left\{\sigma_{\geq 1}, \sigma_{\text {total }}\right\}$. In this approach, which was utilized in Ref. [26] and Ref. [376](Secs. 5.2 and 5.5), one propagates the uncertainties from the $\sigma_{i} \mathrm{~s}$ to derive those for $f_{0}\left(p^{\mathrm{cut}}\right)$. This approach is natural from the perspective of utilizing log-resummed computations for $\sigma_{0}\left(p^{\mathrm{cut}}\right)$. In particular, it maintains the constraint that for large $p^{\text {cut }}$ we have monotonic convergence of $\sigma_{0} \rightarrow \sigma_{\text {total }}$ and $f_{0} \rightarrow 1$, a property that relies on a phase space cut reducing the cross section, but does not depend on perturbation theory.

When using fixed-order predictions for the various cross sections, an alternative to Eq. (90) considered in Ref. [376](Sec. 5.3) is to analyze the perturbation theory for $f_{0}\left(p^{\mathrm{cut}}\right)$ directly. In this case different schemes of organizing the perturbation series, by keeping or dropping various $\mathcal{O}\left(\alpha_{s}^{3}\right)$ terms, give a method to estimate the size of the higher-order perturbative corrections. Three such schemes were considered in Ref. [376](Sec. 5.3) (which we label here by schemes 1,2,3). It is convenient to define the perturbative corrections to the cross section by dividing each of them by the Born cross section $\sigma_{B}$, such that we can write

$$
\begin{align*}
\sigma_{\text {total }} & =\sigma_{B}\left[1+\hat{\sigma}_{\text {total }}^{(1)}+\hat{\sigma}_{\text {total }}^{(2)}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right], \\
\sigma_{\geq 1}\left(p^{\text {cut }}\right) & =\sigma_{B}\left[\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\text {cut }}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\text {cut }}\right)+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] . \tag{91}
\end{align*}
$$

With this notation the result of treating $f_{0}$ as a derived quantity is

$$
\begin{equation*}
\left[f_{0}\left(p^{\mathrm{cut}}\right)\right]^{(\text {scheme } 1)}=1-\frac{\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\mathrm{cut}}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\mathrm{cut}}\right)}{1+\hat{\sigma}_{\text {total }}^{(1)}+\hat{\sigma}_{\text {total }}^{(2)}}+\mathcal{O}\left(\alpha_{s}^{3}\right), \tag{92}
\end{equation*}
$$

while at the same order in perturbation theory we can also consider the following expressions for $f_{0}$ :

$$
\begin{align*}
& {\left[f_{0}\left(p^{\mathrm{cut}}\right)\right]^{\text {(scheme } 2)}=1-\frac{\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\mathrm{cut}}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\mathrm{cut}}\right)}{1+\hat{\sigma}_{\text {total }}^{(1)}}+\mathcal{O}\left(\alpha_{s}^{3}\right),} \\
& {\left[f_{0}\left(p^{\mathrm{cut}}\right)\right]^{(\text {scheme } 3)}=1-\left[\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\mathrm{cut}}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\mathrm{cut}}\right)\right]+\hat{\sigma}_{\geq 1}^{(1)} \hat{\sigma}_{\text {total }}^{(1)}+\mathcal{O}\left(\alpha_{s}^{3}\right) .} \tag{93}
\end{align*}
$$

We will contrast using the expressions in Eq. (92) and Eq. (93) with various methods for analyzing the uncertainty in our discussion below.

### 12.3 Uncertainty Analysis for Exclusive Jet Bins

As described in Sec. 12.21, the phase space restriction defining $\sigma_{0}$ changes its perturbative structure compared to that of $\sigma_{\text {total }}$. In general this gives rise to an additional perturbative uncertainty due to missing higher-order terms depending on $p^{\text {cut }}$. We will call the associated jet-binning uncertainty $\Delta_{\text {cut }}$. This can be thought of as an uncertainty related to the presence of large logarithms of $p^{\text {cut }}$ at higher orders in perturbation theory. In Eq. (83) both $\sigma_{0}$ and $\sigma_{\geq 1}$ depend on the phase space cut, $p^{\text {cut }}$, and by construction this dependence cancels in $\sigma_{0}+\sigma_{\geq 1}$. Hence, the additional uncertainty $\Delta_{\text {cut }}$ induced by $p^{\text {cut }}$ must be $100 \%$ anticorrelated between $\sigma_{0}\left(p^{\text {cut }}\right)$ and $\sigma_{\geq 1}\left(p^{\text {cut }}\right)$, such that it cancels in their sum. For example, using a covariance matrix to model the uncertainties and correlations, the contribution of $\Delta_{\text {cut }}$ to the covariance matrix for $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ must be of the form

$$
C_{\mathrm{cut}}=\left(\begin{array}{cc}
\Delta_{\mathrm{cut}}^{2} & -\Delta_{\mathrm{cut}}^{2}  \tag{94}\\
-\Delta_{\mathrm{cut}}^{2} & \Delta_{\mathrm{cut}}^{2}
\end{array}\right) .
$$

The questions then are: (1) How can we estimate $\Delta_{\text {cut }}$ in a simple way, and (2) how is the perturbative uncertainty $\Delta_{\text {total }}$ of $\sigma_{\text {total }}$ related to the uncertainties of $\sigma_{0}$ and $\sigma_{\geq 1}$ ?

### 12.31 Perturbative Uncertainties for Method A

When using method A to estimate the perturbative uncertainties one simply uses a common scale variation to estimate the uncertainty $\Delta_{0}$ in $\sigma_{0}$ and the uncertainty $\Delta_{\geq 1}$ in $\sigma_{\geq 1}$. By doing so the uncertainties are $100 \%$ correlated, corresponding to a covariance matrix in method A for $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ given by

$$
C_{A}=\left(\begin{array}{cc}
\Delta_{0}^{2} & \Delta_{0} \Delta_{\geq 1}  \tag{95}\\
\Delta_{0} \Delta_{\geq 1} & \Delta_{\geq 1}^{2}
\end{array}\right)
$$

Here $\Delta_{\text {total }}=\Delta_{0}+\Delta_{\geq 1}$ is the scale uncertainty in $\sigma_{\text {total }}$. When instead of $\sigma_{0}$ we directly calculate the 0 -jet event fraction $f_{0}$ using Eq. (92) or one of the expressions in Eq. (93), we can again determine the method A uncertainty estimate by scale variation in $f_{0}$ (we will refer to these results as methods $A_{1}, A_{2}$, and $A_{3}$ respectively).

In this method $\Delta_{\text {cut }}$ is not included because, as explained below Eq. (88), varying the perturbative scale in $\Delta_{0}$ does not probe the presence of the higher order large logarithms depending on $p^{\text {cut }}$. This method can lead to an underestimate of the perturbative uncertainty in $\sigma_{0}$ (and hence $f_{0}$ ), since there is a region of $p^{\text {cut }}$ values where scale variation is no longer a reasonable estimate of higher order corrections because of the vanishing of the $\mu$ dependence.

### 12.32 Perturbative Uncertainties for Method B

Since the perturbative series for $\sigma_{\geq 1}$ in Eq. (87) is dominated by the large logarithms of $p^{\text {cut }}$, we can use its scale variation $\Delta_{\geq 1}$ to get an estimate for their size by taking $\Delta_{\text {cut }}=\Delta_{\geq 1}$ [26]. Since $\Delta_{\text {cut }}$ and $\Delta_{\text {total }}$ are by definition uncorrelated, by setting $\Delta_{\text {cut }}=\Delta_{\geq 1}$ we are effectively treating the perturbative
series for $\sigma_{\text {total }}$ and $\sigma_{\geq 1}$ as independent with uncorrelated perturbative uncertainties. That is, considering $\left\{\sigma_{\text {total }}, \sigma_{\geq 1}\right\}$, the covariance matrix is diagonal,

$$
\left(\begin{array}{cc}
\Delta_{\text {total }}^{2} & 0  \tag{96}\\
0 & \Delta_{\geq 1}^{2}
\end{array}\right)
$$

where $\Delta_{\text {total }}$ and $\Delta_{\geq 1}$ are evaluated by separate scale variations in the fixed-order predictions for $\sigma_{\text {total }}$ and $\sigma_{\geq 1}$. This is consistent, since for small $p^{\text {cut }}$ the two series have very different structures. In particular, there is no reason to believe that the same cancellations in $\sigma_{0}$ will persist at every order in perturbation theory at a given $p^{\text {cut }}$. It follows that the perturbative uncertainty in $\sigma_{0}=\sigma_{\text {total }}-\sigma_{\geq 1}$ is given by $\Delta_{\text {total }}^{2}+\Delta_{\geq 1}^{2}$, and the resulting covariance matrix for $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ in method B is

$$
C_{B}=\left(\begin{array}{cc}
\Delta_{\geq 1}^{2}+\Delta_{\text {total }}^{2} & -\Delta_{\geq 1}^{2}  \tag{97}\\
-\Delta_{\geq 1}^{2} & \Delta_{\geq 1}^{2}
\end{array}\right) .
$$

Note that all of $\Delta_{\text {total }}$ occurs in the uncertainty for $\sigma_{0}$. This is reasonable from the point of view that $\sigma_{0}$ starts at the same order in $\alpha_{s}$ as $\sigma_{\text {total }}$ and contains the same leading virtual corrections. The method B uncertainty for the event fraction $f_{0}$ follows most naturally by error propagation from the cross sections, treating it as a derived quantity.

The limit $\Delta_{\text {cut }}=\Delta_{\geq 1}$ that Eq. (97) is based on is of course an approximation. However, the preceding arguments show that it is a more reasonable starting point than method A , since the latter does not account for the additional $p^{\text {cut }}$ induced uncertainties.

The generalization of the above discussion to more jets and several jet bins is straightforward. For the $N$-jet bin we replace $\sigma_{\text {total }} \rightarrow \sigma_{\geq N}, \sigma_{0} \rightarrow \sigma_{N}$, and $\sigma_{\geq 1} \rightarrow \sigma_{\geq N+1}$. If the perturbative series for $\sigma_{\geq N}$ exhibits large $\alpha_{s}$ corrections due to its logarithmic series or otherwise, then the presence of a different series of large logarithms in $\sigma_{\geq N+1}$ will again lead to cancellations when we consider the difference $\sigma_{N}=\sigma_{\geq N}-\sigma_{\geq N+1}$. These two cross sections will have different series for their double logarithms since the number of active partons and their color structure differ. In this situation $\Delta_{\geq N+1}$ will again give a better estimate for the extra $\Delta_{\text {cut }}$ type uncertainty that arises from separating $\sigma_{\geq N}$ into $\sigma_{N}$ and $\sigma_{\geq N+1}$.

### 12.33 Perturbative Uncertainties for Method C

In method C we assess the perturbative uncertainties using resummed predictions for variables $p^{\text {cut }}$ that implement a jet veto, following Refs. [375, 26]. An advantage of using resummed predictions is that they contain perturbation theory scale parameters which allow for an evaluation of two components of the theory error, one which is $100 \%$ correlated with the total cross section (as in method A), and one related to the presence of the jet-bin cut which is anti-correlated between neighboring jet bins (as in method B).

The resummed $H+0$-jet cross section predictions of Ref. [375] follow from a factorization theorem for the 0 -jet cross section [374], $\sigma_{0}\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)=H \mathcal{I}_{g i} \mathcal{I}_{g j} \otimes S f_{i} f_{j}$, where $H$ contains hard virtual effects, the $\mathcal{I}_{\text {s }}$ and $S$ describe the veto-restricted collinear and soft radiation, and the $f$ s are standard parton distributions. Fixed-order perturbation theory is carried out at three scales, a hard scale $\mu_{H}^{2} \sim m_{H}^{2}$ in $H$, and beam and soft scales $\mu_{B}^{2} \sim m_{H} \mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$ and $\mu_{S}^{2} \sim\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)^{2}$ for $\mathcal{I}$ and $S$, and are then connected by NNLL renormalization group evolution that sums the jet-veto logarithms, which are encoded in ratios of these scales. The perturbative uncertainties can be assessed by considering two sources: i) an overall scale variation that simultaneously varies $\left\{\mu_{H}, \mu_{B}, \mu_{S}\right\}$ up and down by a factor of two which we denote by $\Delta_{H 0}$, and ii) individual variations of $\mu_{B}$ or $\mu_{S}$ that each hold the other two scales fixed [375], whose envelope we denote by the uncertainty $\Delta_{S B}$. Here $\Delta_{H 0}$ is dominated by the same sources of uncertainty as the total cross section $\sigma_{\text {total }}$, and hence should be considered $100 \%$ correlated with its uncertainty

Fig. 31: Relative uncertainties for the 0 -jet bin cross section from resummation at NNLL+NNLO for beam thrust $\mathcal{T}_{\mathrm{cm}}$ on the left and $p_{T}^{\text {jet }}$ on the right.
$\Delta_{\text {total }}$. The uncertainty $\Delta_{S B}$ is only present due to the jet-bin cut, and hence gives the $\Delta_{\text {cut }}$ uncertainty that is anti-correlated between neighboring jet bins.

If we simultaneously consider the cross sections $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ then the full correlation matrix in method C is

$$
C_{C}=\left(\begin{array}{cc}
\Delta_{S B}^{2} & -\Delta_{S B}^{2}  \tag{98}\\
-\Delta_{S B}^{2} & \Delta_{S B}^{2}
\end{array}\right)+\left(\begin{array}{cc}
\Delta_{H 0}^{2} & \Delta_{H 0} \Delta_{H \geq 1} \\
\Delta_{H 0} \Delta_{H \geq 1} & \Delta_{H \geq 1}^{2}
\end{array}\right),
$$

where $\Delta_{H \geq 1}=\Delta_{\text {total }}-\Delta_{H 0}$ encodes the $100 \%$ correlated component of the uncertainty for the ( $\geq 1$ )jet inclusive cross section. Computing the uncertainty in $\sigma_{\text {total }}$ gives back $\Delta_{\text {total }}$.

Eq. (98) can be compared to $C_{A}$ for method A in Eq. (95), which corresponds to taking $\Delta_{S B} \rightarrow 0$ and obtaining the analog of $\Delta_{H 0}$ by up/down scale variation without resummation ( $\mu_{H}=\mu_{B}=\mu_{S}$ ). It can also be compared to $C_{B}$ for method B in Eq. (97), which corresponds to taking $\Delta_{S B} \rightarrow \Delta_{\geq 1}$ and $\Delta_{H \geq 1} \rightarrow 0$, such that $\Delta_{H 0} \rightarrow \Delta_{\text {total }}$. The numerical dominance of $\Delta_{S B}^{2}$ over $\Delta_{H 0} \Delta_{H \geq 1}$ in the 0 -jet region is another way to justify the preference for using method B when only given a choice between methods A and B. For example, for $p_{T}^{\mathrm{cut}}=30 \mathrm{GeV}$ and $\left|\eta^{\text {jet }}\right| \leq 5.0$ we have $\Delta_{S B}^{2}=0.17$ and $\Delta_{H 0} \Delta_{H \geq 1}=0.02$.

In Fig. 31 we show the uncertainties $\Delta_{S B}$ (light green) and $\Delta_{H 0}$ (medium blue) as a function of the jet-veto variable, as well as the combined uncertainty adding these components in quadrature (dark orange). From the figure we see that the $\Delta_{H 0}$ dominates at large values where the veto is turned off and we approach the total cross section, and that the jet-cut uncertainty $\Delta_{S B}$ dominates for the small cut values that are typical of experimental analyses with Higgs jet bins. The same pattern is observed in the left panel which directly uses the NNLL+NNLO predictions for $\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$, and the right panel which shows the result from reweighting these predictions to $p_{T}^{\mathrm{cut}}$ as explained in Sec .12 .34 below.

### 12.34 Comparison of Uncertainty Methods

In Fig. 32 we compare the uncertainties for the 0 -jet bin cross section from methods A (medium green), B (light green), and C (dark orange). In the upper panels we use $\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$ as the jet-veto variable and full results for the NNLO and NNLL+NNLO cross sections, while in the lower panels we use $p_{T}^{\text {cut }}$ as the jet-veto variable with the full NNLO and the reweighted NNLL+NNLO results (as explained below). The upper panels use a cut on beam thrust, $\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$ while the lower panels use $p_{T}^{\mathrm{cut}}$. The right panels show the same results as those on the left, but are normalized to the highest-order result to better show the relative differences and uncertainties. The uncertainties in methods $\mathrm{A}, \mathrm{B}$, and C are computed from the upper left entry of the matrices $C_{A}, C_{B}$, and $C_{C}$, respectively.

Fig. 32: Comparison of uncertainties for methods A, B, C for the 0 -jet bin cross section for beam thrust $\mathcal{T}_{\text {cm }}$ (top) and $p_{T}^{\text {jet }}$ (bottom). Results are shown at NNLO with uncertainties from methods A and B and for the NNLL+NNLO resummed result using method C (reweighted for $p_{T}^{\mathrm{cut}}$ ). On the right all curves are normalized relative to the NNLL+NNLO central value.

From Fig. 32 we see that in method A (medium green bands) for small values of $p_{T}^{\text {cut }}$ the cancellations that take place in $\sigma_{0}\left(p^{\text {cut }}\right)$ cause the error bands to shrink and eventually almost vanish at $p_{T}^{\text {cut }} \simeq 25 \mathrm{GeV}$, where there is an almost exact cancellation between the two series in Eq. 88). This is avoided by using method B (light green bands). For large values of $p_{T}^{\text {cut }}$ method B reproduces the method A scale variation, since $\sigma_{\geq 1}\left(p^{\text {cut }}\right)$ becomes small. On the other hand, for small values of $p_{T}^{\text {cut }}$ the uncertainties estimated using method B are more realistic, because they explicitly estimate the uncertainties due to the presence of higher order large logarithmic corrections.

The features of this plot are quite generic. In particular, the same pattern of uncertainties is observed for the Tevatron, when using $\mu=m_{H}$ as our central scale (with $\mu=2 m_{H}$ and $\mu=m_{H} / 2$ for the range of scale variation), whether or not we only look at jets at central rapidities, or when considering the exclusive 1 -jet cross section. We also note that using independent variations for $\mu_{f}$ and $\mu_{r}$ does not change this picture, in particular the $\mu_{f}$ variation for fixed $\mu_{r}$ is quite small.

For method C with $\mathcal{T}_{\mathrm{cm}}$ we make use of resummed predictions for $H+0$ jets from gluon fusion at next-to-next-to-leading logarithmic order (NNLL+NNLO) from Ref. [375]. This includes the correct NNLO fixed-order corrections for $\sigma_{0}\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)$ for any cut. The resulting cross section $\sigma_{0}\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)$ has the jet veto implemented by a cut $\mathcal{T}_{\mathrm{cm}} \leq \mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$. This cross section contains a resummation of large logarithms at two orders beyond standard LL parton shower programs. A similar resummation for the case of $p_{T}^{\text {jet }}$ is not available. Instead, we use MC @ NLO and reweight it to the resummed predictions in $\mathcal{T}_{\mathrm{cm}}$, doing so for both the central curve as well as each of the six scale variation curves needed for the uncertainty

Fig. 33: In the left panel we show the same three curves as in the bottom-left panel of Fig. 32, but for the event fraction $f_{0}\left(p_{T}^{\mathrm{cut}}\right)$ treated as a derived quantity from the jet-bin cross sections. In the right panel we contrast the uncertainties obtained using Eqs. (92) and (93) together with method A, with the uncertainty obtained using method B.
determination in method $C{ }^{24}$ We then use the reweighted Monte Carlo sample to obtain cross section predictions for the standard jet veto, $\sigma_{0}\left(p_{T}^{\mathrm{cut}}\right)$. We will refer to this as the reweighted NNLL+NNLO result. Since the Monte Carlo here is only used to provide a transfer matrix between $\mathcal{T}_{\text {cm }}$ and $p_{T}^{\text {jet }}$, and both variables implement a jet veto, one expects that most of the improvements from the higherorder resummation are preserved by the reweighting. However, we caution that this is not equivalent to a complete NNLL+NNLO result for the $p_{T}^{\text {cut }}$ spectrum, since the reweighting may not fully capture effects associated with the choice of jet algorithm and other effects that enter at this order for $p_{T}^{\text {cut }}$. The dependence on the Monte Carlo transfer matrix also introduces an additional uncertainty, which should be studied and is not included in our numerical results. The transfer matrix is obtained at the parton level, without hadronization or underlying event, since we are reweighting a partonic NNLL+NNLO calculation.

From Fig. 32 one observes that the resummation of the large jet-veto logarithms (dark red central curve) lowers the cross section for both $\mathcal{T}_{\mathrm{cm}}^{\text {cut }}$ and $p_{T}^{\text {cut }}$. Comparing to NNLO for cut values $\gtrsim 25 \mathrm{GeV}$ the relative uncertainties in the resummed result of method C (dark orange bands) and the reduction in the resummed central value are similar for both jet-veto variables. Since one expects resummation to decrease the uncertainties, one can also see that the NNLO uncertainties from method B are more consistent with the higher order NNLL+NNLO resummed method C results than those in method A . We observe that the uncertainties in method C are reduced by about a factor of two compared to those in method B. Since the zero-jet bin plays a crucial role in the $H \rightarrow W W$ channel for Higgs searches, and these improvements will also be reflected in uncertainties for the one-jet bin, the improved theoretical precision obtained with method C has the potential to be quite important.

In Fig. 33 we show results for the 0 -jet event fraction $f_{0}$, with $p_{T}^{\text {cut }}$ as the jet-veto variable. In the left panel we compare the uncertainties in $f_{0}\left(p_{T}^{\text {cut }}\right)$ that result from propagating the uncertainties from the jet-bin cross sections obtained from methods A (medium green), B (light green), and C (dark orange). The conclusions are analogous to the corresponding cross-section results in the bottom-left panel of Fig. 32, namely that method B provides a better estimate for the perturbative fixed-order uncertainties than method A, and that the higher-order logarithmic summation present in method C leads to a slightly smaller central value together with the decrease to the uncertainty one expects from incorporating the resummation. In the right panel of Fig. 33 we show the results of the different perturbative schemes for $f_{0}$ defined in Eq. 92) (middle dark green band) and Eq. 93) (lower narrow blue band and upper wide

[^134]|  | method A | method B | method C |

yellow band) each at NNLO and in each case obtaining the uncertainties using method A (direct scale variation) [376](Sec. 5.3). For comparison, the middle light green band shows the uncertainties obtained from method B. The different method A schemes have a wide spread, which demonstrates the large size of the higher-order perturbative corrections in the total and inclusive 1-jet cross sections. The central values of the alternative methods $A_{2}$ and $A_{3}$ are not covered by the method $A_{1}$ uncertainty band, but all three central curves are covered by the larger uncertainty band from method B (except at small $p_{T}^{\text {cut }}$ where scheme 3 starts to diverge earlier than the other schemes). This can be taken as a confirmation that method A tends to underestimate the perturbative uncertainties in the fixed-order results [376](Sec. 5.3), while method B produces more realistic fixed-order uncertainties.

To appreciate the effects of the different methods on the correlation matrix we consider as an example the results for $p_{T}^{\text {cut }}=30 \mathrm{GeV}$ and $\left|\eta^{\text {jet }}\right| \leq 5.0$. The inclusive cross sections are $\sigma_{\text {total }}=(8.76 \pm$ $0.80) \mathrm{pb}$ at NNLO, and $\sigma_{\geq 1}=(3.31 \pm 0.64) \mathrm{pb}$ at NLO. The relative uncertainties and correlations at these cuts for the three methods are shown in Table 9 . The numbers for the cross sections are also translated into the equivalent results for the event fractions, $f_{0}\left(p_{T}^{\text {cut }}\right)=\sigma_{0}\left(p_{T}^{\text {cut }}\right) / \sigma_{\text {total }}$ and $f \geq 1\left(p_{T}^{\text {cut }}\right)=$ $\sigma_{\geq 1}\left(p_{T}^{\text {cut }}\right) / \sigma_{\text {total }}$. Note that method A should not be used due to the lack of a contribution corresponding to $\Delta_{\text {cut }}$ in this method, and the resulting underestimated $\delta \sigma_{0}$. In methods B and C we see, as expected, that $\sigma_{0}$ and $\sigma_{\geq 1}$ have a substantial anti-correlation due to the jet-bin boundary they share.

### 12.4 Conclusion

To summarize, we have discussed the implications of separating LHC cross sections into jet bins, using Higgs production from gluon fusion as a concrete example. The jet binning induces logarithmic dependences on the jet-bin boundary which is important to properly take into account when making predictions and estimating perturbative uncertainties. When using fixed-order predictions only, the additional logarithms at higher orders in perturbation theory caused by the jet binning can be taken into account in the perturbative uncertainty estimate using method B. By resumming the jet-binning logarithms one can obtain improved predictions with reduced (and more sophisticated) uncertainties using method C.

Here we have focused our discussion on $\sigma_{0}$ and $\sigma_{\geq 1}$ and how to take into account the resulting jet-bin boundary. To further separate $\sigma_{\geq 1}$ into a one-jet bin $\sigma_{1}$ and a $\sigma_{\geq 2}$ one can use method B for this boundary by treating $\Delta_{\geq 2}$ as uncorrelated with the total uncertainty for $\sigma_{\geq 1}$ from either methods B or C. Examples of utilizing method B for this jet bin boundary can be found in Ref. [26]. Once it becomes available one can also use a resummed prediction with uncertainties for this boundary with method C .

## 13. A NLO BENCHMARK COMPARISON FOR INCLUSIVE JET PRODUCTION AT HADRON COLLIDERS ${ }^{25}$

#### Abstract

We present a benchmark comparison of two next-to-leading order (NLO) calculations for inclusive jet and jet pair production at hadron colliders. A new version of the NLO code EKS is adapted for computation of differential cross sections and compared to an independent calculation based on the FastNLO code. A percent-level agreement between the two codes is observed for specified settings of computations at typical transverse momenta and rapidities of Tevatron and LHC measurements. We identify theoretical prerequisites for achieving such level of agreement and comment on the stability of NLO calculations with respect to the factorization scale choice.

### 13.1 INTRODUCTION

Inclusive jet production at hadron colliders provides an excellent opportunity to test perturbative QCD (PQCD) and look for possible new physics beyond the Standard Model (SM) over a wide range of energy scales. Single inclusive jet production in the Tevatron Run-2 has been recently used to determine the QCD coupling constant [377] and constrain parton distribution functions (PDF) in the proton in global QCD analyses by several groups [255, 378, 262, 311]. Jet production data provide constraints on the gluon PDF at large $x$ values, possibly in a combination with small- $x$ quark PDFs, as discussed in Section 7. Invariant mass distributions of dijets [379], angular distributions [380, 381], and other jet observables at the LHC [382, 293, 292] provide a unprecedented opportunity to extend searches for quark compositeness and new particle resonances toward the highest energies attainable.

In this contribution, we examine agreement between the computer programs that are available for NLO calculations of jet production cross sections. NLO QCD predictions for jet production work remarkably well in a wide kinematical range and across many orders of magnitude of the cross sections. Nonetheless, the latest PDF analysis evaluates many scattering processes up to NNLO in perturbative QCD. Jet production observables are pivotal for constraining the large- $x$ gluon PDF, but remain known to NLO only. We identify and document main factors affecting NLO jet cross sections at a few-percent level of accuracy and compare the numerical results for typical collider kinematics. Differences between the programs used, and choices for the theoretical inputs made, may be responsible for some differences observed between CT10 and other PDFs, as explained below. Such NLO benchmark comparison will be useful for quantifying or reducing the uncertainties on the resulting PDFs and for the future implementation of NNLO and higher-order resummed contributions to the jet cross sections.

From the experimental point of view, jet production has an advantage of very high statistics and a drawback of sizeable systematical errors associated with complexities of jet reconstruction. NLO theoretical uncertainties due to the QCD scale dependence and the fixed-order model for the jet algorithm are comparable to the experimental errors. Control of numerical accuracy involves, in particular, careful tuning of Monte-Carlo integration to handle steeply falling jet cross sections.

An early numerical code (EKS) for the NLO calculation of single-inclusive jet and dijet distributions was developed by S. D. Ellis, Z. Kunszt and D. E. Soper in 1990's [383] based on the subtraction method. Two other widely used numerical programs are NLOJET++ [384, 385] and FastNLO [290, 291].

[^135]The latter provides a fast interface to obtain NLO predictions in kinematical bins of already published experimental jet cross sections by interpolating table files produced by NLOJET++. Besides these fixedorder calculations, POWHEG combines the NLO jet production cross sections with leading-logarithm QCD showering effects [386]. Some phenomenological studies also include partial NNLO contributions to jet cross sections obtained by threshold resummation [387].

The agreement between the above NLO numerical programs is not automatically met, which motivates the present benchmark comparison. The past CTEQ PDF analyses computed NLO jet cross sections using NLO K-factor tables produced by the EKS code, while other PDF analysis groups use FastNLO. Since the CT10 NLO gluon PDF behaves somewhat differently at large $x$ than the gluon PDF from MSTW'08 or other groups [262], one must compare the EKS and FastNLO computations for the same input values to confirm that these programs do not cause the observed disagreement.

Here we show that the results for the Tevatron $(\sqrt{s}=1.96 \mathrm{TeV})$ and LHC $(\sqrt{s}=7 \mathrm{TeV})$ from EKS and FastNLO agree well when the computation parameters are chosen as described in the next section. These settings must be consciously controlled in order to reach acceptable agreement. As a result of this work, the EKS code has been revised to improve its stability and efficiency and to implement output into new differential cross sections [388].

### 13.2 Theoretical setup and inputs

Several theoretical inputs must be matched exactly between the EKS and FastNLO programs in order to reach the level of agreement shown in the figures below.

- Jet algorithm. When calculating the distribution of jet observables, we need to use the same jet algorithms as the ones in the experimental measurements. In this comparison, we utilized the cone-based Midpoint algorithm [389] for the Tevatron observables and cluster-based anti- $k_{T}$ algorithm [341] for the LHC. The only difference between the Midpoint algorithm and modified Snowmass algorithm [389] used in the original EKS program is that the Midpoint algorithm always starts with the middle point between the two partons' directions as a seed for a new protojet, no matter how large their separation is. In the NLO theoretical calculations for single-jet or dijet production that include at most three final-state partons, the cluster-based $k_{T}$ [390], anti- $k_{T}$, and Cambridge-Aachen (CA) [391] algorithms are equivalent.
- The recombination scheme is a procedure for merging two nearby partons into one jet. For example, the energy scheme (4D, based on adding the 4-momentum) or $E_{T}$ scheme (based on adding the scalar $E_{T}$, then averaging over the partons' directions using $E_{T}$ as the weights) can be employed to find the momentum of the merged jet [392]. Our comparison uses the energy scheme for both the Tevatron and LHC measurements, as it is often used by the recent experiments. Different choices of the recombination scheme can cause differences of up to ten percent in the NLO distributions, as will be shown later. Note that, with the energy scheme, the jet could be massive, which means that the jet's pseudorapidity will not be equal to its rapidity.
- The jet trigger imposes acceptance conditions on each jet's $p_{T}$ or rapidity when deciding if this jet's contribution is included into the jet observable. In NLO calculations of single-inclusive jet distributions, the jet trigger conditions have no influence. In dijet production, they may change the cross sections by small amounts by affecting the selection of two leading jets in some cases. In our dijet calculations we choose $p_{T}>40 \mathrm{GeV},|y|<3$ for each jet at the Tevatron and $p_{T}>30 \mathrm{GeV}$, $|y|<3$ at the LHC.
- Renormalization and factorization scales. The scale choice is only related to theory and has no correspondence in experiment. It is conventional to choose the renormalization and factorization scales to be of order of the typical transverse momentum $p_{T}$ of the jet(s): $\mu_{R} \sim \mu_{F} \sim p_{T}$. In contributions with two resolved jets, $p_{T}$ naturally corresponds to the transverse momentum of either of the final-state jets (which are equal by momentum conservation). More ambiguity
is present in contributions with three resolved jets, when $p_{T}$ can correspond to the transverse momentum of either of the jets in each event or to a combination of three transverse momenta. A meaningful comparison must use equivalent definitions of " $j$ et $p_{T}$ " in the renormalization and factorization scales of both NLO calculations.
When FastNLO interpolates tables of NLOJET++ cross sections for single inclusive-jet production, it sets $\mu_{R}$ and $\mu_{F}$ proportional to the $p_{T}$ value at a fixed point in each $p_{T}$ bin of the experimental data. Given the high precision of the latest PDF analyses, the FastNLO scale convention produces a numerically different result than the scale proportional to the $p_{T}$ of the leading jet or the average $p_{T}$ of two leading jets in each event. It depends on the binning of the experimental data and is numerically close to the average $p_{T}$ in each bin for small enough bins.
In the EKS calculations for single-jet production, we set the scale proportional to $p_{T}$ of each individual jet in any $p_{T}$ bin, which means that we repeat the evaluation of the matrix elements with three resolved jets (contributing to three $p_{T}$ bins) by successively setting $\mu_{R, F}$ to be proportional to the $p_{T}$ of each jet in the event. Such matrix elements are thus evaluated three times. This event-level scale setting of EKS turns out to be numerically close to the bin-level scale setting of FastNLO if the bin sizes are small. However, a few-percent differences are still observed at the largest rapidities and $p_{T}$. For dijet production, FastNLO and EKS choose the $\mu_{R}$ and $\mu_{F}$ scales that are proportional to the average $\left|p_{T}\right|=\left(\left|p_{T 1}\right|+\left|p_{T 2}\right|\right) / 2$ of the two leading jets.
- Monte-Carlo integration. Precision calculations for jet production are numerically challenging because of the rapid falloff of the cross sections with the jet's $p_{T}$ and rapidity, and also because of large numerical cancellations occurring between some $2 \rightarrow 2$ and $2 \rightarrow 3$ contributions. Both EKS and NLOJET ++ evaluate differential cross sections by Monte-Carlo integration, which requires to generate of order $10^{9}$ of sample points to achieve percent-level accuracy for the whole kinematical region. The upgraded EKS code performs the Monte-Carlo integration using the VEGAS method from the CUBA2.1 library [393]. The EKS output is produced in the form of two-dimensional cross sections ( $\left.d^{2} \sigma /\left(d p_{T} d y\right), d^{2} \sigma /\left(d M_{j j} d y\right), \ldots\right)$ and stored in finely binned two-dimensional histograms. Such output is "almost fully differential" in the sense that the finely grained histograms can be rebinned into any set of coarse bins of the given experiment at the stage of the user's final analysis. This format is different from the FastNLO format, which provides the cross sections in coarse bins taken from pre-existing experimental publications.
The fine binning in EKS is introduced at the stage of Monte-Carlo integration in order to improve convergence and to better handle the NLO cancellations. The Monte Carlo sampling pattern is tuned automatically to ensure that all fine bins are filled with comparable numbers of sample points, regardless of the momentum and scattering angle values associated with each bin. Then we get uniform relative errors on the cross sections in all bins without consuming too much CPU time, and despite the dramatic variation of cross sections across the bins. Finally, EKS includes a module to allow for flexible choices of scales $\mu_{R}$ and $\mu_{F}$, and another module for calculating differential cross sections of user-provided jet observables.

### 13.3 RESULTS

Figs. 3439 compare our representative numerical results with the ones provided by FastNLO for $p_{T}$ distributions of single jets, invariant mass distributions of dijets, and (in the case of D0 Run-2) angular distributions ( $\chi$ ) of dijets. Kinematical bins of the Tevatron $(\sqrt{s}=1.96 \mathrm{TeV}$ ) [287, 285, 289, 394] and LHC $(\sqrt{s}=7 \mathrm{TeV})$ [293, 292] measurements, and CTEQ6.6 PDFs [256] were used. The cone sizes $R$ of the jets are indicated in the figures.

Left panels in the figures show ratios of EKS to FastNLO cross sections, $\sigma_{\text {EKS }} / \sigma_{\text {FastNLO }}$, at the LO (red points) and $\mathrm{NLO}=\mathrm{LO}+\mathrm{NLO}$ correction (blue points), in kinematical bins provided by the experiments. The horizontal axis indicates the ID of each bin, which are arranged in the order of increasing jet rapidity $y$ and then jet's $p_{T}$ for inclusive jet production, $y$ and then $M_{j j}$ for dijet production, and $M_{j j}$
then $\chi$ for dijet angular dependence. Vertical lines indicate the boundaries of each rapidity interval for single-jet and dijet distributions, and of each dimass interval for the $\chi$ distribution. For example, Fig. 34 shows $\sigma_{\text {EKS }} / \sigma_{\text {FastNLO }}$ in 6 bins of jet rapidity, with bins $1 . . .23$ corresponding to the first rapidity bin ( $|y|<0.4$ ), bins $24 \ldots 45$ corresponding to the second rapidity bin $(0.4<|y|<0.8$ ), and so on.

The left panel includes, from top to bottom, three plots obtained with the renormalization and factorization scales equal to $1 / 2,1$, and 2 times the center scale. We can see a good overall agreement between EKS and FastNLO both at LO and NLO. The only significant discrepancies are found in the highest $p_{T}$ bins for both the Tevatron and LHC single inclusive jet production, which may be due to the difference in the scale choices used in EKS and FastNLO. [These differences reduce when going to NLO]. In the EKS single-jet calculation, we use the actual $p_{T}$ of the partonic jet filled into the bin as the scale input. FastNLO sets the scale according to a fixed $p_{T}$ value in each experimental bin, which tends to be different from the EKS scale in the highest $p_{T}$ bins, which have large widths. The same reason causes a small normalization shift in the other $p_{T}$ bins.

For dijet production, we only observe random fluctuations at highest $M_{j j}$ that are mainly due to numerical integration errors.

In the right panels of Figs. 34 39, we present plots of the NLO K factor from EKS for each distribution, defined as the ratio of the NLO differential cross section to the LO one. The value of the K factor and its stability with respect to the scale choice may provide an indication of the magnitude of yet higher-order corrections.

To minimize the potential effect of higher-order terms, one might opt to choose the renormalization and factorization scales that bring the K factor close to unity in most of the kinematical region. An alternative approach for setting the scale is based on the minimal sensitivity method, which suggests to choose the $\mu_{R}$ and $\mu_{F}$ values (taken to be equal and designated as $\mu$ in the following) at the point where the scale dependence of the NLO cross section is the smallest.

In (di)jet production at central rapidities at the Tevatron, both requirements ( $K \approx 1$ and $d \sigma_{N L O}(\mu) / d \mu \approx 0$ ) could be satisfied by choosing $\mu \approx 0.5 p_{T}$; see, e.g., the appendix in Ref. [395]. For this reason, the scale $p_{T} / 2$ was used in the CT10 study. However, the point of the minimal sensitivity shifts to higher values (close to $p_{T}$ or even higher) at forward rapidities at the Tevatron or at all rapidities at the LHC. For such higher scales, however, it is hard to satisfy the requirement that $K$ remains close to unity at the same time.

This point is illustrated by our plots of the $K$ factors. At the central rapidities and $\mu_{R}=\mu_{F}=$ $0.5 p_{T}$ at the Tevatron (the lowest 3 rapidity bins in Figs. 34.37), $K \approx 1$ and is relatively independent of $p_{T}$, as seen in the top subpanels. However, with this scale choice the K factor deviates significantly from unity and has strong kinematic dependence if the rapidity and $p_{T}$ are large. If one chooses the scale that is equal to $p_{T}$ or even $2 p_{T}$ (the middle and bottom figures), in accord with the minimal sensitivity method for the forward bins, the kinematical dependence of the K factor reduces, but its value increases to 1.3-1.6 in most of the bins.

For CMS kinematics (Figs. 38|39), the $K$ factor has significant kinematical dependence for all central scale choices, however, the choice $\mu_{R}=\mu_{F}=p_{T}$ (the middle subpanels) results in a comparatively flatter $K$ factor that is also closer to unity. We can see that it is hard to find a fixed scale (or a scale of the type $p_{T} \times($ a function of $y)$ [383]) that would simultaneously reduce the magnitude of the NLO correction and stabilize its scale dependence and kinematical dependence. The scale $0.5 p_{T}$ may be slightly more optimal at the Tevatron, and the scale $p_{T}$ may be slightly better at the LHC. In the absence of a clearly superior scale choice, it may be necessary to vary the scale of jet cross sections in the global fit in order to estimate its effect on the PDF errors.

In Figs. 40 and 41, we plot the ratios of the NLO distributions calculated using different recombination schemes, where $\sigma_{4 D}$ is obtained with the energy scheme, and $\sigma_{E_{T}}$ is with the $E_{T}$ scheme. For single inclusive jet production at both the Tevatron and LHC, $\sigma_{E_{T}}$ is larger then $\sigma_{4 D}$. An opposite trend
is observed in dijet production. Differences of the predictions based on the two schemes are larger with the Midpoint algorithm (used at the Tevatron) than with the anti- $k_{T}$ algorithm (used at the LHC). In an NLO calculation, the Midpoint algorithm allows a larger maximal angular separation $(2 R)$ between the two partons forming a jet, compared to the anti- $k_{T}$ algorithm that only allows the angular separation up to $R$. This produces the shown kinematical differences between the two schemes.

## CONCLUSIONS

Jet production plays an important role at hadron colliders and is a main background process in the bulk of new physics searches. A benchmark comparison of NLO QCD predictions for jet production from different numerical codes can be useful for both the ongoing phenomenological studies and upcoming higher-order calculations. In this work we modify the original EKS program and compare the singlejet and dijet cross sections that it produces with the ones from the FastNLO program. We find a good agreement between two programs, apart from differences of up to $5-10 \%$ occuring at the highest jet $p_{T}$ 's and rapidities. We document the exact combination of theoretical settings in EKS that are needed to reproduce the FastNLO results. Based on the EKS calculation, we attempted to identify the choice of the renormalization and factorization scales that could simultaneously reduce the magnitude of NLO $K$ factors and/or scale dependence of the NLO cross section. Since we could not easily find such a scale combination, we propose to vary the factorization and renormalization scales in future (N)NLO PDF fits to better estimate theoretical uncertainties in the resulting PDFs. There is a plan to publish the updated EKS program in the near future [388].

## 14. PHENOMENOLOGICAL STUDIES WITH AMC@ NLO ${ }^{26}$

#### Abstract

We present four phenomenological studies of hadron collider processes performed within the aMC @ NLO framework

### 14.1 Introduction

aMC@NLO (http://amcatnlo.cern.ch) is a fully automated approach to complete event generation and subsequent parton shower at the NLO accuracy in QCD, which allows accurate and flexible simulations for both signals and backgrounds at hadron colliders. All calculational aspects in aMC @ NLO are automated. One-loop contributions are evaluated with MadLoop [8, 396], that uses the OPP integrand reduction method [121] as implemented in CutTools [135]. The other matrix-element contributions to the cross sections, their phase-space subtractions according to the FKS formalism [397], their combinations with the one-loop results, and their integration are performed by MadFKS [398] ${ }^{27}$. The matching of the NLO results with HERWIG [399] or PYTHIA [400] parton showers is performed with the MC@NLO method [401], and it is also completely automatic. Finally, aMC @ NLO can compute scale and PDF uncertainties at no extra CPU-time cost with the help of the process-independent reweighting technique described in [402].

For all technical details we refer to the original publications. We report here on the physics results obtained with aMC @ NLO for observables of interest at hadron colliders [15, 403, 402, 404]. We stress that they are simulated at the hadron level, namely including parton shower and hadronization effects. In Sects. 14.2, 14.3, and 14.4 we present results for the production of $t t H, V b b$, and four-lepton final states at the LHC, respectively. Section 14.5 reports on a study of the $W j j$ process at Tevatron. Finally, in sect. 14.6 we draw our conclusions. The list of the processes considered here should convince the reader that one can perform realistic analyses of experimental data, for signals and backgrounds, entirely within the aMC@NLO framework.

### 14.2 The $t t H$ process at the LHC

The production process of a $H$ boson in association with a top pair [15] is a classic mechanism for Higgs production at the LHC [24, 405], where the large $t t H$ Yukawa coupling and the presence of top quarks can be exploited to extract the signal from its QCD multi-jet background. As an example of the use of aMC @ NLO for this process we present, in Fig. 42, the Higgs transverse momentum distribution and the transverse momentum of the $t t H$ or $t t A$ system at the $\sqrt{s}=7 \mathrm{TeV}$ LHC for a Standard Model (scalar) Higgs with $M_{H}=120 \mathrm{GeV}$ and for a pseudoscalar one with $M_{A}=120 / 40 \mathrm{GeV}$. The total NLO cross sections in the three cases are $\sigma_{\mathrm{NLO}}\left(M_{H}=120\right)=103.4 \mathrm{fb}, \sigma_{\mathrm{NLO}}\left(M_{A}=120\right)=31.9 \mathrm{fb}$, and $\sigma_{\mathrm{NLO}}\left(M_{A}=40\right)=77.3 \mathrm{fb}$, respectively. At moderate values of the Higgs transverse momentum, the scalar and pseudoscalar cases are clearly distinguishable, while at larger values the three distributions tend to coincide. Parton shower effects give in general small corrections with respect to the a pure NLO calculation, except for variables involving all produced particles, such as the transverse momentum of the $t t H$ or $t t A$ system shown in the right panel of Fig. 42.

### 14.3 The $V b b$ process at the LHC

With $V b b$ we understand $\ell \nu b b$ and $\ell^{+} \ell^{-} b b$ final states [403], which are the main backgrounds to searches for SM Higgs production in association with vector bosons $(W H / Z H)$, with the subsequent Higgs decay into a $b b$ pair. The aMC @ NLO framework allows a realistic study including

- NLO corrections;

[^136]

Fig. 42: Higgs transverse momentum distributions (left) and transverse momentum of the $t t H$ or $t t A$ system (right) in $t t H / t t A$ events at the LHC ( $\sqrt{s}=7 \mathrm{TeV}$ ), with aMC @ NLO in the three cases: Scalar (blue) and pseudoscalar (magenta) Higgs with $m_{H / A}=120 \mathrm{GeV}$ and pseudoscalar (green) with $m_{A}=$ 40 GeV . In the lower panels of the left part, the ratios of aMC @ NLO over LO (dashed), NLO (solid), and aMC@LO (crosses) are shown. Solid histograms in the right panel are relevant to aMC@NLO, dashed ones to a pure NLO calculation.

- bottom quark mass effects;
- spin-correlation and off-shell effects;
- showering and hadronization.

As an example we show, in Fig. 43, the invariant mass of the pair of the two leading b-jets, compared with the signal distributions for a standard Higgs with $m_{H}=120 \mathrm{GeV}$. Fig. 43 is interesting because both signal and background are studied at the NLO accuracy. It should be noted that, since completely hadronized events are simulated, sophisticated studies of the jet sub-structure are possible within the aMC@NLO framework, as presented in Fig. 44 , where the fractions of events containing zero $b$-jets, exactly one $b$-jet, and exactly two $b$-jets are plotted. The $b$-jet fractions are fairly similar for $W b b$ and $Z b b$ production, and the effects of the NLO corrections are consistent with the fully-inclusive $K$ factors. On the other hand, the $b b$-jet contribution to the $b$-jet rate is seen to be more than three times larger for $\ell^{ \pm} \nu b b$ than for $\ell^{+} \ell^{-} b b$ final states. This fact is related to the different mechanisms for the production of a $b b$ pair in the two processes. At variance with the case of $\ell^{ \pm} \nu b b$ production, in a $\ell^{+} \ell^{-} b b$ final state the two $b$ 's may come from the separate branchings of two initial-state gluons, and thus the probability of them ending in the same jet is much smaller than in the case of a $g \rightarrow b b$ final-state branching, which gives the only possible contribution to a $\ell^{ \pm} \nu b b$ final state.

### 14.4 Four-lepton production at the LHC

Vector boson pair production is interesting in at least two respects. Firstly, it is an irreducible background to Higgs signals, in particular through the $W^{+} W$ and $Z Z$ channels which are relevant to searches for a standard model Higgs of mass larger than about 140 GeV . Secondly, di-boson cross sections are quite sensitive to violations of the gauge structure of the Standard Model, and hence are good probes of scenarios where new physics is heavy and not directly accessible at the LHC, yet the couplings in the vector boson sector are affected. We consider here the neutral process [402]

$$
p p \rightarrow\left(Z / \gamma^{*}\right)\left(Z / \gamma^{*}\right) \rightarrow \ell^{+} \ell^{-} \ell^{(\prime)+} \ell^{(\prime)-},
$$

Fig. 43: Invariant mass of the pair of the two leading $b$-jets. $W H(\rightarrow \ell \nu b b), Z H\left(\rightarrow \ell^{+} \ell^{-} b b\right), \ell \nu b b$, and $\ell^{+} \ell^{-} b b$ results are shown, with the former two rescaled by a factor of ten.

Table 10: Total cross sections for $e^{+} e^{-} \mu^{+} \mu^{-}$and $e^{+} e^{-} e^{+} e^{-}$production at the $\mathrm{LHC}(\sqrt{S}=7 \mathrm{TeV})$ within the cuts $M\left(\ell^{ \pm} \ell^{(1) \mp}\right) \geq 30 \mathrm{GeV}$. The first and second errors affecting the results are the scale and PDF uncertainties (also given as fractions of the central values).
which, although smaller than the $W^{+} W^{-}$channel, may provide a cleaner signal due to the possibility of fully reconstructing the decay products of the two vector bosons. aMC @ NLO predictions for the cross sections are given in Tab. 10, which also includes aMC @ NLO estimates for scale and PDF uncertainties. The four-lepton invariant mass and the transverse momentum distribution are presented in Fig. 45, where comparisons between the results obtained with aMC @ NLO matched to HERWIG and to PYTHIA are also given. We stress that these results include the contributions due to $g g$-initiated processes, which have also been computed automatically. These are formally of NNLO, but may play a non-negligible phenomenological role owing to their parton-luminosity dominance at a large-energy collider such as the LHC.

### 14.5 Wjj at Tevatron

In [406] CDF reported an excess of events in two-jet production in association with a $W$ boson, in the form of a broad peak centered at $M_{j j}=144 \mathrm{GeV}$ in the dijet invariant mass ${ }^{28}$. Motivated by this fact, we present in Fig. 46]the aMC @ NLO prediction [404] for the dijet invariant mass in $W j j$ events, using the same cuts as CDF and D0 in the signal region, also comparing with a pure NLO computation and with the Alpgen [408] findings (one-, two-, and three-parton multiplicities have been consistently matched to

[^137]

Fig. 44: Fractions of events (in percent) that contain: zero $b$-jets, exactly one $b$-jet, and exactly two $b$-jets. The rightmost bin displays the fraction of $b$-jets which are $b b$-jets. The two insets show the ratio of the aMC @ NLO results over the corresponding NLO (solid), aMC @ LO (dashed), and LO (symbols) ones, separately for $W b b$ (upper inset) and $Z b b$ (lower inset) production.
obtain the latter). Perturbative, parton-level results agree well with those obtained after shower, and PDF and scale uncertainties (also reported in Fig. 46) are well under control. In summary, we do not observe any significant effects in the shape of distributions due to NLO corrections, which therefore cannot be responsible for the excess of events observed by the CDF collaboration.

### 14.6 Conclusions

The results we have presented in this contribution are based on the strategic assumption that, for the word automation to have its proper meaning, the only operation required from a user is that of typing-in the process to be computed, and other analysis-related information (such as final-state cuts). In particular, the codes that achieve the automation may only differentiate between processes depending on their general characteristics, but must never work on a case-by-case basis. The aMC@NLO framework is based on such an assumption, providing a very powerful tool to compare, at the NLO accuracy including showering and hadronization, theory and experiment in high energy collisions. As an example of the flexibility of aMC@NLO we have presented results for the processes $p p \rightarrow t t H, p p \rightarrow V b b, p p \rightarrow$ $\ell^{+} \ell^{-} \ell^{(1)+} \ell^{(1)-}$ at the LHC, and a study of $p \bar{p} \rightarrow W j j$ at Tevatron.

## 15. PROBING CORRECTIONS TO DIJET PRODUCTION AT THE LHC ${ }^{29}$

## Abstract

We compare and discuss a few kinematic distributions for dijet production at the LHC, computed with a fixed next-to-leading order code, with the

[^138]

Fig. 45: Four-lepton invariant mass and the transverse momentum distributions for aMC@NLO $+g g$ HERWIG (solid black) and PYTHIA (dashed blue) results. The rescaled $g g$ contributions with HERWIG (open black boxes) and PYTHIA (open blue circles) are shown separately. Middle insets: scale (dashed red) and PDF (solid black) fractional uncertainties. Lower insets: aMC@NLO/(aMC@NLO+gg) with HERWIG (solid black) and PYTHIA (dashed blue).

POWHEG BOX and with HEJ. Previous experimental studies have dealt with kinematic distributions where the predictions of the three approaches were very similar. In this proceeding, we investigate kinematic distributions where the resummed effects in POWHEG and HEJ are clearly shown and enhanced with respect to the fixed NLO result, since different QCD-radiation regimes are probed.

### 15.1 Introduction

Dijet production is one of the cornerstone processes at the LHC. The cross section for jet production is very large, making it an important testing ground for our understanding of QCD at high-energy scales. In addition, jet production is an important background for many searches for new physics. It is therefore essential to probe and test our theoretical predictions. Dijet-production studies can bring insights in jet production in association with other particles too: for example, Higgs boson production plus two jets in gluon fusion, a key process for assessing the CP properties of the Higgs boson, can benefit from these studies.

There have been a number of very interesting experimental studies in dijet production by both the ATLAS [410, 411, 294] and CMS [412, 413, 414, 415] Collaborations. It is already clear that higher order QCD contributions beyond a fixed order, low multiplicity calculation can be important because the large available phase space for jet emission at the LHC compensates for the suppression of extra powers of the strong coupling constant.

In this contribution, we compare two theoretical approaches to dijet production that include higher order effects: POWHEG [416, 417, 386, 13] and HEJ [418, 419, 64]. The POWHEG method successfully merges a fixed next-to-leading order (NLO) calculation with a parton shower program, that resums leading logarithmic contributions from collinear emissions. In this study, the POWHEG results obtained with the POWHEG BOX [13] are interfaced with the transverse-momentum-ordered shower

Fig. 46: Invariant mass of the pair of the two hardest jets, with CDF/D0 cuts of [406] (left) and of [409] (right).
provided by PYTHIA 6.4.21 [400]. In contrast, the starting point for HEJ is an all-order approximation to the hard scattering matrix element in the regime of wide-angle QCD emissions. HEJ is accurate at leading logarithmic precision in the invariant mass of any two jets. This is then supplemented with the missing contributions (through a merging and reweighting-procedure) necessary to also ensure tree-level accuracy for final states with up to four jets. The tree-level matrix elements are taken from Standalone Madgraph [163].

The POWHEG and HEJ approaches are clearly very different in their description of QCD radiation. Nevertheless, for several kinematic distributions (see for example ref. [410]) the predictions from POWHEG and HEJ are very similar. In this study, we investigate various observables which can expose the differences in the two approaches and we compare them with the fixed NLO results.

### 15.2 A comparison between NLO, POWHEG and HEJ in dijet production

In order to avoid biasing our event sample, we impose a minimal set of cuts, avoiding symmetric cuts on the jet transverse momenta that would give an unphysical cross section at fixed NLO level [420, 421], due to the presence of unresummed logarithms. Neither the POWHEG or HEJ descriptions suffer from this instability. However, in order to have a sensible fixed NLO cross section to compare with, we impose asymmetric cuts

$$
\begin{equation*}
p_{\mathrm{T}}^{j}>35 \mathrm{GeV}, \quad p_{\mathrm{T}}^{j_{1}}>45 \mathrm{GeV}, \quad\left|y_{j}\right|<4.7, \tag{99}
\end{equation*}
$$

i.e. all jets are required to have a minimum transverse momentum of 35 GeV , and the hardest-jet transverse momentum, $p_{\mathrm{T}}^{j_{1}}$, is required to be greater than 45 GeV . In order to comply with the experimental acceptance, all jets are further required to have an absolute rapidity $\left|y_{j}\right|$ less than 4.7. Jets are defined according to the anti-kt jet algorithm, with radius $R=0.5$. Only events with at least two jets fulfilling Eq. (99) are kept.

In the following, we compare the fixed NLO cross section with the POWHEG first emission results, with the POWHEG results showered by PYTHIA and with the HEJ predictions. The renormalization and factorization scales have been chosen equal to the transverse momentum of the hardest jet in each event, for the HEJ predictions. For the NLO computation (and for computing the POWHEG $\bar{B}$ function), scales are set to the transverse momentum of the so called underlying Born configuration. Scale-uncertainty bands obtained by varying these scales by a factor of two in each direction are shown for the NLO and HEJ results. The scales entering in the evaluation of parton distribution functions and

Fig. 47: The average number of jets as a function of $\Delta y_{\mathrm{fb}}$ (left plot) and of $H_{\mathrm{T}}$ (right plot), as predicted by a fixed NLO calculation, by POWHEG first emission, by POWHEG+PYTHIA and by HEJ. The dotted red lines around the HEJ prediction and the green ones around the NLO result are obtained by varying the renormalization and factorization scales by a factor of two around their central value.
of the strong coupling in the POWHEG Sudakov form factor are instead evaluated with a scale equal to the transverse momentum of the POWHEG hardest emission [417, 386].

In Fig. 47 we plot the average number of jets as a function of the rapidity difference between the most forward and most backward of the jets fulfilling Eq. (99), $\Delta y_{f b}$, on the left-hand side, and as a function of $H_{\mathrm{T}}=\sum_{j} p_{\mathrm{T}}^{j}$ on the right-hand side. The wide-angle resummation implemented in HEJ produces more hard jets than POWHEG and the fixed NLO calculation, as the rapidity separation between the most forward and the most backward jet in the event increases. Both the NLO and the firstemission POWHEG results have at most 3 jets, so that the average number of jets cannot exceed 3 , and give similar results. Additional jets are instead produced by the PYTHIA shower, so that the average number of jets is increased by roughly $20 \%$ with respect to the NLO one, for $\Delta y_{\mathrm{fb}} \approx 7$. For the same separation in rapidity, the HEJ prediction is $45 \%$ larger than the NLO result, with a chance to distinguish among the three approaches.

The dependence of the average number of jets from $H_{\mathrm{T}}$ (right plot) displays a different behaviour: here the showered events have on average more jets than HEJ and the NLO results, as the sum of the transverse momentum of all the final-state jets increases. It is interesting here to comment on the NLO result obtained with the factorization and renormalization scales set to $p_{\mathrm{T}}^{\mathrm{UB}} / 2$, i.e. half of the transverse momentum of the underlying Born configuration. In fact, from the plot, an unphysical behaviour of this quantity emerges: the average number of jets is greater than 3 above $H_{\mathrm{T}} \approx 270 \mathrm{GeV}$. This is due to the fact that the high $H_{\mathrm{T}}$ region is populated mostly by events with 3 jets, two of which have approximately the same high transverse momentum, and the third one is softer with respect to the other two (the cuts in Eq. (99) are always in place). In this configuration, the exclusive two-jet cross section becomes negative, due to incomplete cancellation of the virtual (negative) contribution, now enhanced by a higher value of the strong coupling constant, evaluated at a lower renormalization scale. A more detailed discussion can be found in ref. [422].

As a last example of a kinematic distribution that displays different behaviour if evaluated at NLO or using POWHEG or HEJ, we plot in Fig. 48 the average value of $\cos \left(\pi-\phi_{\mathrm{fb}}\right)$, where $\phi_{\mathrm{fb}}$ is the azimuthal angle between the most forward and backward jets, as a function of their rapidity separation $\Delta y_{\mathrm{fb}}$. For dijet events at tree-level, $\phi_{\mathrm{fb}}=\pi$ since the two jets must be back-to-back, and the average value of the cosine is 1 . Deviation from 1 then indicates the presence of additional emissions, so that

Fig. 48: The average value of $\cos \left(\pi-\phi_{\mathrm{fb}}\right)$ as a function of $\Delta y_{\mathrm{fb}}$, where $\phi_{\mathrm{fb}}$ is the azimuthal angle separation between the most forward and most backward jet. The dotted red and green lines are obtained by varying the renormalization and factorization scales by a factor of 2 in both directions.
this kinematic distribution carries information on the decorrelation between the two jets. This quantity is more inclusive than the average number of jets as it is sensitive also to emissions below the jet $p_{\mathrm{T}}$ cut. The higher radiation activity in POWHEG+PYTHIA and in HEJ, with respect to the fixed NLO and the POWHEG first-emission results, is clearly visible in the figure: the stronger jet activity produced by HEJ at higher rapidity separation (see the left plot of Fig. 47) lowers the average value of the cosine below the POWHEG+PYTHIA result. As expected, the average value predicted by the POWHEG first-emission and the NLO calculation is closer to 1 , since they contain at most one radiated parton.

## Conclusions

In this proceeding, we have discussed the results obtained using a fixed NLO calculation, HEJ and POWHEG+PYTHIA, in the description of three kinematic distributions, selected in order to display more clearly the differences among the three approaches: the average number of jets and azimuthal decorrelation between the most forward and the most backward jet, plotted as a function of the rapidity separation of the most forward and the most backward jet, and the average number of jets plotted as a function of the sum of the transverse momenta of all the jets in the event.

While the limitations of the NLO calculation are clearly visible when we probe regions of the phase space where multi-jet emissions becomes important, the predictions of POWHEG+PYTHIA and HEJ are distinguishable when dealing with the average number of jets as a function rapidity span. Less marked differences are found as a function of Ht , and in the study of the azimuthal decorrelation of the most forward and backward jet.

An experimental analysis of the dijet data, collected at the LHC, should then follow to investigate to which extent our theoretical knowledge for these kinematic distributions is under control.

## 16. W+JETS PRODUCTION AT THE LHC: A COMPARISON OF PERTURBATIVE TOOLS 30

#### Abstract

In this contribution, we discuss several theoretical predictions for $W$ plus jets production at the LHC, compare the predictions to recent data from the ATLAS collaboration, and examine possible improvements to the theoretical framework.

### 16.1 Motivation

Experimentalists are reliant on a number of tools, at LO and NLO, at parton level and at hadron level, in order to understand both simple and complex final states at the LHC. One of the benchmark processes, for both signals to new physics and for their backgrounds, is the production of $W$ plus jets. In this contribution, we discuss several different predictions for the $W$ plus jets final state, concentrating on the $H_{T}$ distribution. We examine where the predictions agree, and where they disagree and compare the predictions to LHC data. We introduce the idea of NLO 'Exclusive Sums', and discuss the performance of this technique and consider also how LoopSim may be able to improve the predictions. We document the use of ROOT ntuples for $W$ plus jets predictions produced by the BlackHat+Sherpa collaboration, indicating how they can be used to examine the variation of the cross sections with jet size/algorithm, PDFs, and scale choices. We also study the possibility of using the LoopSim method together with BlackHat+Sherpa type ntuples, since this may offer the opportunity to improve on the results from NLO Exclusive Sums.

### 16.2 Theory tools: strengths and weaknesses

NLO is the first order at which the normalization (and sometimes the shape) of LHC cross sections can be realistically calculated. The state of the art is in parton-level programs such as BlackHat+Sherpa, where $W+n$-jet cross sections are available, with $n$ up to 4 at NLO [70, 51, 22] (and soon up to 5 [423]). Of course, such parton-level final states do not allow for the full comparisons to the data allowed by the full parton shower Monte Carlo programs such as Sherpa. NLO matrix elements have been included into parton shower Monte Carlos, but only for relatively simple final states (although we note that the NLO matrix elements for $W+2$ jets [404] and $W+3$ jets [424] have recently been implemented in parton shower Monte Carlo programs).

The Sherpa Monte Carlo program [146, 425] includes the exact LO $W+n$-parton ( $W+n$ jet) matrix elements, with $n$ up to 4 (in this study), using the newer ME\&TS scheme as introduced in Refs. [426, 427, 428] for the addition of states with different jet multiplicities with the correct normalizations. The newer matrix-element plus parton-shower merging scheme improves over the CKKW [429, 430] formalism by allowing for a better interplay between the matrix-element and partonshower descriptions. This in particular required the implementation of truncated showers ('TS'). As before, additional jets are, of course, then produced by the parton shower. Both BlackHat+Sherpa and Sherpa rely on DGLAP-based evolution of gluon emission, on the assumption that the gluon emissions are strongly ordered in transverse momentum. For an alternative prediction, we use the program HEJ [418, 419, 431]. The High Energy Jets (HEJ) framework provides a leading-log resummation of the dominant terms in the limit of large invariant mass between jets. In addition, HEJ contains a merging procedure to ensure tree-level accuracy for final states with two, three or four jets.

[^139]A NLO $n$-jet prediction produces events with with either $n$ or $n+1$ partons. For observables for which higher multiplicities have a significant impact, this limitation can be detrimental. If one has predictions for different multiplicities, one can try to combine them by avoiding double counting by requiring that the $n$-jet prediction is used only to describe $n$-jet events (except for the highest multiplicity where ( $n+1$ )-jets configurations are allowed). This procedure is crude and does not increase the formal accuracy of the prediction which is that of NLO of the smallest multiplicity. The idea is that, in observables where higher multiplicities events dominate, a better prediction might be obtained. This has been denoted as the 'Exclusive Sums' technique. The impact of the Exclusive Sums approach depends on the kinematic variable under consideration. For this contribution, we consider only the $H_{T}$ variable, defined as the sum of the transverse momenta of all of the leptons (including neutrinos) and jets in the event. The impact of the approach is expected to depend on the observable under consideration and it may be more beneficial for variables sensitive to multi-jet radiation, such as $H_{T}$, than for more inclusive variables such as $p_{t, W}$. Comparisons for the latter are left to a study now in progress.

### 16.3 Use of BlackHat+Sherpa ntuples

As has been partially detailed in these proceedings, there have been many advances in the computation of the NLO corrections for multi-parton final states. Often such calculations do not exist in a compact user-friendly form, and other means must be taken to allow experimentalists to have access to the results. The BlackHat+Sherpa collaboration has chosen to make available ROOT tuples that contain all of the parton-level information needed to form flexible predictions. The ROOT ntuple framework is a very efficient way to store such information and the use of ROOT tuples is very familiar to experimentalists.

The ROOT ntuples store the four-vectors for the final state partons, as well as their flavor information. The calculation is originally performed using a specific choice of PDF, $\alpha_{s}\left(m_{Z}\right)$, renormalization scale $\mu_{R}$ and factorization scale $\mu_{F}$, but weight information is also stored in the ntuples that allows each event to be easily re-weighted to any other (reasonable) values for the above parameters. (PDFs are varied through calls to LHAPDF [432].) No jet clustering has been performed on the final state partons; jet reconstruction is left to the user, for any jet algorithm/size for which the correct counter-events are present in the ntuple. For the results presented here, the SISCone [433], $k_{T}$ [361] and anti- $k_{T}$ [341] algorithms, with jet radii $R$ of $0.4,0.5,0.6$ and 0.7 can be used. Each of the above jet algorithms were run and the results stored in SpartyJet ntuples ${ }^{31}$ The SpartyJet tuples were 'friended' with the BlackHat+Sherpa ntuples, allowing the analysis script access to all jet information. Such a flexibility allows for an investigation of the dependence of the physics on the details of the manner in which the partons are combined into jets, in a manner difficult to achieve prior to this.

The four-vector information stored in the BlackHat+Sherpa ntuples is shown in Table 11. Note the variety of entries needed for the re-weighting of the cross section results, especially for the case of the variation of the two scales $\mu_{R}$ and $\mu_{F}$. Information is stored in separate ntuples for the different categories of events, which are typically Born, loop (leading color and sub-leading color), real and subtraction terms. For large $n$, in $W+n$-parton final states, there are many divergences present when two partons become collinear or one parton becomes soft. These divergences are controlled using the traditional Catani-Seymour approach [236], which involves the generation of many counter-events. Many of the events have negative weights; only the sum is guaranteed to be positive-definite. Predictions with reasonable statistical precision may require the sum of billions of events. The resultant tuples may amount to several Terabytes. However, the output can be subdivided into ROOT files of order 5-10 GB, allowing for simultaneous parallel processing of the events over multiple nodes, such as in the Tier3 facility at Michigan State University used for these comparisons.

[^140]
### 16.4 BlackHat+Sherpa predictions

We have generated NLO predictions with the BlackHat+Sherpa predictions implementing the cuts used in the 2010 ATLAS $W$ plus jets paper [436]. For completeness, the cuts are reproduced below:

- $p_{T}^{\text {lepton }}>20 \mathrm{GeV}$,
- $\left|\eta^{\text {lepton }}\right|<2.4$,
- $E_{T}^{\text {miss }}>25 \mathrm{GeV}$,
- $m_{T, W}>40 \mathrm{GeV}$,
- $p_{T}^{\text {jet }}>30 \mathrm{GeV}$,
- $\left|y^{\text {jet }}\right|<4.4$,
- $\Delta R^{\text {lepton-jet }}>0.5$.

In Figure 49, we show the NLO BlackHat+Sherpa prediction for the $H_{T}$ distribution for $W+\geq 1$ jets (left) using the anti- $k_{T}$ jet algorithm with $R=0.4$. As the prediction is an inclusive NLO calculation for $W+\geq 1$ jets, there are contributions from both the one-jet and the two-jet final states. Note that as $H_{T}$ increases, the contributions from the $W+2$-jet subprocess also increases. On the right, we again show the $H_{T}$ distribution, but now compute the prediction using the 'Exclusive Sums' technique, adding in the NLO $W+2$-jet information. Now there is a significant contribution at high $H_{T}$ from the $W+3$ -

Table 11: Branches in a BlackHat+Sherpa ROOT file.

Fig. 49: The $W$ plus jets cross section, as a function of $H_{T}$, for the NLO inclusive $W+\geq 1$-jet prediction (left) and for the Exclusive Sums approach, adding in $W+2$-jet production at NLO (right). The cross sections have been evaluated at a central scale of $H_{T} / 2$ and the uncertainty is given by varying the renormalization and factorization scales independently up and down by a factor of 2 , while ensuring that the ratio of the two scales is never larger than a factor of 2 .
jet final state as well. In Figure 50, the $H_{T}$ prediction is shown using the Exclusive Sums approach, adding $1+2+3$ jets at NLO (left) and $1+2+3+4$ jets at NLO (right). It is evident that as $H_{T}$ increases, contributions from higher jet multiplicities that are only present implicitly in a traditional inclusive NLO $W+\geq 1$-jet calculation, become important. The Exclusive Sums $H_{T}$ predictions agree with that for the inclusive NLO $W+\geq 1$-jet calculation at low $H_{T}$, but are larger at higher $H_{T}$, and in better agreement with the ATLAS data (as discussed below).

However, it can also be noticed that the scale dependences for the Exclusive Sums predictions apparently get better when the 2 -jet NLO information is added, but significantly worse when the 3 -jet and 4 -jet information is added. As discussed in the Appendix, the reduction in scale dependence with the addition of the 2-jet NLO terms may be due to the stabilization of the predictions for the $q q \rightarrow W q^{\prime} q$ topologies. Adding the 3 -jet and 4 -jet NLO terms seems to destabilize the predictions. There are missing Sudakov terms needed to properly 'stitch' the different multiplicity samples together; it is hoped that the LoopSim technique may offer one way in supplying those missing terms.

Below in Figure 51, we show the NLO BlackHat+Sherpa predictions for the $H_{T}$ distribution for $W+\geq 2$ jets: the inclusive calculation to the left, the Exclusive Sums result adding $2+3$-jet NLO information in the middle and the Exclusive Sums result adding 2+3+4-jet NLO information to the right. Over the kinematic range covered in these plots, the Exclusive Sums technique adds less to the cross section at high $H_{T}$, although there is still a degradation of the scale dependence.

Fig. 50: The $W$ plus jets cross section, as a function of $H_{T}$, for $W+\geq 1$-jet production using the Exclusive Sums approach, and adding up to 3 jets at NLO (left) and 4 jets at NLO (right). The cross sections have been evaluated at a central scale of $H_{T} / 2$ and the uncertainty is given by varying the renormalization and factorization scales independently up and down by a factor of 2 , while ensuring that the ratio of the two scales is never larger than a factor of 2 .

Fig. 51: The $W$ plus jets cross section, as a function of $H_{T}$, for $W+\geq 2$-jet production using the inclusive NLO production (left) and the Exclusive Sums approach, adding up to 3 jets at NLO (center) and 4 jets at NLO (right). The cross sections have been evaluated at a central scale of $H_{T} / 2$ and the uncertainty is given by varying the renormalization and factorization scales independently up and down by a factor of 2 , while ensuring that the ratio of the two scales is never larger than a factor of 2 .

### 16.5 Towards interfacing BlackHat+Sherpa ntuples with LoopSim

LoopSim is a method to simulate higher order QCD corrections, in particular those beyond NLO. It is expected to work best for processes with large NLO-to-LO $K$-factor, however it was found to be advantageous even in some cases where the $K$-factor is moderate [437]. The method is based on unitarity and its main ingredient is a procedure that takes events from a process with $n+m$ partons in the final state and produces counter-term events with $n+m-1, n+m-2, \ldots, n$ particles, which approximate 1-loop, 2-loop, etc. contributions. In contrast to the Exclusive Sums method, it enables one to introduce (approximate) virtual corrections beyond 1-loop, thus ensuring that the $\alpha_{s} L^{2}$ type terms cancel for all the orders that are included. While we will not show LoopSim results that are directly comparable to the ATLAS data (the samples were generated before those cuts were made public), we will examine below the dependence on the $p_{t, \min }$ choice (which sets the size of $L=\ln O_{t} / p_{t, \min }$ where $O_{t}$ is a transverse observable) and see that it vanishes as $p_{t, \text { min }} \rightarrow 0$.

To distinguish between the exact result at the order $\mathrm{N}^{p} \mathrm{LO}$ and the result with simulated loops we use a notation in which we replace N by $\bar{n}$ for the orders simulated by LoopSim. So for example, $W+1$ jet at $\bar{n} \mathrm{LO}$ has approximate 1 -loop diagrams and is obtained by combining $W+1$ jet at LO with $W+2$ jet at LO where the latter is passed through LoopSim. Similarly $W+1$ jet at $\bar{n}$ NLO has exact 1-loop diagrams but simulated 2-loop contributions (by using $W+2$ jet at NLO as an input to LoopSim).

As argued in the previous section, the BlackHat+Sherpa ntuples allow one to efficiently perform a broad range of analyses. They have however a limitation. In order to reduce the size of stored files, the only partonic events that are recorded for the $W+n$-jet sample are those in which there are at least $n$ jets above a 20 GeV threshold. Since this threshold is below the jet cuts used by ATLAS and CMS, it is adequate for any NLO study of LHC jet cross sections. The situation is slightly more complex if we want to use the BlackHat+Sherpa ntuples to compute predictions beyond NLO using LoopSim. This is because the cut that is present in the $W+2$-jet BlackHat+Sherpa NLO sample eliminates part of the real contribution to the $W+1$-jet phase space at NNLO, for example $W+3$-parton events in which the 3 partons all form part of a single jet, or in which 2 partons form part of one jet, while the third is well separated in angle but below the 20 GeV jet threshold.

Since we plan to use LoopSim interfaced to BlackHat+Sherpa ntuples in our future study of multijet processes, it is important to directly check the effect of the finite generation $p_{t}$ cut, $p_{t, \mathrm{gen}}^{\min }$, on the predictions of the $p_{t}$ and $H_{T}$ distributions. We have performed such a study for $W^{-}+1$ jet generated with MCFM, where we varied a 'parton'- $p_{t}$ generation cut from 1 to $20 \mathrm{GeV}{ }^{32}$ This is not entirely equivalent to the cut in the BlackHat+Sherpa samples (which is applied to the standard jets, not to the partons), but should be adequate from the point of view of estimating the potential order of magnitude of finite generation cuts. The output from MCFM was interfaced to LoopSim which produced the additional loop diagrams. Then, the events were analyzed with the following set of cuts: $\left|y^{\text {lepton }}\right|<2.5, p_{T}^{\text {lepton }}>$ $20 \mathrm{GeV},\left|y^{\mathrm{jet}}\right|<4.5, p_{T}^{\text {jet }}>25 \mathrm{GeV}, m_{T, W}<20 \mathrm{GeV}$, where the anti- $k_{T}$ algorithm with $R=0.4$ was used for clustering.

The results are presented in Figure 52 where the ratios of cross sections obtained with a range of generation cuts are shown as functions of the $p_{t}$ of the leading jet and $H_{T, \text { jets }}$. At NLO, the only artefact we see is for the $p_{t, \text { gen }}^{\min }$ of 20 GeV in the bin below 40 GeV . This is as expected, since a 20 GeV cut on each of two partons can at most affect jets up to 40 GeV (such an artefact would not be present in the BlackHat+Sherpa samples). At $\bar{n} \mathrm{LO}$ and $\bar{n} \mathrm{NLO}$, however, the dependence on $p_{t, \mathrm{gen}}^{\min }$ is extended to a larger range of $p_{t, \text { lead.jet }} / H_{T, \text { jets }}$ and it is visible also for values of $p_{t, \text { gen }}^{\min }<20 \mathrm{GeV}$. However, even if the $p_{t, \text { gen }}^{\min }$ dependence of the $\bar{n} \mathrm{LO}$ and $\bar{n} \mathrm{NLO}$ results is stronger than at NLO, it dies out quickly with increasing $p_{t, \text { lead.jet }} / H_{T, \text { jets }}$ and becomes irrelevant at $\sim 100 \mathrm{GeV}$, depending on the observable and the

[^141]

Fig. 52: Ratios of cross sections from runs with a certain range of $p_{t, g e n}^{\min }$ values taken wrt. the cross section generated with $p_{t, \mathrm{gen}}^{\min }=1 \mathrm{GeV}$ for the distributions of $p_{t}$ of the leading jet (left) and the scalar sum of jets' transverse momenta, $H_{T, \text { jets }}$ (right).
order. This appears to be consistent with the expectation that the effect of the cut should vanish as a power of $p_{t, \text { gen }}^{\min } / p_{t, \text { lead.jet }}$ or $p_{t, \text { gen }}^{\min } / H_{T, \text { jets }}$.

Therefore we conclude, that in spite of the finite generation cut one should be able to trust the results obtained using BlackHat+Sherpa ntuples, above a moderate $p_{t}$ limit, even for more complex analyses such as those involving LoopSim.

### 16.6 Comparisons to data, Sherpa and HEJ predictions

In Figure 53 (left), we compare the ratio of the 2010 ATLAS $W$ plus jets data for the $H_{T}$ distribution for $W+\geq 1$ jets to predictions using the generic NLO calculation for $W+\geq 1$ jet, the Exclusive Sums approach adding up to 4 jets at NLO and the Monte Carlo event generator Sherpa. The agreement between the data and the pure NLO result is rather poor; it improves substantially with the inclusion of the Exclusive sums up to two jets at NLO, with further small improvements coming from higher multiplicities. As a reminder, we previously noted that the scale dependence improved when adding the 2 -jet NLO information, but degraded when adding higher jet multiplicities. The Sherpa prediction slightly overshoots the data for $H_{T}$ in the inclusive $W+1$-jet bin. We however note that the data versus Sherpa $H_{T}$ ratio has been formed based on the absolute normalization as given by the Monte Carlo simulation. Comparing the inclusive 1-jet cross sections, we find a factor of 0.97 between the data and the Sherpa result.

In Figure 53 (right), we compare the ratio of the 2010 ATLAS $W$ plus jets data for the $H_{T}$ distribution for $W+\geq 2$ jets to predictions using the generic NLO calculation for $W+\geq 2$ jet, the Exclusive Sums approach adding up to 4 jets at NLO, and to predictions from HEJ and from Sherpa. As noted previously, there is some increase in the predictions from the Exclusive Sums approach at the highest $H_{T}$ values, but not nearly as much as in the $W+\geq 1$-jet case. These increases go in the direction of closer agreement with the data, but the statistical error does not allow a clear judgement to be made. The Sherpa and HEJ predictions for this ratio are in reasonable agreement with the data but appear to fall off somewhat more rapidly at large $H_{T}$ than either the data or the various BlackHat+Sherpa predictions. Again this partly is the result of relying on the absolutely normalized Monte Carlo predictions, which yield $W+\geq 2$-jet normalization factors of 0.95 or 0.93 between data and Sherpa or HEJ, respectively.

Fig. 53: The ratios of the ATLAS $W+\geq 1$-jet (left) and $W+\geq 2$-jet (right) cross sections, as a function of $H_{T}$, taken wrt. various theory predictions. The absolute normalization has been kept as given by the calculations. The error bars represent the total fractional error (statistical plus systematic added in quadrature) at each point.

Fig. 54: (left) The fraction of the $H_{T}$ cross section for $W+\geq 1$-jet events arising from the $W+\geq 2$-jet, $W+\geq 3$-jet and $W+\geq 4$-jet final states derived from the Exclusive Sums approach, from Sherpa and from HEJ, compared to the 2010 ATLAS data. (right) The ratio of the cross sections for $W+\geq 3$ jets to $W+\geq 2$ jets, as a function of $H_{T}$, using predictions from the Exclusive Sums approach, from Sherpa and from HEJ, compared to the ratio from the 2010 ATLAS data.

In Figure 54 (left), we show the predictions for the fractions of the $H_{T}$ cross section in the inclusive $W+1$-jet bin arising from the inclusive $W+2$-jet, $W+3$-jet and $W+4$-jet final states as obtained from the Exclusive Sums approach and from Sherpa, compared to the 2010 ATLAS data. In Figure 54
(right), we show the ratio of the cross sections for $W+\geq 3$ jets to $W+\geq 2$ jets, as a function of $H_{T}$, again using predictions from the Exclusive Sums approach and from Sherpa but also from HEJ. We again compare to the ratio given by the 2010 ATLAS data. All three predictions agree with each other and with the data over the range considered, despite the big differences in the approaches. There may be an indication of some separation between the predictions at the very highest $H_{T}$ values.

### 16.7 Conclusions, outlook and future studies

The advances achieved over the last few years in calculating NLO corrections for multi-jet final states allow a more serious consideration of the possibility to combine various $n$-jet NLO predictions into an inclusive jet sample. The Exclusive Sums approach discussed in this contribution is a first promising step into this direction. More studies are required to understand the uncertainties related to this procedure. One way of doing so would be to test the stability of the predictions against variation of the jet algorithm and/or parameters of the jet algorithm used to obtain and separate the different NLO predictions for the fixed-multiplicity sets that eventually make up the sum of exclusive $n$-jet contributions. ${ }^{33}$

For the Exclusive Sums approach, outlined here for the case of $W+\geq 1$ jets, contributions are added proportional to $\alpha_{s}^{2}\left(W+1\right.$ jet at NLO), $\alpha_{s}^{3}$ ( $W+2$ jets at NLO), $\alpha_{s}^{4}(W+3$ jets at NLO) and $\alpha_{s}^{5}\left(W+4\right.$ jets at NLO), i.e. this procedure mixes powers of $\alpha_{s}$ and thus is missing essential Sudakov form factors that effectively bring each term to the same power of $\alpha_{s}$. One could imagine accomplishing this by embedding the NLO matrix elements in a parton shower Monte Carlo framework, however the technology for merging different multiplicities of NLO calculations with a parton shower is still under development. Note that at LO the tree-level matrix-element plus parton-shower merging methods (e.g. as implemented in Sherpa) are designed to satisfy this same- $\mathcal{O}\left(\alpha_{s}\right)$ requirement by including the (allorders) leading-log effects to the 'LO Exclusive Sums' exhibiting the LO analog of the Exclusive Sums discussed here. Compared to the matrix-element plus parton-shower merging, we see that the 'NLO Exclusive Sums' technique only accounts for Sudakov effects up to $\mathcal{O}\left(\alpha_{s}\right)$ while it describes each jet bin at full NLO instead of LO accuracy.

Relying on the parton shower Monte Carlo framework is not the only way to go in refining the Exclusive Sums strategy. Alternatively, the LoopSim method can be used to provide approximations to the higher-loop terms missing in the Exclusive Sums approach. As we have seen here, prospects for using it together with BlackHat+Sherpa ntuples seem promising. A detailed comparison of the LoopSim results to LHC data is however beyond the scope of this Les Houches contribution, though we look forward to it being carried out in the near future.

The ATLAS data taken in 2011 is about a factor of 130 times as large as the data taken in 2010 (the only published data for $W$ plus jets so far). This will allow a much further reach in all kinematic variables. To get an idea, we show in Figure 55 the ratio of the predictions from the Exclusive Sums to the respective inclusive NLO predictions for $W+\geq 1,2,3$ jets. At an $H_{T}$ value of 2 TeV , the ratio for $W \geq 1$ jet is of the order of 2 ; the ratio for $W \geq 2$ jets rises to about 1.4. The NLO-to-LO $K$ factor for $W+\geq 1$ jet rises rapidly with increasing $H_{T}$, while the $K$-factor for $W+\geq 2$ jets increases only moderately (because no new subprocesses are being introduced). It will be interesting to see if (a) the additional factor of 2 (for the $W+\geq 1$-jet case) and (b) the additional factor of approximately 1.4 (for the $W+\geq 2$ jet case) lead to better agreement with the data. The LHC data from 2011 (and the higher statistics expected in 2012) will reach these kinematic values and should shed further light on the necessity and the efficacy of this theoretical technique, not only for $W+\geq 1$ jet, but for higher jet multiplicities as well.

[^142]

Fig. 55: The ratio of the predictions obtained from the NLO Exclusive Sums approach to the inclusive NLO predictions for $W \geq 1$ jets, $W \geq 2$ jets and $W \geq 3$ jets. The ' jitter ' is due to the limited BlackHat+Sherpa statistics for these predictions.

## Appendix: a double logarithmic analysis of the Exclusive Sums method

To help understand the structure of the Exclusive Sums method, it can be useful to consider how it works in a simple double logarithmic approximation. We use $p_{t, \min }$ to represent the minimum $p_{t}$ for the jets in the Exclusive Sums sample, and first study the cross section for $W$ production as a function of $p_{t, W}$ at high $p_{t, W}\left(\gg m_{W}\right)$, considering in particular the terms that go as $\alpha_{s}^{n} L^{2 n}$ where $L=\ln p_{t, W} / p_{t, \min }$. The 0 -jet sample does not contribute at all to non-zero $p_{t, W}$, so the first term comes from the exclusive 1 -jet contribution. If calculated to all orders in the double logarithmic approximation (DLA), it would have the form

$$
\begin{equation*}
\sigma_{1, \operatorname{excl}}^{\mathrm{DLA}}\left(p_{t, W}\right)=\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \exp \left(-\frac{2 C \alpha_{s}}{\pi} L^{2}\right) \tag{100}
\end{equation*}
$$

where $C=2 C_{F}+C_{A}$ for the (dominant) $q g \rightarrow W^{ \pm} q^{\prime}$ scattering process. The $n$ exclusive jet rate would be given by

$$
\begin{equation*}
\sigma_{n, \mathrm{excl}}^{\mathrm{DLA}}\left(p_{t, W}\right)=\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \frac{1}{(n-1)!}\left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)^{n-1} \exp \left(-\frac{2 C \alpha_{s}}{\pi} L^{2}\right) \tag{101}
\end{equation*}
$$

and one sees that the sum over all multiplicities is given by

$$
\begin{equation*}
\sigma\left(p_{t, W}\right)^{\mathrm{DLA}}=\sum_{n=1}^{\infty} \sigma_{n, \mathrm{excl}}^{\mathrm{DLA}}\left(p_{t, W}\right)=\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \tag{102}
\end{equation*}
$$

i.e. in the double logarithmic approximation, there are no corrections to the $p_{t, W}$ distribution at high $p_{t, W}$. Now let us consider what happens if we expand each of the exclusive sums to NLO. For the $n$-jet cross section, we have

$$
\begin{equation*}
\sigma_{n, \mathrm{excl}}^{\mathrm{NLO}(\mathrm{DLA})}\left(p_{t, W}\right) \simeq \sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \frac{1}{(n-1)!}\left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)^{n-1}\left(1-\frac{2 C \alpha_{s}}{\pi} L^{2}\right) \tag{103}
\end{equation*}
$$

Performing the sum over $n$, which corresponds to summing an infinite tower of NLO exclusive jet calculations, leads to

$$
\begin{align*}
\sigma\left(p_{t, W}\right)^{\mathrm{DLA}} & =\sum_{n=1}^{\infty} \sigma_{n, \mathrm{excl}}^{\mathrm{NLO}(\mathrm{DLA})}\left(p_{t, W}\right)  \tag{104a}\\
& =\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \exp \left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)\left(1-\frac{2 C \alpha_{s}}{\pi} L^{2}\right)  \tag{104b}\\
& =\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right)\left(1-\frac{1}{2}\left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)^{2}+\mathcal{O}\left(\alpha_{s}^{3} L^{6}\right)\right) . \tag{104c}
\end{align*}
$$

As long as $L^{2}$ is not large, the difference between this and the correct answer of Eq. 102 is a straightforward NNLO correction, i.e. small. However when $p_{t, W} \gg p_{t, \min }$ the logarithms become large, the $\alpha_{s}^{2} L^{4}$ term can be of order 1 and the Exclusive Sums method may then no longer be a good approximation. A similar analysis can be performed for an exclusive sum truncated at some finite order, as used in our study.

Given the above discussion, one may wonder then if there are any circumstances in which the Exclusive Sums method will bring benefits. For the observable studied in this contribution, $H_{T}$, the key difference with respect to $p_{t, W}$ is that it is subject to a 'giant' $K$-factor at NLO. This phenomenon is associated with 'dijet' topologies in which a soft or collinear $W$ is radiated off the dijet system, leading to a double logarithmic (electroweak) enhancement. In addition these topologies can be created by $q q$ type scattering (whereas the LO process involves only $g q$ or $q \bar{q}^{\prime}$ scattering), leading to further enhancement in $p p$ collisions at large $H_{T}$. Dijet type topologies contribute significantly to the $H_{T}$ distribution, even when the $W$ is soft, because the variable sums all particles' transverse momenta (whereas the softness of the $W$ limits these topologies' contribution to the $p_{t, W}$ distribution).

Because of the giant $K$-factor, for the $H_{T}$ variable the behaviour of the Exclusive Sums method is more subtle than for $p_{t, W}$ : while the $\sigma_{W+2}^{\mathrm{NLO}}$ contributions destabilize the prediction for the $q g \rightarrow W q^{\prime}$ type topologies, they instead stabilize the prediction for the much larger $q q \rightarrow W q^{\prime} q$ topologies (present only at LO in a NLO $W+1$-jet calculation). Going further in the exclusive sum, however, i.e. including $\sigma_{W+3}^{\mathrm{NLO}}$ and $\sigma_{W+4}^{\mathrm{NLO}}$ contributions can however destabilize the predictions for both kinds of topologies. Traces of this behaviour were visible in the numerical studies shown above.

## 17. $W$ PRODUCTION IN ASSOCIATION WITH MULTIPLE JETS AT THE LHC ${ }^{34}$

#### Abstract

We compare the results from four different theoretical predictions for the production of a $W$ boson in association with at least two jets at the Large Hadron Collider. We discuss a possible method for combining next-to-leading order samples with different jet multiplicity from BlackHAT+SHERPA. We then compare these results with the next-to-leading order $W$ plus two jet calculation, the leading order ME\&TS merged approach of SHERPA and the highenergy resummation approach of High EnERGY JETS in an attempt to determine if these approaches can be distinguished at the LHC.

### 17.1 INTRODUCTION

The production of a $W$ boson in association with jets at the Large Hadron Collider (LHC) is an extremely important process. It contributes to three distinct areas of the rich physics program at the LHC. Firstly, it is a key Standard Model signal and therefore important to test our understanding of the Standard Model in the TeV -scale energy range. Secondly, it is an important background in many searches for new physics where, for example, new heavy coloured particles have cascade decay chains. Thirdly, it provides an ideal testing ground for experimental techniques such as a jet veto: what is learned in the relatively well-understood treatment of $W$ plus jets can be directly applied to Higgs searches for example.

It has been observed that the ratio of $W+(n+1)$-jet events to $W+n$-jet events can be substantially larger than one might naïvely expect by considering the $\alpha_{s}$ suppression only. This is especially true in phase-space regions of large four-momenta, such as the high- $H_{T}$ tail, because the available phase space for extra jet emission at the LHC is extremely large. It can therefore compensate for the effect of an additional factor of the strong coupling. This effect is more visible in distributions where additional radiation leads to a significant change in the value of the observable, as is the case for the $H_{T}$ distribution, the scalar sum of the transverse momenta of identified leptons, jets and missing energy. The change will be more moderate in an observable like $H_{T, 2}$, whose definition differs from that of $H_{T}$ by truncating the jet sum to include only the two hardest jets in the event. To make an impact here requires the radiation to lead to an additional jet with transverse momentum as large as that of the second hardest jet, not only larger than the jet $p_{T}$ threshold. The effects will also be smaller in more inclusive variables like the transverse momentum of the $W$ boson, $p_{T, W}$, or the leading jet, $p_{T, j_{1}}$.

There are a number of different theoretical approaches to describing the emission of large numbers of jets. In order to probe to what extent the differences in these will be accessible at the LHC, we will compare, in this study, the predictions for the jet activity in inclusive $W(\rightarrow e \nu)+2$-jet production from (a) BLACKHAT+SHERPA $(B H S)$ [70, 51, 22], (b) combined $B H S$ samples (to be described below), (c) Sherpa [146, 425] run in ME\&TS mode (S-MEPS) [426, 427, 428] and (d) High Energy Jets (HEJ), an all-order resummation of wide-angle radiation [418, 419, 438].

The current state-of-the-art next-to-leading order (NLO) predictions for $W$ production in association with jets are those of $B H S$, which have been calculated up to $W$ plus four jets with a leading-colour approximation for the virtual part [22], and up to $W$ plus three jets with a full color treatment [70, 51]. In this study, we consider the inclusive $W+2$-jet prediction at NLO accuracy, and further, discuss and show predictions from an inclusive sample where $W+2,3,4$-jet events generated by $B H S$ are combined in a simple manner, nevertheless without introducing any double counting of phase-space regions.

The $S$-MEPS predictions are obtained from merging at leading order (LO) tree-level Matrix Elements for $W+0, \ldots, n$-parton final states with (Truncated) parton Showers (hence the name ME\&TS) preserving the leading logarithmic accuracy to which soft and collinear multiple emissions are described by the parton shower. The newer ME\&TS merging scheme was introduced in Ref. [426] and optimised

[^143]as documented in Refs. [427, 428] to improve over the original SHERPA implementation based on the CKKW approach [429, 430]. ME\&TS guarantees a better matching regarding the usage of scales as occurring in the evaluation of the matrix elements and those scales driving parton showering. The $S$-MEPS sample used in our study was generated by including $W(\rightarrow e \nu)$ production matrix elements with up to five extra partons (massless quarks, $u, d, s, c, b$, and gluons).

The HEJ framework is a resummation of the leading logarithmic terms occurrung in pure, or $W$, $Z$ or $H$ plus, multi-jet production in the limit of large invariant mass between each pair of jets, to all orders in $\alpha_{s}$. This is then matched to tree-level accuracy for final states with two, three or four jets. In principle, the HEJ framework can be merged with a parton shower to add the collinear pieces which are not included in the HEJ description (HEJ does include soft emissions down to around 2 GeV ). First steps in this direction for pure jet production were taken in [431]. Here, the HEJ predictions are calculated at the parton level.

In the 17.2 section, we will elaborate on the method (b) for combining NLO samples of different jet multiplicities. Then, in the 17.3 section, we will first show explicit results of the sizable impact of large multiplicity events by comparing predictions from the combined BHS sample and the S-MEPS merged sample. Secondly, we will study variables chosen to probe the differences in the treatment of the QCD radiation. We will show and compare the predictions for all four descriptions mentioned above focusing on the following observables:

- the average number of jets as a function of $H_{T}=\sum_{i} p_{T, j_{i}}+p_{T, e}+p_{T, \nu}$ and $\Delta y$, the rapidity difference between the most forward and most backward jets, and also
- the ratio of the inclusive 3-jet rate to the inclusive 2-jet rate as a function of $H_{T}$ and $\Delta y 35$

We will then discuss the areas of agreement and difference that we find, before we finally conclude in the 17.4 section.

### 17.2 NLO EXCLUSIVE SUMS

An NLO $n$-jet prediction contains events with $n$ or $n+1$ partons. For observables for which higher multiplicites have a significant impact, this limitation can be detrimental. If one has predictions for different multiplicities ( $m, m+1, \ldots, M$ ), one can try to combine them by avoiding double counting by requiring that the $n$-jet prediction is used only to describe $n$-jet events (except for the highest multiplicity where ( $n+1$ )-jets configurations are allowed). The total cross section can be rewritten as a decomposition based on exclusive (exc) and inclusive (inc) jet bins:

$$
\begin{equation*}
\sigma^{\mathrm{tot}} \equiv \sigma_{m}^{\mathrm{inc}}=\sum_{n=m}^{M-1} \sigma_{n}^{\mathrm{exc}}+\sigma_{M}^{\mathrm{inc}} \tag{105}
\end{equation*}
$$

The exclusive-sums procedure describes each jet bin at NLO accuracy, i.e. at $\mathcal{O}\left(\alpha_{s}^{n+1}\right)$, or, alternatively, only the $(M+1)$-th (inclusive) jet bin is predicted with LO precision. We hence note that the combination of the terms shown in Eq. 105) occurs at different orders of the strong coupling. Furthermore, the definition of an exclusive $n$-jet sample requires a detailed treatment of jet vetoing. For these reasons, the simple combination procedure is crude and does not increase the formal accuracy of the prediction, which is that of NLO of the smallest multiplicity. However, one can hope that the procedure will lead to a better prediction in observables where higher multiplicity events dominate.

More studies are required to understand the uncertainties related to this procedure. One way of doing so would be to vary the jet algorithm and/or parameters of the jet algorithm used to separate the different NLO predictions into fixed multiplicities sets and test the stability of the prediction ${ }^{36}$ This is left to a future study.

$$
\begin{array}{ll}
\left|\eta_{e}\right|<2.5 & p_{T, e}>20 \mathrm{GeV} \\
M_{\perp, W}>20 \mathrm{GeV} & p_{T, \nu}>20 \mathrm{GeV} \\
\left|\eta_{j}\right|<4.5 & p_{T, j}>25 \mathrm{GeV}
\end{array}
$$
\]

Table 12: Summary of the cuts applied in the analysis.

Fig. 56: The average number of jets as a function of $p_{T, W}$ (left) and $p_{T, j_{1}}$ (right). The $p_{T, W}$ plot shows the $B H S$ exclusive sums prediction, while the $p_{T, j_{1}}$ plot is obtained from $S$-MEPS.

### 17.3 RESULTS OF THE COMPARISON

In this section, we compare the results of different theoretical descriptions for $W+n$-jets production at the LHC. The number $n$ can take values from 2 and above, as we will mostly consider inclusive samples. The four descriptions, which we will compare here in more detail, are

- the $B H S$ calculation of $W+2$-jets at NLO,
- the combined sample of $W+2,3,4$-jet events at NLO from $B H S$, as described in the 17.2 section,
- the $S$-MEPS merged $W+n$-jets sample using LO tree-level matrix elements up to $n=5$, and
- the approach of HEJ.

Throughout this study, we will consider inclusive samples of $W^{-}$boson production in association with at least two hard jets identified by the anti- $k_{T}$ jet algorithm using $R=0.4$. The jets are required to have $p_{T, j}>25 \mathrm{GeV}$. We look only in the $W^{-} \rightarrow e^{-} \bar{\nu}_{e}$ decay channel and use the cuts given in Tab. 12 where $M_{\perp, W}$ is defined as $M_{\perp, W}=\sqrt{\left(\left|\vec{p}_{T, e}\right|+\left|\vec{p}_{T, \nu}\right|\right)^{2}-\left(\vec{p}_{T, e}+\vec{p}_{T, \nu}\right)^{2}}$.

The HEJ predictions use the geometric mean of the jet transverse momenta to determine the renormalisation and factorisation scale, i.e. $\left(\prod p_{T, j}\right)^{1 / n}$. This central choice will be varied by a factor of two in either direction to provide an envelope (marked by dotted lines in the corresponding figures) around the HEJ default prediction. The BHS predictions instead use $\hat{H}_{T}^{\prime} / 2$ as the NLO calculation becomes unstable for a scale which is too low. In the $S$-MEPS calculation, scales are chosen according to the default prescription given by ME\&TS [426].

The variables $H_{T, 2}, p_{T, W}$ and $p_{T, j_{1}}$ are less sensitive to the presence of additional radiation than $H_{T}$, as discussed in the introduction. The plots, which we present in Figs. 56 and 57 address the alternative question: given a particular value of $H_{T}, H_{T, 2}$ etc. how many jets are typically found in the event?

Figs. 56 and 57 show the stacked results for the average number of jets as a function of $p_{T, W}, p_{T, j_{1}}$, $H_{T}$ and $H_{T, 2}$ visualising the contributions from each exclusive 2,3,4-jet sample and the inclusive 5 -jet

Fig. 57: The contribution from different multiplicities to the average number of jets as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the BHS exclusive sums prediction, while the lower ones are extracted from S-MEPS.
sample. The left (right) plot in Fig. 56 and the upper (lower) rows of plots in Fig. 57 depict the results as obtained from the combined BHS sample (the $S$-MEPS sample). In all cases the different colours correspond to the terms in the numerator of the formula for the average number of jets,

$$
\begin{equation*}
\langle N\rangle_{5}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{106}
\end{equation*}
$$

where blue, green, red and magenta stand for $i=2,3,4$ and $i=5$, respectively. The subscript to $\langle N\rangle$ clarifies that we truncate the determination of the average after the fifth jet bin, noting that $\langle N\rangle_{k} \rightarrow\langle N\rangle$ for a sufficiently large number of jet bins. This makes no difference for the BHS predictions employed here since the jet multiplicity de facto is limited to five, but it does for the $S$-MEPS and HEJ computations where events with $i>5$ jets do occur. We have defined $n_{k}^{\text {exc } / \mathrm{inc}}=d \sigma_{k}^{\text {exc } / \mathrm{inc}} / d O$ where $O$ denotes an observable like $H_{T}$, or $\Delta y$ presented later on. Note that in Fig. 57 the 5 -jet part contributes to the average number of jets with a factor of 5 , while the 2 -jet part, for example, contributes with a factor of 2 only.

The layout of Fig. 58 (including the colour coding) is the same as before: here, we however display, wrt. $n_{2}^{\text {inc }}$, the relative fractions of the different multiplicities corresponding to the terms in the denominator of Eq. (106). In other words, in Fig. 58 we consider the partitioning of

$$
\begin{equation*}
1=\frac{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{107}
\end{equation*}
$$

Fig. 58: The fraction of the total rate from different multiplicities as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the $B H S$ exclusive sums prediction, while the lower ones are extracted from $S$-MEPS.

Although there is just a $30 \%$ fraction of inclusive 5 -jet events to the total cross section, we observe that their contribution to the build-up of $\langle N\rangle\left(H_{T}\right)$ for very large $H_{T}$ gets close to $50 \%$. Also, for an $H_{T} \sim$ 500 GeV , the average number of jets is composed evenly between the 2,3 -jet and 4,5 -jet contributions, while the relative fraction of the 2,3 -jet events is nearly $70 \%$. This emphasizes the dominance of multijet events in forming large $H_{T}$ values. It also can be seen that for medium $H_{T}$ values, $400<H_{T}<$ 700 GeV , all the multiplicities give roughly the same contribution to the variable $\langle N\rangle\left(H_{T}\right)$, while for low $H_{T}$, the average is primarily described by 2-jet events.

Going clockwise through Figs. 56 and 57 we see that the average number of jets is indeed sensitive to higher multiplicities when considered as a function of $p_{T, W}, p_{T, j_{1}}$ and $H_{T, 2}$, but in all these cases this happens to a lesser extent as if considered as a function of $H_{T}$. As expected, the dependence is mildest for $p_{T, W}$, the most inclusive observable studied here. We also observe that the jet-bin decomposition of $p_{T, j_{1}}$ and $H_{T, 2}$ turns out very similar. Most strikingly we note the increase in the contribution from the highest multiplicity events, the ones containing more or at least five jets. For $H_{T, 2}$, we furthermore display to the right of Fig. 58 the relative fractions as done in the $H_{T}$ case. Even for largest $H_{T, 2}$ values, the fraction arising from 2,3 -jet events remains close to $65 \%$ stressing once more the lower sensitivity of $H_{T, 2}$ versus $H_{T}$ regarding multiple jet production.

Finally, we compare the plots from the combined BHS samples in all figures to the corresponding ones generated with the $S$-MEPS sample. Interestingly, the outcome looks very similar although ME\&TS handles the single terms in Eq. (105) rather differently. They are calculated at least at leading (soft/collinear) logarithmic accuracy improved by LO $n$-jet effects. Presumably, for the exclusive jet bins, this description (which allows a better treatment of jet vetoes) is not too far off the exclusive sums

Fig. 59: Average number of jets as a function of $H_{T}$ (left) and $\Delta y$ (right) in two BHS descriptions, from $H E J$ and from $S$-MEPS, the latter using the $\langle N\rangle_{7}$ definition. The bands shown with dotted lines for the HEJ prediction are a result of varying the scale by a factor of 2 in each direction.
approach, since the unresolved $\mathcal{O}\left(\alpha_{s}\right)$ corrections are also present in the Sudakov form factors applied in the ME\&TS approach. Also, the combined BHS samples as well as the $S$-MEPS sample use the same tree-level matrix elements, namely up to $W+5$-parton matrix elements. Clearly, it has to be studied further whether this similarity in the results is a coincidence or not.

It is clear that the impact of the higher multiplicity samples is significant throughout, especially in the high $H_{T}$ tail. This is precisely the region, which would be probed for signs of new physics, and therefore it is essential that we fully understand our theoretical descriptions in this region. This is the subject of the remainder of this contribution, where we compare all four different methods of modelling hard QCD radiation in inclusive $W+2$-jet events.

The left plot of Fig. 59 shows the final comparison plot between the exclusive sums and inclusive 2-jet $B H S$ results as well as the $H E J$ and $S-M E P S$ predictions for the average number of jets as a function of $H_{T}$. The differences in the descriptions are significantly larger than the scale uncertainty band on the $H E J$ prediction. For the $W+2$-jet NLO result, the number of jets rises to 2.6 already at $H_{T}=500 \mathrm{GeV}$ but that levels off significantly below the $S-M E P S$, exclusive $B H S$ sum and $H E J$ results. The $H E J$ results level off at a higher value of about 3.0 , starting to clearly disagree with the exclusive sums and $S$-MEPS predictions above 500 GeV , from where those two curves keep rising to a final level of around 3.7 to 4.0. The $S$-MEPS comes in highest at largest $H_{T}$, where $\langle N\rangle_{7}$ is shown, cf. Eq. (106), in order to determine the average number of jets for this $S$-MEPS result. The reason for giving slightly higher $\langle N\rangle$ than the exclusive sums lies in the contribution of additional parton-shower jets present in the $S$-MEPS calculation and more accurately accounted for by the use of the $\langle N\rangle_{7}$ definition as compared to the earlier result based on $\langle N\rangle_{5}$ presented in Fig. 57 to the lower left.

In the right panel of Fig. 59, we have plotted the average number of jets as a function of the rapidity span, $\Delta y$, instead of $H_{T}$ as before. Again the differences are larger than the scale variation shown on the HEJ result, but the ordering is different to that of the left plot of Fig. 59. All four descriptions increase linearly with $\Delta y$ but the gradient is steepest for the HEJ predictions where the average rises above 3.0 for $\Delta y$ values as large as 6.0. The BHS exclusive sum result is consistently below this, reaching about 2.8 at $\Delta y=6.0$, and agrees pretty well with the $S$-MEPS result based on $\langle N\rangle_{7}$. The NLO $W+2$-jet prediction given by $B H S$ is lower still, between 2.4 and 2.5 for $\Delta y \sim 5.0$.

It may seem surprising that on the plot on the left-hand side the exclusive sums and S-MEPS lie higher for most of the distribution whereas on the right-hand side these approaches as well as $H E J$ give predicitions that are commensurate. The region of high $H_{T}$ and that of high $\Delta y$ however are largely distinct as it is very expensive to have both a large rapidity and large $p_{T}$ for the jets. Also while radiating

Fig. 60: The ratio of the inclusive 3 -jet and 2 -jet rates in the inclusive $W+2$-jet NLO and exclusive sum description of $B H S$ as well as in the $S$-MEPS and $H E J$ approaches as a function of $H_{T}$ (left) and $\Delta y$ (right). Again, the dotted lines indicate the uncertainty band from varying the scale in $H E J$ by a factor of 2 in each direction.
an additional jet automatically moves an event towards the higher $H_{T}$ direction, radiating an additional jet tends to not change the rapidity difference. So, we expect the higher multiplicies to have a smaller effect on the average number of jets as a function of $\Delta y$ compared to as a function of $H_{T}$. This is indeed the case in Fig. 59.

Lastly, in Fig. 60 we plot the ratio of the inclusive 3 -jet to the inclusive 2 -jet rate as a function of $H_{T}$ (left) and $\Delta y$ (right), again for all four descriptions used here. The predicted $\left(d \sigma_{3}^{\text {inc }} / d H_{T}\right) /\left(d \sigma_{2}^{\text {inc }} / d H_{T}\right)$ all agree very well below 400 GeV . The fixed order $B H S$ result for $W+2$ jets is highest for large $H_{T}$, however is known to become unreliable here, since the probability that an inclusive 2 -jet event is at least a 3 -jet event turns too large, being in conflict with the expected behaviour of an $\mathcal{O}\left(\alpha_{s}\right)$ correction. The BHS exclusive sums, the S-MEPS and the HEJ results, in this order, level off considerably lower with the HEJ fraction staying below $60 \%$ to $70 \%$, which leaves the other predictions again above the $H E J$ uncertainty envelope. In contrast, when the same ratio of jet rates is plotted against $\Delta y$, the $H E J$ prediction is consistently higher throughout. This again emphasises that differences in the descriptions come to light in different kinematic regions. However, in both cases here the magnitude of the differences is relatively small and would be rather difficult to distinguish in present experimental data.

### 17.4 CONCLUSIONS

We have compared a number of theoretical descriptions of $W^{-}$production in association with at least two jets. After outlining one possible method of combining NLO calculations of different multiplicities, we compared this with a pure NLO calculation of $W+2$-jets production obtained by BLACKHAT+SHERPA, a sample of leading-order events merged using the ME\&TS method of SHERPA, and the high-energy resummation of the HEJ framework.

We studied the average number of jets and the ratio of the 3 -jet and 2 -jet inclusive cross sections as a function of $\Delta y$ and of $H_{T}$. We find, with these simple cuts, some clear differences in the predictions when we study the average number of jets as a function of both $\Delta y$ and $H_{T}$. Smaller differences, which would be more difficult to disentangle experimentally, are found when we study the ratio of inclusive rates.

It would be very valuable to have an experimental study, which probed the average number of jets in $W$ production in association with at least two jets, to test our different descriptions of these important Standard Model processes.

## ACKNOWLEDGEMENTS

## 18. UNCERTAINTIES IN THE SIMULATION OF $W+$ JETS - A CASE STUDY 37

#### Abstract

In this contribution, uncertainties in the simulation of a large variety of observables related to the production of $W$ in association with jets at the LHC and the Tevatron are discussed. This work aims to - serve as a compendium of currently publicly accessible tools in addition to the ones presented in a previous publication [439] with a similar topic, and to compare their results; - discuss the origin and generic size of various uncertainties in the simulation of perturbative and non-perturbative aspects of this process; - trace the interplay of these uncertainties in various stages of the full event simulation; - hint at those uncertainties in each of the various tools considered here which the respective authors find relevant; - guide their users in how to assess the related uncertainties in a way the authors recommend.

### 18.1 Introduction

The production of $W$-bosons in association with jets constitutes an important process at the Tevatron and the LHC, for a variety of reasons. First of all, it represents a major background to Standard Model signatures such as top-pair and single-top production, and it also plays a role in searches for the Higgs boson in the Standard Model. Furthermore, this reaction, together with the fairly similar channel of $Z$ production in association with jets, provides one of the most important backgrounds in those searches for new physics where large missing transverse energy and high jet multiplicities characterise the respective signal. Thirdly, this process has become a standard reaction for QCD studies at hadron colliders, ranging from the validation of simulation tools for multijet signatures to measurements related to multiple parton scattering. Finally, this process also provides one of the main testbeds for novel techniques in the automation of higher-order QCD corrections and their matching or merging with subsequent parton showers in the framework of event generators.

In the spirit of this last point, providing a testbed for the combination of fixed order calculations with the parton shower, this process has been analysed in quite some depth in [439] about five years ago. A number of reasons provide motivation to update and extend this previous study, namely

- the LHC being up and running and starting to provide highly precise data such that a proper treatment of uncertainties becomes an important issue;
- major improvements in the ability to calculate higher-order corrections including up to four jets in the final state accompanying the $W$ bosons [51, 117, 22];
- the advent of such next-to leading order calculations - albeit for lower final state multiplicities fully matched to the parton shower [440, 404, 424];
- an improved understanding of the leading order merging prescription for towers of multijet multiplicities with the parton shower [426, 441];

[^145]- the combination of matching and merging methods [442, 443];
- and new methods to simulate multijet topologies based on the high-energy limit [64].

Therefore this study aims at being a first step towards a more complete update of [439], with a shift in focus towards a discussion of theoretical uncertainties in different approximations, including perturbative and non-perturbative effects. Apart from tracing the origin and determining the generic size of various uncertainties in the theoretical description of various observables related to this process, also the interplay of them at various stages of the simulation, from the matrix element to the hadron level will be discussed. Consequently, the most important causes for theory uncertainties in various tools are highlighted. Therefore, one of the more practically relevant goals is to also provide methods to reliably and robustly estimate such uncertainties for the various tools used in this study, as recommended by authors or users.

The outline is as follows: After briefly presenting the various tools included in this study and discussing the way they have been used here in Sec. 18.2 , example results for them will be presented individually, tool by tool in Sec. 18.3 . In Sec. 18.4 these results are compared in order to see and quantify relative differences. In this endeavour, experimental results have not yet been included. We reserve this comparison with relevant data for a later, full-fledged analysis, which will hopefully include even more tools.

### 18.2 Codes

In this work a variety of different codes has been employed, which allow to study the process at various different stages:

1. Fixed order matrix elements:

By now, the description of $W$ boson production in association with jets is possible for up to 4 additional jets at NLO. Here, results from two NLO codes, GoSAM+SHERPA [12, 425, 146] and BLACKHAT+SHERPA [70, 51, 22], which are either publicly available or provide publicly available event files, are presented. The corresponding results therefore are on the matrix element level.
2. All-order resummed matrix elements:

Approximations to the partonic matrix elements for the processes of $n$-jet production, and $W, Z, H+n$-jets, $n \geq 2$, was recently calculated to any multiplicity, and including all-order resummations for the leading virtual corrections. The all-order scheme [418, 419], implemented in the HEJ [64] code, becomes exact in the limit of large invariant mass between each parton (the MRK limit of BFKL). The resummation scheme is merged with LO matrix elements (much like in MEPS, see later). The resummation of HEJ can also be interfaced to a parton shower [431]; the results presented here, however, are on the matrix element level. It should also be stressed that due to the nature of the approximation of HEJ, the simulation here are relevant for the production of at least two jets in addition to the $W$ boson.
3. Parton showers:

The pure parton shower code relies on the collinear approximation to produce additional jets. By using a matrix element reweighting, however, in the process of $W$ production, typically one additional jet can correctly be described. For this simulation, PYTHIA8 [348] has been used here, with results available on the parton shower level, hadron level and hadron level including UE.
4. LO matrix elements merged with the parton shower (MEPS):

By now, the use of towers of multijet matrix elements with increasing multiplicity merged to the parton shower following ideas presented in [444, 429, 445, 430] is common practise in the experimental collaborations. In fact, a first comparison of different codes and implementation has been presented a while ago [439]. Here, three implementations of these ideas are included, namely the ones in MADGRAPH+PYTHIA [165, 446, 163, 191, 400], PYTHIA8+ME [441] and SHERPA [146]. Here results are available on all levels matrix element level, parton shower level, hadron level,
hadron level including UE, and hadron level including UE and QED final state radiation in different combinations of codes.
5. NLO matrix elements matched to the parton shower ( $\mathrm{NLO} \otimes \mathrm{PS}$ and MENLOPS):

In principle two methods by now have been proposed and fully implemented which consistently match full NLO calculations to the parton shower, namely Mc@NLO [401] and Powheg [416, 417]. Here the latter is being used, with its implementation in the Powheg Box [13], and interfaced to the PYthia [400] parton shower in its $k_{T}$-ordered version [447]. In addition, a combination of such matching with the merging methods described in the previous point is available [442, 443], ranging under the name MENLOPS. In this paper we use an implementation of such methods provided in the SHERPA framework. In both cases, results are available on all levels matrix element level, parton shower level, hadron level, and hadron level including UE.

### 18.21 BLACKHAT + SHERPA

The NLO predictions are obtained by combining BLACKHAT [4] for the virtual part and SHERPA [147, 448] for the real part. It is currently possible to obtain predictions at NLO for a $W$-boson in combination with up to four jets [70, 51, 22].

The plots have been produced by re-analysing large event files produced by the combination of BLACKHAT and SHERPA. These files contain particle four-momenta as well as the coefficients of all scale dependent functions, including the PDFs so that it makes it possible to easily change factorisation and renormalisation scales as well as the PDF set.

We used a common factorisation and renormalisation scale $\mu_{F}=\mu_{R}=\hat{H}_{T}^{\prime} / 2$ with $\hat{H}_{T}^{\prime}=$ $\sum_{j} p_{T}^{j}+E_{T}^{W}$ where the sum runs over all jets and $E_{T}^{W}=\sqrt{M_{W}^{2}+\left(p_{T}^{W}\right)^{2}}$.

Estimation of uncertainties The estimation of the uncertainties for the NLO calculation obtained with BLACKHAT+SHERPA is obtained by combining in quadrature the pdf uncertainties obtained using the pdf error set and the uncertainties obtained by varying the factorisation and renormalisation scales simultaneously by factors of $1 / 2$ and 2 . To this error we also add in quadrature the integration error estimate. Another way of estimating the uncertainties due to the choice of scales is to compare predictions obtained using different choice of basis scales, but this has not been done for this study.

We used the CTEQ6.6 PDF set. The value of $\alpha_{s}$ used for this calculation has also been taken as that provided with this PDF set. The PDF uncertainties are estimated using the hessian method and PDF 'error' set provided with the CTEQ6.6 PDF set.

### 18.22 GOSAM + SHERPA

GOSAM [12] is a new framework which allows the automated computation of one-loop scattering amplitudes for multi-particle processes. The one-loop scattering amplitudes are generated in terms of algebraic $d$-dimensional unintegrated amplitudes, which are obtained via Feynman diagrams. This allows to perform symbolic manipulations of the expressions prior any numerical step. For the reduction, the program offers the possibility to use either a $d$-dimensional extension of the OPP method [121, 122, 119], as implemented in SAMURAI [6], or tensor reduction as implemented in golem95 [130, 131] interfaced through tensorial reconstruction at the integrand level [124].

The GoSAM framework can be used to calculate one-loop corrections within both QCD and electroweak theory. Beyond the Standard Model theories can be interfaced using FeynRules [137] or LanHEP [136].

To produce results for a certain process specified by the user, the program must be fed with an "input card" with the details of the process. Alternatively, when interfacing the program with a Monte

Carlo (MC) event generator which supports the Binoth-Les-Houches-Accord (BLHA) interface [145], the specific order file produced by the MC event generator can be passed to GoSAM.

The analysis presented here was performed using this latter generation mode and SHERPA [425] 146] was chosen as MC event generator. SHERPA provides therefore the matrix elements for the production of $W$ and exactly one jet at the Born-level and the NLO real corrections to it, together with the needed subtraction terms and their integrated counter-parts. GOSAM provides the NLO virtual-part. The generation of the code follows the standards of the BLHA-interface [145]. During the first call of Sherpa an "order file" is written by the MC program. This file is read-in by GOSAM to produce the code for the one-loop evaluation of needed process. If this happens successfully, a contract file with information on the different possible subprocesses is produced by GoSAM and can be later read by the MC generator to recognize the numbering of the different partonic subprocesses. At running time all information between GoSAM and SHERPA is also passed using the BLHA-interface standards.

The steering of the event generation and the analysis interface with RIVET [360] is done using SHERPA cards. Each curve in the analysis consists of 100 combined runs of 50 million events. The renormalisation and factorisation scales are set according to the choice made for this analysis in Les Houches to

$$
\mu_{F}=\mu_{R}=\hat{H}_{T}^{\prime} / 2
$$

where $\hat{H}_{T}^{\prime}$ is defined in the previous section.

Estimate of uncertainties The estimation of the uncertainties for the NLO calculation obtained with GoSAM+SHERPA is done combining in quadrature the PDF uncertainties with the uncertainty coming from the separate variation of factorisation and renormalisation scale by factors of $1 / 2$ and 2 . Ideally also the integration error should be added in quadrature to the previous estimate, however the MC integration error obtained with RIVET at NLO is not reliable because of the incapacity of RIVET to take into account properly the correlation between real and subtraction events. For this reason and because of the very high statistics of the MC sample, the MC integration error is neglected. To assess the PDF uncertainty we compute the envelope of the results obtained using the three different PDF sets CT10 [255], used as nominal set, MSTW08 [262] and NNPDF2.1 [312]. The total scale uncertainty is determined by adding in quadrature the factorisation and renormalisation scale uncertainties. Each of them is found by computing the maximum between the nominal value and the up and down variations.

### 18.23 HEJ

The High Energy Jets (HEJ) framework [418, 419] provides an alternative description of collider events to the standard fixed order calculations (possibly interfaced to a parton shower). Instead, HEJ uses approximations to the hard scattering matrix element to all orders in $\alpha_{s}$ which become exact in the High Energy limit. The approximation results in sufficiently simple matrix elements, that these can be explicitly regulated, integrated and summed over any (relevant) multiplicity. This results in an explicit all-order resummation of the dominant contributions from wide-angle QCD radiation.

The building blocks of the HEJ framework ensure the correct leading logarithmic behaviour in the Multi-Regge Kinematic limit (aka. the High Energy Limit) of large invariant mass between all partons, for both the real and virtual corrections. The resummed $n$-jet rate is then further matched to tree-level accuracy for events with up to and including four jets, using a merging procedure for the soft radiation.

This procedure has so far been applied to the production of jets [64], $W$ plus jets [449], $Z$ plus jets and Higgs boson plus jets and has currently been implemented in a fully flexible Monte Carlo for the first two of these processes. The implementation integrates explicitly over any number of QCD emissions from a $(W, Z, H+)$ dijet system, and hence produces event samples for processes with two jets or more. Note that one has access to the momenta of all final state particles for every event and it is therefore extremely simple to restrict to a subset of the events if required, e.g. 3-jet exclusive events.

The HEJ resummation includes emissions at large transverse momentum which are increasingly important as the centre-of-mass energy of particle collisions increases. HEJ is currently the only available flexible Monte Carlo generator to obtain leading logarithmic accuracy in the limit of large invariant mass between emissions. However, the HEJ framework does not include any systematic resummation in the collinear limit. This is included in a parton shower, but a careful merging procedure is required to link one with HEJ, as there is significant overlap between the soft emissions included in each approach; the first steps in this direction have been taken for jet production [431] and are ongoing. In the current study though, only parton level predictions are given.

Estimate of Uncertainty The HEJ framework does not contain any tunable parameters other than the choice of renormalisation and factorisation scale (just like any fixed order calculation). In this study, in common with other approaches, we choose both of these to be given by the geometric mean of the transverse momentum of the jets:

$$
\begin{equation*}
\mu_{R}=\mu_{F}=\left(\prod_{j=1}^{n} p_{T}^{j}\right)^{1 / n} \tag{18.2.1}
\end{equation*}
$$

where the jets are defined according to the relevant cuts in each analysis. This is however only an arbitrary choice, as the framework admits any choice for the scale, including $H_{T}, p_{T}$ of the hardest jet and a fixed scale. For a given scale, $\alpha_{s}$ is evaluated according to the relevant PDF.

In common with standard convention, we calculate the scale variation by changing this scale by a factor of two in both directions. In principle, one could also include the PDF uncertainty, but this is not done in this study (as the scale uncertainty dominates). As described above, HEJ contains matching to tree-level accuracy for up to four jets. However, unlike the merging procedure in a showered sample, the merging scale here is not a free parameter. There is only one rational choice for the merging scale: the minimum $p_{T}$ of a jet in the relevant analysis. However, in an inclusive sample with at least two jets, one could use as a further estimator of uncertainty the variation obtained when matching to three and four jet LO matrix elements. This procedure will be studied in detail in Ref. [449], but in the present study, we quote the uncertainty only from the scale variation.

### 18.24 MADGRAPH + PYTHIA

MADGRAPH [165, 446, 163, 191] is a general purpose leading order matrix element (ME) generator, with a broad variety of models available and easily extensible thanks to its modular structure. The event generation is performed by the MADEVENT component, a tool implementing the Single Diagram Enhanced algorithm for multi-channel phase space integration. When a user provided process is specified, MADGRAPH automatically generates the amplitudes for all the relevant subprocesses and produces the mappings for the integration over the phase space. This process-dependent information is then used by MADEVENT, where the process specific code generated allows the user to calculate cross sections and to produce unweighted events. Once the parton level events have been generated, a traditional parton shower (PS) Monte Carlo library can be run on top of the MADGRAPH output to describe additional QCD radiation, and possibly allow to produce hadron level generated events if a suitable hadronisation model is then applied.

In order to avoid double counting of QCD radiation from the matrix element and the parton shower, the MLM matching approach is used in its ktMLM implementation provided by the MADGRAPH team [191].

For the present study MADGRAPH-5.1.1 [191] has been used for the matrix element generation, while the parton shower and hadronisation has been provided by PyTHIA 6.4.2.4 [400]. The $W+n$ jet process has been simulated up to 4 additional partons. The PDF used in both calculations has been

CTEQ6L1, and in the matrix element calculation the strong coupling costant has been setup to be equal to the one from the PDF used. The factorisation scale and the hadronisation scale are set to the W transverse mass, $m_{\perp, W}$. The parton level clusterisation scale xqcut has been set to 10 GeV , while the ME - PS matching scale qcut has been set to the optimal value of 20 GeV , determined ensuring the smoothness of the differential jet rate.

The Pythia settings have been defined according the so called Tune Z2, an adjustment of Tune Z1 described in [450] for CTEQ6L1, where the $p_{\perp}$ cutoff for the multiple parton interactions is set to $\operatorname{PARP}(82)=1.832$ obtained on top of LHC data as far as the underlying event and multiple parton interactions are concerned, while the fragmentation parameters are those optimized on LEP data by the Professor [451] team.

Estimate of uncertainties To estimate the uncertainties due to the factorisation scale and the renormalisation scale, which are set to $m_{\perp, W}$, we varied them simultaneously by a factor two. In addition we have independently varied by a factor two the ME - PS matching scale.

While applying these modifications, the total cross-section is kept fixed to the value obtained with the default parameters, 27.77 nb . That is because we are only interested in shape variations of the distributions, rather than in the total cross-section of the process calculated by MADGRAPH, which is accurate only at the leading order.

### 18.25 PoWhEG BOX + PYTHIA8

The Powheg Box [13] is a computer framework to ease the Powheg [416] implementation of new processes. It only requires as input the individual components of the NLO calculation under consideration, i.e., the Born process, its virtual radiative corrections and the real emission contributions. Then it automatically combines them, canceling the emerging soft and collinear singularities in the Frixione-Kunszt-Signer (FKS) subtraction scheme, and produces the required events. The Powheg Box is also a library, where previously implemented processes are available in a common framework.

For the present study we make use of the $W+$ jet implementation presented in [440].
The produced events are passed to PYthia8 [348] through the Les Houches interface [452] and showered with the default transverse-momentum ordered shower, vetoing further emissions harder than the one already present in the input events. This is achieved by setting the starting scale of the shower as the transverse momentum of the hardest emission 38

When multiple partonic interactions (MPI) are turned on, these are allowed to be harder than the first Powheg emission. Indeed, since the $W+1$ jet process is not accounted for in MPI, there is no over-counting.

Eventually, the relevant distributions are evaluated by interfacing the MonteCarlo output to the RIVET [360] analysis, for the two given sets of ATLAS and CMS cuts.

Since we have simulated events starting from a hard process where a $W$ is produced in association with one jet, only observables built from events where at least 1 jet is present will be shown.

Generation of predictions and estimate of uncertainties Predictions presented here are based on a merged sample of $4 \mathrm{M} W^{+}+j$ and $4 \mathrm{M} W^{-}+j$ weighted events, produced with the default Powheg Box choice of parameters. In particular, we have required a minimum cut $p_{\mathrm{T}}=5 \mathrm{GeV}$ on the associated jet at the generation level and, in order to enhance the statistical sampling of the high- $p_{\mathrm{T}}$ tail, we have further suppressed the rapidly rising contribution at low jet $p_{\mathrm{T}}$ by the factor $p_{\mathrm{T}}^{2} /\left(p_{\mathrm{T}, \text { supp }}^{2}+p_{\mathrm{T}}^{2}\right)$, with $p_{\mathrm{T}, \text { supp }}^{2}=100 \mathrm{GeV}$. The inverse of this factor enters the event weight.

[^146]We have adopted the Powheg Box default values for EW parameters, namely

$$
\begin{equation*}
M_{W}=80.398 \mathrm{GeV}, \quad \Gamma_{\mathrm{W}}=2.141 \mathrm{GeV}, \quad\left(\mathrm{ff}_{\mathrm{em}}\right)^{-1}=128.89, \quad \sin ^{2}{ }^{`} \mathrm{~W}=0.222645 \tag{18.2.2}
\end{equation*}
$$

and we have assumed a CKM matrix with a mixing between the first two generations only

$$
\begin{equation*}
\left|V_{u d}\right|=\left|V_{c s}\right|=0.975, \quad\left|V_{u s}\right|=\left|V_{c d}\right|=0.222, \text { and }\left|V_{t b}\right|=1 . \tag{18.2.3}
\end{equation*}
$$

Finally, we have resctricted the integration region to the interval $0<M_{W}<2221 \mathrm{GeV}$.
For the computation of the Powheg $\bar{B}$ function, the renormalisation and factorisation scale was chosen equal to

$$
\begin{equation*}
\mu_{R}=\mu_{F}=p_{\perp, j} \tag{18.2.4}
\end{equation*}
$$

where $p_{\perp, j}$ corresponds to the transverse-momentum of the (single) parton recoiling against the $W$ boson in the so-called underlying Born kinematics [417]. We have also run the code using

$$
\begin{equation*}
\mu_{R}=\mu_{F}=1 / 2\left(\sqrt{M_{W}^{2}+p_{\perp, W}^{2}}+p_{\perp, j}\right) \tag{18.2.5}
\end{equation*}
$$

but no relevant differences were observed with respect to the aforementioned choice, being the two scales similar for the $W+1$ jet processes at hand.

The scales entering in the evaluation of parton distribution functions and of the strong coupling in the Powheg Sudakov form factor are chosen to be equal to the transverse momentum of the PowHEG hardest emission [417, 386].

Scale-uncertainty bands obtained by varying the factorisation and renormalisation scales entering the $\bar{B}$ function by a factor of two in either directions are used as an estimate of the theoretical error associated to higher order missing effects.

The uncertainty due to the PDF choice was estimated generating events using three different sets (CT10 [255], MSTW2008 [262], and NNPDF2.1 [312]). The value of the strong coupling constant at $M_{Z}$ is consistently read from the PDF table used. The further showering performed by PYTHIA8 is instead performed with default PDF and $\alpha_{s}$ definitions, the difference being beyond the claimed accuracy of the calculation. In this study, we have used PYthia8, version 8.153.

### 18.26 Pythias

Pythia8 [348] is the latest incarnation of event generators of the Pythia family. At the heart of the generator are parton showers that evolve high-scale processes to the scale of hadronisation, by generating splittings with DGLAP splitting kernels. The splitting scales are ordered in relative transverse momentum [348, 447], and the phase space is constructed in a dipole-like manner in order to capture soft gluon coherence effects [453]. A key point of the evolution of partonic states in PYTHIA8 is that all perturbative components are interleaved [348, 447, 454], i.e. multiple partonic interactions, space-like and time-like showers are all generated in one transverse-momentum ordered evolution sequence. This means that due to the competition for phase space, all steps in the event generation are correlated. For a detailed discussion how parameters of the interleaved shower evolution are tuned to collider data, see [455]. Pythia8 with additional matrix element corrections has so far not been tuned to data. Since in [441], only very small differences were seen for LEP between PYTHiA8 with and without matrix element merging, we expect only small re-tuning effects in the parameters of the Lund string model [456]. Similarly, since we keep the low-scale modelling of PYTHIA8 largely intact, only small changes in the underlying event tuning are expected. We however expect that some re-tuning will be needed for jet shape data.

It should be noted that Pythia8 includes a selection $2 \rightarrow 1$ and $2 \rightarrow 2$ processes, as well as a limited variety of $2 \rightarrow 3$ processes, but does not contain a general ME generator. New processes, particularly for higher jet multiplicities, have to be made available in form of Les Houches Event (LHE)
[452] files. By virtue of matrix element corrections, Pythia8 describes the first emission in $\mathrm{W}+$ jets with the full matrix element probability. When introducing matrix elements with one additional jet within matrix element merging, this allows to fully cancel the merging scale dependence for the first emission, while small merging scale dependencies enter when including further jets. Current versions of Pythia8 include a general implementation of the CKKW-L matrix element merging prescription [445]. Please consult [441] for a detailed discussion of the implementation in PYTHIA8.

Generation of the predictions To generate predictions with stand-alone Pythia8 (i.e. without inclusion of matrix elements for W production in association with two or more jets), the built-in $q \bar{q} \rightarrow \mathrm{~W}$ matrix element in Pythia8 was used to generate the initial configuration. This was then evolved with to the hadronisation scale and the ensemble of partons hadronised using the Lund string model. For this study, we use the publicly available PyTHIA 8.157, with CTEQ6L1 parton distribution functions, and the associated Tune 4C. Since [441] showed a large dependence of the quality of the matrix element merging on whether rapidity-ordered emissions are explicitly forbidden in space-like showers, results are presented with and without enforced rapidity ordering.

The inclusion of matrix elements for additional jets into PYTHIA8 is achieved with Cккw-L merging. All merging tasks are handled internally in PYthiA 8.157, allowing for a high degree of automation. This means that the user only needs to supply

- Matrix element configurations in form of LHE files.
- An identifier giving the hard process of interest.
- A value of the merging scale. Facilities to allow the user to implement a her/his own merging scale definition are available.
For this report, matrix element configurations with additional jets were generated with MADGRAPH/ MadEvent [163], and read into Pythia8 in form of Les Houches Events. Pythia8 then derives all possible parton shower histories for an event, probabilistically chooses a history, and uses the reconstructed states and splitting scales to perform a re-weighting with Sudakov factors and $\alpha_{s}$ values. This means each event will have a weight

$$
\begin{aligned}
w_{\mathrm{CKKWL}}= & \frac{x_{n}^{+} f_{n}^{+}\left(x_{n}^{+}, \rho_{n}\right)}{x_{n}^{+} f_{n}^{+}\left(x_{n}^{+}, \mu_{F}^{2}\right)} \frac{x_{n}^{-} f_{n}^{-}\left(x_{n}^{-}, \rho_{n}\right)}{x_{n}^{-} f_{n}^{-}\left(x_{n}^{-}, \mu_{F}^{2}\right)} \\
& \times \prod_{i=1}^{n}\left[\frac{\alpha_{s}\left(\rho_{i}\right)}{\alpha_{\mathrm{SME}}} \frac{x_{i-1}^{+} f_{i-1}^{+}\left(x_{i-1}^{+}, \rho_{i-1}\right)}{x_{i-1}^{+} f_{i-1}^{+}\left(x_{i-1}^{+}, \rho_{i}\right)} \frac{x_{i-1}^{-} f_{i-1}^{-}\left(x_{i-1}^{-}, \rho_{i-1}\right)}{x_{i-1}^{-} f_{i-1}^{-}\left(x_{i-1}^{-}, \rho_{i}\right)} \Pi_{S_{+i-1}}\left(\rho_{i-1}, \rho_{i}\right)\right] \Pi_{S_{n}}\left(\rho_{n}, t_{\mathrm{MS}}\right)
\end{aligned}
$$

where $\rho_{i}$ and $x_{i}^{ \pm}$are the the reconstructed shower splitting scales and momentum fractions of the incoming partons in $\pm$ z-direction, and $\Pi_{S_{+i}}\left(\rho_{i}, \rho_{i+1}\right)$ the parton shower no-emission probability when evolving the state $S_{+i}$ from scale $\rho_{i}$ to $\rho_{i+1} . \alpha_{\text {sME }}$ gives the strong coupling used in the matrix element calculation. All reweighting factors are generated dynamically with help of the shower. The interleaved evolution of PYTHIA8 is accommodated by consistently including effects of multiple interactions into the no-emission probabilities. A detailed description of the formalism is given in [441].

As input for the current analysis, we have produced LHE files for $\mathrm{W}^{+}+$jets with up to four (three) additional jets at Tevatron (LHC) energies. The renormalisation scale in MADGRaPH was fixed to $\mu_{R}=\mathrm{M}_{\mathrm{Z}}$. For hadronic cross sections, CTEQ6L1 parton distributions (as implemented in LHAPDF [457]) have been chosen at a factorisation scale $\mu_{F}=\mathrm{M}_{\mathrm{W}}$, and the strong coupling in the ME was correspondingly fixed to $\alpha_{s}\left(\mathrm{M}_{\mathrm{Z}}\right)=0.129783$. To regularise QCD divergences and act as a merging scale, a cut in

$$
k_{\perp}^{2}=\min \left\{\min \left(p_{T, i}^{2}, p_{T, j}^{2}\right), \min \left(p_{T, i}^{2}, p_{T, j}^{2}\right) \frac{\left(\Delta \eta_{i j}\right)^{2}+\left(\Delta \phi_{i j}\right)^{2}}{D^{2}}\right\} \quad \text { with } \quad D=0.4
$$

and a cut value of $k_{\perp, \min }=t_{\mathrm{MS}}=15 \mathrm{GeV}$ has been applied to the matrix element.

Merged Pythia8 predictions are given for the default settings, i.e. using the parameters of Tune 4C, for Tune A2 [458], and for Tune 4C without enforced rapidity ordering (dubbed Tune X). Again, it should be noted that so far, no tuning including additional jets has so far been conducted.

Estimate of uncertainties To estimate uncertainties of a merged prediction of W+jets, it is interesting to study the dependence on the merging scale value. For this, we have generated LHE files with three different $k_{\perp, \text { min }}=t_{\text {MS }}$ cuts $\left(t_{\text {MS }}=15,30,45\right) \mathrm{GeV}$, and performed CKKW-L merging on these samples. Furthermore, to show the effect of tuning, the $t_{\mathrm{MS}}=15-\mathrm{GeV}$-sample was processed for two adequate tunes, Tune 4C and A2.

Uncertainties related to shower ordering In [441], it was shown that restricting shower emissions in Pythia8 to regions of phase space ordered both in transverse momentum and rapidity leads to nonnegligible effects in merged predictions. This can be seen as an effect of limiting the shower accuracy by reducing the phase space over which splitting kernels are integrated, meaning the accuracy of Sudakov form factors is impaired. Loosely speaking, if above the merging scale, the matrix element, integrated over the full phase space ${ }^{39}$, differs substantially from the splitting probabilities integrated over the allowed parton shower phase space, merged results will exhibit substantial merging scale dependencies. Such problems are obviously introduced if the parton shower phase space is heavily constrained.

Changing the phase space regions in which the shower is allowed to radiate thus allows us to estimate the uncertainties of the merging procedure in conjunction with the underlying shower. Particularly, this procedure can test the quality of the matrix element merging beyond the first few emissions, and give hints on how the shower resummation may be improved.

To emphasise the impact of the shower transition probabilities, we choose a fairly small merging scale ( $t_{\mathrm{Ms}}=15 \mathrm{GeV}$ ) to regularise the tree-level matrix elements for this investigation. Then, for each matrix element state, we generate all possible parton shower histories for a matrix element state, by clustering emissions. This is achieved by inverting the shower momentum- and flavour-mappings.

When merging matrix elements with rapidity-ordered showers, we investigate two ways of biasing the selection of a particular history, from which to generate the necessary Sudakov form factors:

1. In a "y-blind" sample, we do not include an additional discriminant based on rapidity. This means that - just like in the standard case - $\rho$-ordered will be preferred over $\rho$-unordered ones.
2. In a " $y$-conscious" sample, we pick histories with rapidity-unordered splittings only if no rapidityordered histories were found. Adopting this strict ordering criterion, histories ordered in $\rho$ and rapidity will be chosen predominantly, and only if no such history exists, histories un-ordered in either $\rho$ and/or rapidity are picked.
It should be noted that to the accuracy of the parton shower, both these prescriptions are equivalent, and switching the choice of histories gives a real estimate of the quality of the merging in conjunction the underlying shower. We believe that including this uncertainty gives a pessimistic view on how wide the range of predictions of one merged calculation can be, indicating that although standard by now, matrix element merging in Pythia8 should be applied with care. However, with reasonable settings, including additional jets can improve the description of multiple hard jets substantially.

### 18.27 SHERPA

ShERPA [425, 146] is a full-fledged event generator capable of simulating all aspects of particle collisions as they occur at particle accelerators such as the Tevatron or the LHC. It includes two independent matrix element generators, AmEGIC++ [147] and Comix [459], to generate cross sections and distributions

[^147]for final state multiplicities of up to six to ten particles. In the former one, methods to automatically generate dipole subtraction terms in the widely used Catani-Seymour scheme [236, 150] have been incorporated [448]; the SHERPA package also supports the BLHA [145] for the interface to one-loop programs such as BlackHat or GoSam. For parton showering, SHERPA employs an algorithm based on Catani-Seymour subtraction kernels, proposed in [460] and implemented in the SHERPA framework in [461]. For the hadronisation, SHERPA uses either its native hadronisation scheme, based on the cluster fragmentation model [462] and its implementation described in [463] or an interface to PYtHIA [400] providing access to the routines of the Lund string model [456]. Both have been successfully tuned to LEP data within the SHERPA framework, with a similar quality in describing the data. The hadron decays are also fully provided in the SHERPA framework, as well as QED final state radiation to both the $W$-boson and the hadron decays, simulated using the YFS approach [464, 465].

In this work, the most recent, publically available SHERPA version, SHERPA-1.3.1, has been used in two ways of running the simulation, namely

1. in the MEPs mode:

In this method, towers of LO matrix elements with increasing jet multiplicity, in the case at hand $W, W+1, W+2, \ldots, W+n_{J}$ jets, are merged in the spirit of [429, 430] to yield an inclusive sample. In fact, codes relying on such algorithms have been compared in a previous publication [439], which helped to establish and validate the methods and their various implementations. In contrast to the original implementation in SHERPA [466], which used analytical forms of Sudakov form factors etc., the current version of the method [426] directly uses the parton shower for Sudakov rejections etc. and is thus closer in spirit to the variant presented in [445, 467] for multijet merging.
2. in the MENLOPs mode:

This method can be understood as the combination of a matching of the parton shower to a NLO matrix element and a merging of additional towers of LO matrix elements with even higher jet multiplicities. Thus, in the case at hand, inclusive $W$ production calculated at NLO accuracy is merged, as above, with LO matrix elements for $W+1, W+2, \ldots, W+n_{J}$ jets. This method has been pioneered in [442, 443] where the implementation employed within Sherpa has been detailed in the second reference.

The respective settings and relevant details for both simulation modes are described below.

Sherpa in MePs mode In the MEPS mode Sherpa was run with up to $n_{J}=6$ jets in the matrix element evaluation including all possible massless (anti-)quark and gluon initial and final states. All matrix elements were generated using Comix. The MEPS-separation parameter was set to $Q_{\text {cut }}=20 \mathrm{GeV}$, for its precise definition see [426]. The scales are chosen as

$$
\begin{equation*}
\alpha_{s}^{k+n}\left(\mu_{\mathrm{eff}}\right)=\alpha_{s}^{k}(\mu) \cdot \alpha_{s}\left(p_{\perp, 1}\right) \cdot \ldots \cdot \alpha_{s}\left(p_{\perp, n}\right), \tag{18.2.6}
\end{equation*}
$$

wherein the relative transverse momenta $p_{\perp, i}$ are the nodal values of the final state partons of the $W+n$ parton matrix element as obtained from recombining it using the inverted splitting probablities given by the parton shower. The core scale $\mu$ is then chosen as the partonic centre-of-mass energy of the reconstructed core process, i.e. $\mu^{2}=\hat{s}_{2 \rightarrow 2}$ where $k=0$ in the process at hand. In all stricly perturbative setups a parton shower cutoff of $t_{0}=(0.7 \mathrm{GeV})^{2}$ has been used.

The parton shower cutoff and all fragmentation parameters of both the internal cluster hadronisation and the interfaced Lund string fragmentation models have been tuned to LEP data and give a similarly good description. Similarly, the parameters of SHERPA's MPI model have been tuned to Tevatron and LHC data using the CT10 [255] parton density parametrisation. These parameters are given in App. 18.71

Sherpa in Menlops mode In the MeNloPs mode Sherpa is run with essentially the same parameters as in the MEPs mode, described in the previous subsection. Hence, $n_{J}=6$ and $Q_{\text {cut }}=20 \mathrm{GeV}$. To be able to describe the inclusive $W$ production process at NLO accuracy, AmEGIC++ was used for all parts of the NLO $W$ production matrix elements (supplemented with a hardcoded one-loop matrix element from the internal library) and the LO $W+1$ parton matrix element. Consecutively, the scales were chosen as above with $k=0$ for all tree-level parts and $k=1$ for the real and virtual corrections entering the next-to-leading order correction of the core process. All non-perturbative parameters remain unchanged wrt. the MEPS mode.

Estimate of uncertainties In order to estimate the uncertainites of the SHERPA predictions, the following procedures have been applied:
(A) PDF uncertainties:

Unlike in the PDF4LHC presciption [468], here only the central predictions of the three NLO PDFs, CT10 [255], MSTW2008 [262] and NNPDF2.1 [312] are compared to estimate the PDF uncertainties. The different parametrisations of PDFs as well as their corresponding value of $\alpha_{s}$, both its value at $M_{Z}$ and its running, enter in the calculation of the matrix elements, the parton shower and the underlying event.
(B) Scale uncertainties:

In a global manner, all scales, renormalisation and factorisation scales are simultaneously modified by the canonical multiplication with 2 and $1 / 2$. This, however, is not only applied to the evaluation of the matrix elements but also to that of the parton shower, the hadronisation, the underlying event simulation and the hadron decays. Regarding the matrix-element evaluation, the MEPs default scale choice forms the starting point for the scale variations to be executed.
(C) Hadronisation uncertainty:

Here the intrinsic modeling uncertainties are evaluated by changing the hadronisation model operating on SHERPA's parton shower final states, namely switching from SHERPA's default cluster hadronisation to PYTHIA's string fragmentation. For both schemes, an independently tuned set of parameters has been employed to perform the parton-to-hadron transition.
(D) Underlying event uncertainty:

To this end the tune of the underlying event based on using the CT10 PDF has been modified such that the plateau of the number of charged particles and sum of transverse momenta in the transverse region are increased or decreased by $10 \%$. This change in the amount of MPI activity is accomplished by varying the $\sigma_{\mathrm{ND}}$ correction factor (SIGMA_ND_FACTOR) by -0.04 or +0.05 , respectively.

### 18.3 Results

In this section we compile results for the individual codes for a number of representative observables at the different levels of the simulation. It should be noted, though, that in all results presented in this section PDF uncertainties have been estimated by typically varying only over a few different sets rather than employing the full procedure as suggested by the PDF4LHC accord [468].

### 18.31 BLACKHAT + SHERPA

The following results have been obtained with BlackHat+SherPa. Uncertainties due to the factorisation/renormalisation scale variation and the that due to the PDF uncertainties are shown. The yellow band corresponds to the addition in quardature of these two uncertainties and the statistical estimation on the integration error. All observables are defined using the ATLAS cuts, cf. App. 18.6.

Fig. 64 displays the inclusive cross section for a $W$ boson in association with $n$ jets, where $n=1,2,3,4$. A NLO computation of $W+4$ jets also provides a leading order calculation of the $W+5$
jets rate, but since it is not at NLO accuracy we refrain here from including it.
In all the plots presented in this section the uncertainties are dominated by the uncertainty arising from the scale variation (it is not the case when the central scale of the process is chosen close to a local maximum, in which case the upper boundary of the scale variation is very close or identical with the central value, as can be seen from the plots corresponding to $W+3,4$ jets). This is partially due to the fact that for the assessment of the PDF uncertainty only error sets have been employed that are closely related to the central set. In addition, the functional form of the scale definition as given by the kineamtics of the final state has not been changed, but rather the emerging scales $\mu_{F}$ and $\mu_{R}$ have been multiplied in parallel by factors of 2 and $1 / 2$.

Fig. 61: Pseudo-rapidity and transverse momentum distributions for the first jet in inclusive $W+1$ jet production (upper panel), for the second jet in inclusive $W+2$ jet production (central panel), anf for the third jet in inclusive $W+3$ jet production (lower panel).

Fig. 62: Pseudo-rapidity and transverse momentum distributions for the fourth jet in $W+4$ jet production.

Fig. 63: HT distributions for event with at least one (top left), two (top right), three (bottom left) or four (bottom right) jets.

Fig. 64: Inclusive cross section for $W+n$ jet production.

### 18.32 GoSAM + SHERPA

The setup described in the previous section for the analysis using GoSAM+SHERPA gives the following theoretical uncertainties. The plots show that in general the scale uncertainties are bigger then the PDF uncertainties and that the renormalisation scale dependence is usually bigger then the dependence on the factorisation scale. To illustrate the decrease in the scale uncertainty given by the NLO calculation we also include the distributions for the pseudo-rapidity and transverse momentum of the second hardest jet, which have only tree-level accuracy. All observables shown are defined using the ATLAS cuts, cf. App. 18.6 Note that errors in the 2 -jet configuration are increased w.r.t. those provided by BLACKHAT+SHERPA, since here only $W+1$ jet configurations are dealt with at NLO, and the 2 -jet configurations therefore are descibed at LO only.

Fig. 65: Pseudo-rapidity and transverse momentum distributions for the hardest jet.

Fig. 66: Pseudo-rapidity and transverse momentum distributions for the second hardest jet. This distribution have formally leading order accuracy and have therefore a much larger scale dependence than the same distribution for the hardest jet, for which a genuine NLO prediction is available.

Fig. 67: HT distributions (left) and $\Delta R$ between lepton and hardest jet (right) for events with at least one jet.

### 18.33 HEJ

This section contains the predictions from the High Energy Jets (HEJ) event generator. This gives predictions for the production of a $W$ boson in association with at least two jets. Throughout, we show results for CTEQ, MSTW and NNPDF parton distributions. We show a scale uncertainty band only for the first of these for clarity. The results for the other two are very similar. The yellow band in the ratio panel shows the statistical uncertainty in each case. The scale variation is seen to be dominant over the statistical uncertainty and the differences in choice of pdf. All observables are defined using the CMS cut definitions, cf. App. 18.6

As discussed in Sec. 18.23, the resummation contained in the HeJ framework is supplemented with a merging procedure to ensure tree-level accuracy for events with up to and including four jets. This leads to the larger drop from the four jet to the five jet cross section, compared to the drop either from

Fig. 68: The Hes prediction for the distribution of the transverse mass of the $W$ boson (top left) and for the angle between the hardest jet and the charged lepton from the decay of the $W$ boson (top right), the transverse momentum of the hardest jet (bottom left) and for the $H_{T}$ distribution (bottom right) in events where a $W$ boson was produced in association with at least two jets.

Fig. 69: The Hes prediction for the cross sections of $W$ plus $n$ jets.
three-jet to four-jet, or from five-jet to six-jet. This can be clearly seen in Fig. 69

### 18.34 MadGraph + PYthia

The following results have been obtained with MadGraph+Pythia. Uncertainties due to the factorisation and renormalisation scale and MEPs matching scale are shown for results on hadron level including UE and QED final state radiation. A comparison of results on parton shower level, hadron level, hadron level including UE, and hadron level including UE and QED final state radiation, is also presented. All observables shown are defined using the CMS cuts, cf. App. 18.6.

From these results we can conclude that the largest uncertainty on all observables is due to the factorisation and renormalisation scale. In addition to that, a large effect is found by switching off the final state QED radiation, while only a small difference is oberved between results at the shower level and all other results prior to the QED radiation.

Fig. 70: MadGraph + Pythia results for $W$ transverse mass.

Fig. 71: MADGraph+PYTHIA results for $\Delta R$ between lepton and hardest jet.

Fig. 72: MadGraph+Pythia results for for $p_{\perp}$ of hardest jet (top), number of jets (middle) and $H_{T}$ of events with at least 2 jets (bottom).

### 18.35 Powheg Box + Pythia8

In this section we show results obtained by running the Powheg Box implementation of $W+1$ jet together with Pythia8. In all the following plots of this section, CMS analysis cuts have been enforced, see App. 18.6. For this study, in the left panels of Figs. 73.75, we show uncertainties obtained from variations of renormalisation and factorisation scales by a factor of two in either directions and by choosing different PDF sets in the computation of the hard scattering. Results are shown at the final level, after the shower, the hadronisation and the inclusion of MPI, all performed by PYTHIA8. In general, we notice that the uncertainty due to scale variations is greater than the changes in the results due to different PDF choices.

In the right panels of Figs. $73 / 75$ we show our results at different stages of the simulation, for a fixed PDF set (chosen to be CT10). The stages considered include from the first emission level up to the full showered events in PYTHIA8, including MPI and also effects due to QED radiation off leptons and quarks. Various stages of the simulation have been obtained setting the PYTHIA8 switches as reported in Sec. 18.73 .

We recall here that results should be considered to be physical only after the the hadron level is reached (possibly including MPI and QED effects). In particular, we stress that the results at the parton level are obtained considering only the POWHEG first emission, and they are therefore only intermediate: indeed at this stage only the hardest radiation has been generated and effects due to further showering are not yet taken into account.

For most of the observables results do not show large variations going from a simulation level to another. In particular, for truly NLO predictions such the plots in Fig. 74 or the bin $n_{\text {jet }}=1$ of Fig. 73 , the major effects that arise at each successive stage of the simulation are a change in the normalisation, due to a slightly different number of events passing the analysis cuts when multiple emissions are allowed, and a moderate shape distortion in the low end of the spectrum. Both these effects may be attributed to multiple QCD radiation due to Sudakov effects introduced by the parton shower. As expected, these effects are of the same size, or smaller, than the theoretical uncertainty due to scale and PDF's variations, when propagated to the hadronic level. Similar effects are also observed when the QED radiation is turned on. In this case, results are lowered as a consequence of the cuts on the lepton transverse momentum and rapidity.

Due to the requirement of having at least two jets, the remaining observables are predicted only at leading order or with leading log accuracy by the Powheg simulation of $W+1$ jet. This is also reflected

Fig. 73: The number of jets, as predicted by Powheg Box + Pythia 8 .

Fig. 74: The hardest jet transverse momentum distribution (upper plots), the $\Delta R$ separation (middle plots) and the invariant mass $m$ (lower plots) of the hardest jets and the hardest lepton, as predicted by Powheg Box + Pythia8.

Fig. 75: The transverse momentum $p_{\perp}$ of the next-to-hardest jet, the scalar sum of the jet transverse energy $H_{T}$ of events with at least 2 jets and the sum of the transverse energies of all the particles in events with 2 or more jets, as predicted by Powheg Box + Pythia8.

Fig. 76: Comparison between predictions using different PYTHIA8 tunes, at hadron level with MPI, as predicted by Powheg Box + Pythia8.
in the larger band associated with the scale variations.
Observables such as $H_{T}$, the scalar sum of the transverse energy of the jets for events with two or more jets, show an enhancement in the high- $H_{T}$ tail. This effect mostly arise as a consequence of the showering, since the successive stages do not change the predictions any longer. The same behaviour, even more enhanced, is also observed in the scalar sum of the transverse energy of all particles, always in events with two or more jets.

In Fig. 76 we instead compare the effect of using different PYTHiA8 tunes on our predictions, obtained in this case at the hadron level, including MPI. Essentially all the observables turned out to be extremely stable under the variations of the PYthia8 tune, as shown in Fig. 76. Major differences only appears for the beam thrust, when it is defined at the particle level (see App. 18.62).

### 18.36 Pythias

For this study, PYthia8 has been run stand-alone and including matrix elements with additional jets. Note that in PYthia8, multiple interactions are interleaved with space- and time-like showers, meaning that in general, MPI and parton showers cannot be disentangled by just switching off secondary scatterings. When referring to "Hadron Level", we mean after the interleaved evolution (including QED

Fig. 77: Tuning variations for Pythia8 at hadron level. The plots show the $H_{T}$-distribution when requiring at least two jets (upper left), the $p_{\perp}$ of the hardest jet (upper right), the $\Delta R$-separation of lepton and the hardest jet (lower left), and the number of jets (lower right). The lower insets show the ratio of the samples in the upper half to ME3PS (Tune 4C, y-blind treatment). All merged plots are produced with a merging scale of $t_{\mathrm{MS}}=15 \mathrm{GeV}$.
splittings), and after hadronisation. For the sake of comparison, "Shower Level" indicates results after (interleaved) final- and initial-state radiation, switching multiparton interactions off. All results presented in this section are generated with CTEQ6L1 parton distributions for protons colliding at $E_{\mathrm{CM}}=7000$ GeV . Cккw-L-merged samples include up to three additional jets, taken from MADGraph/MadEvent.

Fig. 77 exemplifies how changes in the tuning of the event generator can affect the outcome of merged calculations in PYTHIA8. For this, we produce predictions for Tune 4C [455] and Tune A2 [458]. In general we observe only modest shape changes of up to about $20 \%$ in observables, when comparing the two merged predictions, lending confidence to the statement that the tuning did not artificially produce hard scale physics. Normalisation changes between 4 C and A2 can be explained by a difference in Sudakov suppression: Since Tune 4C integrates the splitting kernels over a smaller region of phase space, the suppression generated by trial showers is less pronounced. The increase in the number of jets in Tune A2 with respect to Tune 4C, after the third jet, is expected, because the generation of the fourth jet is handled solely by the parton shower. Since 4C allows less phase space for these emissions by

Fig. 78: Variation of the merging scale value for Pythia8 at shower level. The plots show the $H_{T^{-}}$ distribution when requiring at least two jets (upper left), the $p_{\perp}$ of the hardest jet (upper right), the $\Delta R$-separation of lepton and the hardest jet (lower left), and the number of jets (lower right). The lower insets show the ratio of the samples in the upper half to ME3PS for $t_{\text {MS }}=30 \mathrm{GeV}$. All plots are generated using Tune 4C (y-blind treatment).
enforcing rapidity ordering, A2 will look harder. It is debatable whether including rapidity ordering into the tuning makes the tune mimic hard scale effects. The scales at which the fourth jet is produced are certainly close to the scale of (hard) multiple interactions, which is in turn closely connect to soft physics. Although the enforced rapidity ordering in Tune 4C might be considered questionable, we here take the pragmatic approach of considering the evolution both with and without enforced rapidity ordering. From the fact that up to three jets, the merged predictions of Tune 4C and Tune A2 only differ in normalisation, we anticipate that the effect of rapidity ordering will be reduced by merging more jets, since then, the number of jets above a cut-off will be dictated by the matrix element.

In Fig. 78, we investigate the impact of changes in the merging scale value. Again, we mainly see normalisation changes and only small changes in shape, which in most cases are smaller than changes due to different tunes. The $R$-separation between lepton and hardest jet $\Delta R$ (lepton, hardest jet) shows significant shape changes above $\pi$. This again is an effect of Tune 4C, and is greatly reduced in Tune A2 $2^{40}$, as

[^148]

Fig. 79: Variation of the criterion employed to favour "ordered histories" in Pythia8 at shower level. The plots show the $H_{T}$-distribution when requiring at least two jets (upper left), the $p_{\perp}$ of the hardest jet (upper right), the $\Delta R$-separation of lepton and the hardest jet (lower left), and the number of jets (lower right). The lower insets show the ratio of the samples in the upper half to ME3PS (Tune 4C, y-blind treatment). All merged plots are produced with a merging scale of $t_{\mathrm{MS}}=15 \mathrm{GeV}$.
can be inferred from the tune variation. However, even in Tune A2, small shape changes remain, with the change becoming less pronounced when comparing two large merging scales. We take this as an indication that the shower splitting probability - giving radiative contributions to $\Delta R$ (lepton, hardest jet) $>\pi$ for high $t_{\mathrm{Ms}}$ - and the the matrix element, which fills the same region in for the low merging scale case, are indeed different from the second jet on. This also explains the difference between Tune 4C and Tune A2, which differ by the phase space regions over which the splitting kernels are integrated.

Finally, in Fig.79, we address the interplay of matrix element merging and ordering in the underlying shower more carefully. The effect of different choices manifests itself again mainly in changes of the normalisation of the plots, and is comparable in magnitude to the impact of merging scale variations. At first, the changes may seem counter-intuitive, and need clarification. For this, it is important to remember the definition of " y -blind" and " y -conscious" in section 18.26 . The y -blind treatment will - irrespectively of rapidity configurations - mainly choose histories ordered in the shower evolution variable $\rho$, and only

[^149]pick $\rho$-unordered histories if no other ones have been constructed. However, in the y-conscious approach, once no history ordered both in rapidity and $\rho$ is found, one amongst all un-ordered histories is chosen probabilistically, irrespectively of the history being y-/ $\rho$-/or y- and $\rho$-unordered. Since the ordering criterion is stricter, un-ordered histories will be chosen more frequently, meaning that $\rho$-unordered ones will also contribute more, compared to the y-blind case. Matrix element states with no ordered histories will have a number of jets at very similar scales, so that the Sudakov suppression generated by trial showers will be smaller. Moreover, for matrix element states in which the last reconstructed splitting is unordered, the parton shower will be started at the larger of the unordered scales ${ }^{41}$, which can result in a slightly harder spectrum of resolved parton shower jets. Because $\rho$-unordered states are picked more often when requiring a tighter ordering criterion, this leads in visible differences. The y-conscious method might seem somewhat artificial, considering that it introduces a larger dependence on states outside the range of even the $y$-unordered shower variant. Nevertheless, the $y$-blind and $y$-conscious prescriptions are equivalent to the accuracy of the (y-ordered) shower, so that both should be investigated when assessing the quality of the merging. From the visible changes, we can infer that different treatments of formally sub-leading effects do matter. For the y-ordered evolution, these are more visible since the accuracy of the shower itself is worse, so that the effects of including matrix element states cancel to a lesser degree. It is interesting to note that the deviations between the different prescriptions are considerably smaller if the merging scale is increased, again hinting at a reduced shower accuracy if the evolution is ordered in multiple variables.

Fig. 79 further shows distributions labelled Tune $X$, which have been generated by using Tune 4 C , removing the rapidity constraint on space-like emissions, and treating histories y-blind. Results of these runs, as expected, closely follow Tune A2. The outcome of both Tune A2 and Tune X differs only slightly from the Tune 4 C (y-blind) curves, consolidating the conclusion that shifting fractions of $\rho$-un-ordered histories are responsible for the deviations between the y-blind and y-conscious methods. As in the discussion of tuning variation, the similarity in the results of the merged calculation for Tune 4C and Tune A2 breaks down once we examine jets that are solely produced by the shower, i.e. starting from the fourth jet.

### 18.37 SHERPA

As described in Sec. 18.27 , SHERPA has been run in two modes for this comparison of LHC predictions. The results for the conventional merging of towers of tree-level matrix elements, SHERPA MEPS, are presented in Sec. 18.37 while the results of its enhancement to NLO accuracy in the core $W$ production process, Sherpa MeNloPs, are displayed in Sec. 18.37 . As detailed earlier, all parameters have been chosen identically otherwise. The precise requirements regarding the event selection and the definitions of the observables used in this comparsion follow the CMS cut specifications and can be found in App. 18.6.

SHERPA MEPS Figs. 80,83 show the results as obtained by running SHERPA in the MEPS mode for a variety of inclusive and multi-jet observables at different levels of the event generation. All central results are displayed together with their respective uncertainties related to the different sources listed in Sec. 18.27. The layout in all figures is the same: the upper left and right panels respectively show the matrix element level and parton shower level predictions for a given observable. The matrix element level is defined as the event generation phase right before the parton showering. For the MEPs approach this means that modifications necessary for the procedure to work like $\alpha_{s}$ reweighting and Sudakov rejection have been already included at this level. The predictions presented in all centre panels were generated after enhancing the event generation to include corrections induced by the parton-to-hadron transition and decays of the therein produced primordial hadrons. On top of these soft physics effects, one has to also

[^150]

Fig. 80: SHERPA MEPS. Uncertainty of the transverse mass of the reconstructed $W$ on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 81: Sherpa MePs. Uncertainty of the angular separation of the charged lepton and the hardest jet on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 82: SHERPA MEPS. Uncertainty of the transverse momentum of the hardest jet on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 83: Sherpa MEPs. Uncertainty of the inclusive jet multiplicity on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.
account for multiple parton interactions. The results in the centre right panels of all figures incorporate these additional corrections. Finally, all plots to the lower left show the most complete hadron level predictions, which were obtained by adding to the event generation QED radiation effects as occurring in the decays of the vector boson and the hadrons. To allow a direct comparison of the impact of the consecutive event stages, the way the central results change is summarized in all plots to the lower right of Figs. 80.83 . In these, as in all other panels, the main plots are supplemented by ratio plots stressing the magnitude of the differences and uncertainties. Note that the yellow band throughout illustrates the statistical uncertainty on the central event sample.

Apart from the summary plots at the lower right, all other cases depict predictions documenting the uncertainty of the central predictions at the different levels of event generation. These uncertainty estimates are gained following the procedures outlined in Sec. 18.27. At all event simulation phases, the scales are varied as described under this section's point (B). Note that the variation is applied to all phases used to make up the respective central (or default) sample, which is taken as the reference under all circumstances. For the matrix element level, parton shower level and full hadron level results, PDF variations according to point (A) are shown in addition, whereas for the centre panel plots, the focus is on the outcomes of the model and tune variations instead, as specified in point (C) and point (D) of Sec. 18.27. Notice that the lower left panels also contain the outcomes of scale variations utilizing the alternative PDFs mentioned under point (A); they are much alike the ones stemming from the default set.

As an example for an inclusive observable the transverse mass of the reconstructed $W$ boson is shown in Fig. 80. The scale uncertainties amount to $\sim 15 \%$ at all generation levels, whereas the uncertainties due to the choice of PDF are much smaller. Similarly, the hadronisation uncertainty is negligible. The $m_{\perp, W}$ observable however is more sensitive to the tuning of the MPI model as can be seen from the $\pm 10 \%$ envelope in the centre right plot of Fig. 80. The uncertainty is of the same order as for the scale variations, which generally are more pronounced in the soft region. When considering the impact of each perturbative and non-perturbative event stage (see the plot to the lower right), it is the MPI corrections that are largest in the region of $m_{\perp, W}<m_{W}$, ranging up to $\sim 30 \%$ wrt. the matrix element level prediction. They are small above $m_{W}$. In this region the dominant effect comes from the QED corrections, which themselves are rather small, but they lead to a contamination of the electron isolation. The application of the isolation cuts then yields a reduction of the overall normalisation of the event sample. Finally there is a small shift towards lower transverse masses, pronouncing the deviation in the tail of the distribution somewhat further.

Fig. 81 and Fig. 82 depict observables that require the presence of at least one jet. In the former the geometric separation, $\Delta R$, between the hardest jet and the electron is shown, while in the latter, focus is on the transverse momentum, $p_{\perp}$ of the hardest jet only. As before the dependence of the predictions on PDF and hadronisation model changes remains negligible. While the scale dependence of the $\Delta R$ and $p_{\perp}$ variables increases to $\sim 30 \%$, the uncertainty due to the tuning of the MPI model decreases to $\sim 5 \%$ when compared to the findings concerning the more inclusive observable considered above. In both cases the reason for the sensitivity change obviously lies in demanding at least one (hard) jet. The scale uncertainties primarily result from changes in the overall cross section. Again, comparing the results of the different event stages, one clearly observes the large impact parton showering has on modifying the matrix element level predictions. The non-perturbative effects go in the same direction amplifying the parton shower effects, but as expected this amplification turns out to be rather mild in the well separated and/or hard phase space regions. QED corrections only play a minor role, and are far less important than for the $m_{\perp, W}$ variable.

In Fig. 83 one of the simplest examples of a multi-jet observable is presented, namely the distribution of the inclusive $W+n$ jet cross sections as a function of $n_{\text {jet }}$. Qualitatively, the parameter and model dependencies of the predictions are found to behave as for the inclusive one-jet variables. As one would expect, the scale uncertainties subsequently increase with the order of the jet bin. The same can be noticed for the variation of the PDFs used in the calculation - even though here the effect is considerably
smaller.

Sherpa MeNloPs Following the outline of the previous subsection, Figs. 84.87 compile the results, which were obtained by executing SherPa in the MENLoPs mode, cf. Sec. 18.27. The presentation is based on the same set of figures where the selection of the observables has been taken as in the MEPS case. Again, all (central) predictions are examined towards their scale, PDF, non-perturbative modeling and QED simulation dependence. One small difference has to be pointed out: the plots to the lower left now depict exclusively to what extent the additional QED corrections modify the outcomes including multiple parton interactions and hadronisation effects.

Fig. 84 shows the transverse mass of the reconstructed $W$ boson. In the MENLOPs approach, this observable is described at NLO accuracy, which leads to a reduction of the associated scale uncertainties. The scale variation results for $m_{\perp, W}$ nicely confirm this expectation as can be seen in the upper four plots of Fig. 84. The deviations from the central prediction are much smaller than those found for the MEPs scenario exhibited in Fig. 80, they now are of similar magnitude as the PDF uncertainties. While the scale dependence is reduced, PDF and MPI tune variations as well as QED corrections manifest themselves as in the MEPS case. In particular, the discussion around Fig. 80 explaining the effects of extra QED emissions (as being most relevant in the $W$ decay) can be used to understand the findings illustrated in the bottom left panel of Fig. 84

The MENLOPs method primarily improves the precision of the description of the core process, here the description of the $W$ production process. One also benefits from improving the overall normalisation. However, processes with additional partons in the final state are described in the MENLoPs approach at the same level of accuracy as in the MEPS approach - in both cases by tree-level matrix elements. Thus, the one-jet observables, $\Delta R$ between the lepton and leading jet and the $p_{\perp}$ of the leading jet, and their related uncertainties turn out to be predicted in a very similar manner. This can be clearly observed by comparing Figs. 85486 with Figs. $81 / 82$. Unlike the findings for $m_{\perp, W}$, it particularly can be noticed that the scale dependence associated with the one-jet observables shown here remains unchanged when compared to the respective MEPS results.

Fig. 87 depicts the distribution of the inclusive $W+n$ jet cross sections as obtained for the MeNloPs case. Using the above reasoning, one can understand these results as for the one-jet variables. Note that the scale dependence of the zeroth jet bin shows the expected decrease owing to the NLO accuracy underlying the description of the core process.

Fig. 88 finally, highlights the evolution and uncertainties of two definition of the beamthrust, cf. App. 18.6 a physical observable summing over all final state particles excluding the $W$-constituent lepton and a pseudo-observable including the $W$ itself. For both observables small perturbative uncertainties are completely burried underneath much larger non-perturbative effects and modelling uncertainties, an effect also seen in results from the Powheg Box+Pythia simulation, cf. Fig. 76. This can only be interpreted as this observable being dominated by non-perturbative effects and in particular the underlying event, which somewhat invalidates statements about the merit of this observable in a clean determination of initial state radiation effects made in [469, 26].

Fig. 84: Sherpa MeNloPs. Uncertainty of the transverse mass of the reconstructed $W$ on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 85: Sherpa MeNloPs. The lower right panel shows the evolution of the central value.

Fig. 87: Sherpa MENLoPs. Uncertainty of the inclusive jet multiplicity on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 88: Sherpa MeNloPs. Evolution and uncertainty of two definitions of the beamthrust, calculated using all particles not constituting the $W$ (left) and including the $W$ (right). Exemplary, the combined PDF and scale uncertainty on the matrix element level prediction (yellow) and the modeling uncertainty of the hadron level prediction (blue) are shown.

### 18.4 Comparisons

In this section we compare the results of different tools with each other. While the aim of this study was to have a fairly tuned comparison with as many aspects of the calculations as possible being centrally defined, there are still important residual differences in the various results. Obviously, the different codes produced results at different stages of the simulation, which are not always directly comparable; in addition, some of these stages are not very straightforward to obtain: for instance, running PyTHIA8 without multiple parton interactions included in the interleaved showering obviously changes the overall logic of the parton shower model of this code. In addition, other, more obvious differences occur, ranging from inconsistent choices of PDFs to different strategies in scale setting procedures. For the case of the PDFs, by directly comparing results obtained with BlackHat+SHERPA using CTEQ6.6 and with GoSAM+SHERPA using CT10, it appears as if at NLO these differences are minor. However, it is not clear how much of the differences between MADGraph+PYTHIA and PYTHIA8, which both employ CTEQ6L1, and the other codes, which employ NLO PDFs, can be attributed to differences in PDFs.

In addition, results obtained with the NLO codes typically include at least one jet - Powheg Box+Pythia8 and GoSam+Sherpa take $W+1$ jet at NLO as their core process - while Hej starts at $W+2$ jets, and BlackHat+Sherpa presents results for up to 4 jets accompanying the $W$ boson in different jet bins. Obviously, on the other hand, the multijet merged samples of MadGraph + PYthia, Pythia8 MePs and Sherpa include LO matrix elements for up to 3 to 6 jets.

In the plots in this section each code is shown with a yellow error band, which is the envelope of the variations presented in Sec. 18.3. The only exception is BLACKHAT+SHERPA, which is shown with a blue error band. In the ratio plots the codes are plotted relative to BLACKHAT+SHERPA, also at the parton shower level.

### 18.41 Inclusive observables

In this section we present some inclusive observables, which are typically all obtained from codes employing multijet merging. By and large, all codes agree in the shapes of the $m_{\perp, W}$ distribution at different stages, although there are sizable differences in the respective normalisation of the samples.

Fig. 89: Transverse mass of the reconstructed $W$ on all levels of the simulation, for the exact definition see App. 18.62 and for the cuts employed in the analysis App. 18.61 Note that PyTHIA8 and MadGraph+PyTHia use the CTEQ6L1 pdf, while Sherpa uses CT10.

### 18.42 Observables with at least one jet

As a first and fairly telling observable the $p_{\perp}$-spectrum of the hardest jet is compared, cf. Fig. 90, At the parton level, the results of the NLO calculations - BLACKHAT+SHERPA and GOSAM+SHERPA- agree nearly perfectly with each other and within about $20 \%$ with the multijet merged samples of SHERPA, both at LO (Sherpa MePs) and in the MeNloPs (Sherpa MenloPs) sample. The increase of the latter with respect to the former at relatively low transverse momenta of about 50 GeV or below can probably be related to the different scale definition in the argument of the strong coupling, where the NLO calculations choose $\mu_{R}^{2}=\left(H_{T}^{\prime} / 2\right)^{2} \approx M_{W}^{2} / 4+p_{\perp, j}^{2}$ while in the SHERPA simulation the transverse momentum of the jet has been chosen. Clearly, for small transverse momenta this will lead to visible differences. Going from the matrix element to the parton shower level typically leads to the jets becoming softer and to losing some of them, due to partons emitted outside the jet and a corresponding energy loss. This explains why the SHERPA distribution at the shower level is softer than the NLO result, and thus the SHERPA result at the matrix element level, although the size of the difference seems to be larger than one would naïvely expect. This finding is, however, somewhat at odds with the results obtained from MADGRAPH+PYTHIA, which seem to be slightly harder in shape and significantly larger in normalisation. The PYthia8 MEPS sample, on the other hand, has a smaller one-jet inclusive cross section than SHERPA, but the jet spectrum exhibits a somewhat harder tail, corresponding to a shape difference of about 30$40 \%$ with respect to both the Sherpa results. The same finding, a somewhat harder tail, is also true for the Powheg Box+Pythia8 results. The same trends can be also found at the hadron and hadron + MPI level. For the Powheg Box result the difference can be attributed to the usage of a scale defined at the "underlying-Born" level (cf. Sec. 18.25 for more details). Indeed it has been checked explicitly that a NLO computation performed with the same scale choice used in Powheg Box gives a result in complete agreement with the POWHEG Box result shown here. Clearly, the differences between different

Fig. 90: Transverse momentum of hardest jet on all levels of the simulation, where jets are reconstructed using the anti- $k_{\perp}$ with $R=0.4$ within $|\eta|<4.4$ (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BlackHat+ShERPA (on matrix element level).
calculations and codes exhibited here deserve a more in-depth study, which, unfortunately, is beyond the scope of this comparison.

Similar findings are also true for the next observable, the $\Delta R$ distribution between the lepton stemming from the $W$ decay and the hardest jet displayed in Fig. 91. Again, the two Sherpa samples are compared with the two NLO samples, this time exhibiting a sizable shape difference towards an increase at smaller and a decrease at larger distances of about $40 \%$ relative cross section. While higher jet configurations typically tend to be a bit more central, it seems far-fetched to attribute this difference only to them. At the same time, large differences in $R$ are most likely due to jets which are pretty much forward ${ }^{42}$. This region of phase space for jet production, however, is known to be quite susceptible to mismatches in scale and/or PDF definitions. However, it is worth noting that this difference vanishes almost completely at the parton shower level. The Pythia8 MEPs sample, despite a sizable difference in cross section, appears to follow the shape of the NLO and SHERPA results. Further comparing these results to those of the other codes at the shower level suggests that the MadGraph+Pythia merged sample, apart from a drastically enhanced cross section, also shows an enhancement in shape at smaller $\Delta R \leq 2$ w.r.t. the NLO result. Interestingly enough, the Powheg Box+Pythia8 sample exhibits the

[^151]

Fig. 91: $\Delta R$ between hardest lepton and hardest jet on all levels of the simulation (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).
opposite behaviour: while the cross section seems fairly consistent with the SHERPA and the NLO ones, the shape shows some enhancement of up to $40 \%$ at large distance $\Delta R$, which following the reasoning for the jet $-p_{\perp}$ spectrum may also hint at being due to a difference in the definition of scales. As before, the same trends visible at the parton shower level can also be found at the hadron and hadron + MPI level.

### 18.43 Multi-jet observables

In observables including at least two jets, consider first the case of the $H_{T}$ distribution depicted in Fig. 92 , Over the full range and obscured by large statistical fluctuations both SHERPA samples seem to follow the NLO prediction from BlackHat+Sherpa. The LO result from GoSam+Sherpa, on the other hand, appears to fall off at the hard end of the distribution. The prediction from HEJ is a bit more subtle to judge: at low $H_{T}$ (around 100 GeV ), we see that it is in good agreement with the predictions from the other approaches. However, as higher values of $H_{T}$ are probed, the Hes prediction becomes noticeably larger than the fixed-order descriptions, including those from SHERPA where different multiplicities are merged. This is the region in $H_{T}$ where we would expect high multiplicities to have a noticeable effect, and therefore where we would expect to see the impact of the resummation in Hej. This is, however, slighlty at odds with the fact that the SHERPA prediction included up to 6 jets and that the multijet rates and the $p_{\perp}$ distributions of the fifth and sixth jet from HeJ undershoot those from SHERPA, cf. Fig. 93

Fig. 92: $H_{T}=\sum_{i \in\{\mathrm{jets}\}} E_{\perp i}$ of events with at least 2 jets on all levels of the simulation (for exact definitions and cuts see App. 18.61 and App. 18.62. Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).
and Fig. 95. However, a similar trend concerning the hard tail of this distribution appears also on the shower level in the MadGraph+Pythia sample, which includes up to 4 extra jets, and in the Powheg Box + PYthia8 sample, which includes 2 jets at LO and 1 jet at NLO. The trend is even more pronounced with an even harder tail for the PYTHIA8 MEPS sample, which includes 3 extra jets. At this level, SHERPA more or less follows the NLO result. It should be noted, though, that all approaches remain within the scale variation band indicated on the BlackHat prediction. This findings are consistently carried over to the hadron and hadron+MPI level.

Turning to the $n$-jet rates, at the matrix element level, SHERPA follows fairly closely the NLO results in different jet multiplicity bins, while HeJ seem to overshoot the central value in the 3-and 4-jet bin, but staying inside the NLO scale uncertainty band. going back to the tree-level result of SHERPA in the 5- and 6-jet bins. As discussed in Sec. 18.33, the HeJ framework includes tree-level matching for final states with up to and including four jets in the final state. Therefore it is fair to assume that the absence of matching for five jets and above leads to the larger drop in cross section observed in Fig. 93 from four-jet to five-jet as compared to that from either three-jet to four-jet or from five-jet to six-jet and lends support to the suspicion that in HEJ a matched sample would also provide larger 5- and 6-jet multiplicities. At the shower level, the trend already visible at the $H_{T}$ distribution repeats itself. The smaller cross section in the PYTHIA8 MEPS sample is mainly due to the low multiplicity bins, such that the shape of the $n$-jet distribution also has a relatively harder tail than the SHERPA sample. In contrast,

Fig. 93: Number of jets on all levels of the simulation (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that Powheg Box+Pythia8 and GoSam calculate $W+1$ jet on matrix element level, while Hej starts with $W+2$ jets and that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).
the Powheg Box +Pythia8 result, starting consistently at 1 jet, appear to be at the upper end of the NLO uncertanities throughout.

Looking at the correlation of the two leading jets in Fig. 94 at the matrix element only, both the $\Delta R$ and the $m_{12}$ distribution provided by SHERPA have a slight tilt against the NLO prediction from BLACKHAT+ SHERPA, undershooting the latter result by up to about $40 \%$ for large $\Delta R$ and by up to about $20 \%$ for large $m_{12}$. While HEJ seems to roughly follow the shape of SHERPA for $\Delta R$, it is significantly harder than SHERPA and the NLO result for large values of $m_{12}$. In addition, in both cases, HeJ also predicts a larger cross section that the other tools.

Fig. 95 shows the transverse momentum distributions for the third to sixth jets ordered in $p_{\perp}$, and at the matrix element level. For the third hardest jet, the prediction from HEJ is similar in shape but higher in cross section than the results obtained at NLO from BLACKHAT+SHERPA or the two SHERPA samples. For the fourth jet, the Hej cross section still seems higher than the other ones, but this discrepancy seems to be mainly around comparably low jet $p_{\perp}$. For larger values of $p_{\perp}$ all tree-level type or resummed predictions are below the NLO result. Surprisingly, for the fifth and sixth hardest jets, the HEJ predictions follow the SHERPA ones for low values of $p_{\perp}$ below about 60 GeV , before they fall off nearly instantly. This again may be an artefact of tree-level matching not being included in HeJ for the production of fiveand six-jets or of missing statistical support in this region of phase space.

Fig. 94: $\Delta R$ of two leading jets (left) and invariant mass of two hardest jets (right) matrix element level (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).

Fig. 95: Transverse momentum of third to sixth hardest jet on matrix element level (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, PYTHIA8 and MadGraph+PyTHIA CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BlackHat+Sherpa (on matrix element level).

### 18.5 Conclusions

In this study first steps towards an update and extension of the comparison in [439] have been made. In contrast to the older study, a larger variety of tools including fixed-order and resummation tools as well as NLO matched and tree-level merged simulations have been included. Not surprisingly, some observables appear to be described fairly consistently between different tools, while others exhibit large deviations, sometimes clearly beyond the formal accuracy claimed by the different methods, and also beyond the best estimates of intrinsic modelling or calculational uncertainties provided by the authors. In some instances the relative differences are way beyond naïve expectations by most of the authors of this study. This clearly hints at the need to carefully cross-validate different tools before deploying them for large scale simulations, and it also necessitates an increased collaboration of the authors of such tools in order to arrive at a more consistent picture.

We hope that this study triggered some future work towards the latter goal.

## Acknowledgements

We would like to thank the organisers of Les Houches 2012 for repeatedly hosting such a fantastic and fruitful workshop. We would also like to thank all participants for a lively and stimulating atmosphere and lots of inspiring discussions.

MS's and DM's work was supported by the Research Executive Agency (REA) of the European Union under the Grant Agreement number PITN-GA-2010-264564 (LHCPhenoNet). SA and ER also acknowledge funding from LHCPhenoNet for travel expenses. LL's and SP's work was supported by the Swedish research council (contract 621-2009-4076). Table 13: Cuts used in this study inspired by common ATLAS and CMS cuts.

Tab. 13 presents the cuts applied to define the event selection in both the ATLAS and CMS specifications.

### 18.62 Analysis procedure and definition of observables

A common analysis was implemented within the RIVET framework and used by all codes providing individual events. This analyses is carried out as defined in the following:

1. remove all neutrinos from all final states (i.e. 'all particles' from now on means 'all particles without neutrinos')
2. find hardest isolated lepton (electron or muon) ('lepton' from now on means 'hardest isolated lepton')
3. cut on lepton $p_{\perp}$ and $|\eta|$
4. compute missing transverse energy $E_{\perp}$ :
(a) sum the three-momenta of all particles within $|\eta|<10$, this yields $-\not p$
(b) compute missing energy as $\notin=|\boldsymbol{p}|$
(c) assume resulting four-vector $\not p$ corresponds to neutrino
5. for ATLAS cut on $E_{\perp}$
6. resonstruct $W$ four-momentum as $p^{W}=p^{\text {lepton }}+\not p$
7. compute $W$ transverse mass squared as $m_{\perp, W}^{2}=\left(p_{\perp}^{\text {lepton }}+\not p_{\perp}\right)^{2}-\left(p_{\perp}^{W}\right)^{2}$
8. cut on $W$ transverse mass
9. remove lepton from final state
10. cluster into jets keeping only those passing the $p_{\perp}$ and $|\eta|$ cuts
11. compute $H_{T}=\sum_{i \in\{\text { jets }\}} E_{\perp i}$
12. compute beam thrust $\tau_{B}=\sum_{i \in\{\text { particles }\}}\left(E_{i}-\left|p_{i}^{z}\right|\right)$ using all visible particles

It should be noted that this defintion of the $W$ is infra-red safe only for transverse observables.

### 18.7 Detailed settings

### 18.71 Sherpa

For this study Sherpa-1.3.1 was used. Except for the underlying event, which was tuned for the CT10 [255] parton distribution functions and whose parameters are given below, all other nonperturbative parameters were kept at their default values. The underlying model was tuned for the cluster hadronisation.

| K_PERP_MEAN_1 | 1.17 |
| :--- | :--- |
| K_PERP_MEAN_2 | 1.17 |
| K_PERP_SIGMA_1 | 0.760 |
| K PERP_SIGMA_2 | 0.760 |
| PROFILE_PARAMETERS | $0.576,0.353$ |
| RESCALE_EXPONENT | 0.238 |
| SCALE_MIN | 2.52 |
| SIGMA_ND_FACTOR | 0.465 |

### 18.72 Pythia8

To produce the results, we have used two tunes of Pythia8, Tune 4C and Tune A2, both of which use CTEQ6L1 parton distributions. Tune 4C is the default tune in PYTHIA8- no additional input settings are necessary. For completeness, below we list all parameters that are implicitly set by choosing the default Tune 4C.

```
PDF:pSet = 8
SigmaProcess:alphaSvalue = 0.135
SigmaDiffractive:dampen = on
SigmaDiffractive:maxXB = 65.0
SigmaDiffractive:maxAX = 65.0
SigmaDiffractive:maxXX = 65.0
```

```
TimeShower:dampenBeamRecoil = on
TimeShower:phiPolAsym = on
SpaceShower:alphaSvalue = 0.137
SpaceShower:samePTasMPI = false
SpaceShower:pT0Ref = 2.0
SpaceShower:ecmRef = 1800.0
SpaceShower:ecmPow = 0.0
SpaceShower:rapidityOrder = on
SpaceShower:phiPolAsym = on
SpaceShower:phiIntAsym = on
MultipartonInteractions:alphaSvalue = 0.135
MultipartonInteractions:pT0Ref = 2.085
MultipartonInteractions:ecmRef = 1800.
MultipartonInteractions:ecmPow = 0.19
MultipartonInteractions:bProfile = 3
MultipartonInteractions:expPow = 2.0
BeamRemnants:primordialKTsoft = 0.5
BeamRemnants:primordialKThard = 2.0
BeamRemnants:halfScaleForKT = 1.0
BeamRemnants:halfMassForKT = 1.0
BeamRemnants:reconnectRange = 1.5
```

A detailed discussion of these choices can be found in [455]. All other parameters remain with their default values. For our purposes, it might be interesting to remark that the starting value for $\alpha_{s}$-evolution in time-like splittings is given by

SpaceShower:alphaSvalue $=0.1383$
To investigate the impact of rapidity ordering in space-like showers, we chose to remove enforced rapidity ordering by setting

SpaceShower:rapidityOrder = off
If rapidity ordering is enforced in ISR, the question arises how it should be treated when picking histories. For this purpose, PYTHIA8 supplies the switch

Merging:enforceStrongOrdering
When switched "on", this parameter will result in picking non-rapidity-ordered histories only if no rapidity-ordered paths where found, thus disfavouring non-rapidity-ordered parton shower histories for matrix element states. To have a more complete understanding of the impact of tuning, we also changed to the recently proposed Tune A2 [458]. For this, we have to set

Tune:pp $=7$
Pythia8 will then reset the following parameters:

```
PDF:pSet = 8
SigmaProcess:alphaSvalue = 0.135
SigmaDiffractive:dampen = on
SigmaDiffractive:maxXB = 65.0
SigmaDiffractive:maxAX = 65.0
```

```
SigmaDiffractive:maxXX = 65.0
TimeShower:dampenBeamRecoil = on
TimeShower:phiPolAsym = on
SpaceShower:alphaSvalue = 0.137
SpaceShower:samePTasMPI = false
SpaceShower:pT0Ref = 2.0
SpaceShower:ecmRef = 1800.0
SpaceShower:ecmPow = 0.0
SpaceShower:rapidityOrder = false
SpaceShower:phiPolAsym = on
SpaceShower:phiIntAsym = on
MultipartonInteractions:alphaSvalue = 0.135
MultipartonInteractions:pTORef = 2.18
MultipartonInteractions:ecmRef = 1800.
MultipartonInteractions:ecmPow = 0.22
MultipartonInteractions:bProfile = 4
MultipartonInteractions:a1 = 0.06
BeamRemnants:primordialKTsoft = 0.5
BeamRemnants:primordialKThard = 2.0
BeamRemnants:halfScaleForKT = 1.0
BeamRemnants:halfMassForKT = 1.0
BeamRemnants:reconnectRange = 1.55
```

Apart from not enforcing rapidity ordering in space-like splittings, this tune differs from Tune 4C in that the proton size is considered $x$-dependent. This is in the spirit of Tune $4 C X$, which was introduced in [470]. In general, since we include matrix element states for two and three jets, we do not apply additional matrix element corrections in PYTHIA8 after the first emission, by setting

```
SpaceShower:MEafterFirst = off
TimeShower:MEafterFirst = off
```

### 18.73 Powheg Box + PYtHiA8

For this study we used Powheg Box rev1282 and Pythia 8.153. Except for the specific subprocess requested, the parton distribution functions set and the renormalisation/factorisation scale factors chosen, all the other parameters were kept fixed below during all the runs. Here is a sample Powheg Box input file:

```
! W^+ + jet production parameter
idvecbos 24 ! PDG id of vector boson (24: W+, -24: W-)
vdecaymode 1 ! decay channel (1: electron, 2: muon, 3: tau)
numevts 4000000 ! number of events to be generated
ih1 1 ! hadron 1 (1 for protons, -1 for antiprotons)
ih2 1 ! hadron 2 (1 for protons, -1 for antiprotons)
ebeam1 3500d0 ! energy of beam 1 in GeV
ebeam2 3500d0 ! energy of beam 2 in GeV
lhans1 192800 ! pdf set for hadron 1 (LHA numbering)
lhans2 192800 ! pdf set for hadron 2 (LHA numbering)
ncall1 100000 ! number of calls for initializing the ...
itmx1 5 ! number of iterations for initializing the ...
ncall2 250000 ! number of calls for computing the integral ...
```

| itmx2 | 4 | ! number of iterations for computing the ... |
| :--- | :--- | :--- | :--- |
| foldcsi | 1 | ! number of folds on csi integration |

When interfacing to Pythia8 we have changed the following settings with respect to Pythia8 defaults, for the various stages under investigations:
///Hadron Level w MPI and QED
BeamRemnants:reconnectRange $=1.50000$
MultipleInteractions:alphaSvalue $=0.13500$
MultipleInteractions:bProfile = 3
MultipleInteractions:ecmPow $=0.1900$
MultipleInteractions:expPow $=2.0000$
MultipleInteractions:pT0Ref $=2.0850$
PDF:pSet $=8$
SigmaDiffractive:dampen $=$ on
SigmaDiffractive:maxAX $=65.0000$
SigmaDiffractive:maxXB $=65.0000$
SigmaDiffractive:maxXX $=65.0000$
SigmaProcess:alphaSvalue $=0.13500$
SpaceShower:MEafterFirst $=$ off
SpaceShower:MEcorrections = off
SpaceShower:pTmaxMatch $=0$
SpaceShower:rapidityOrder = on
TimeShower:MEcorrections $=$ off
TimeShower:MEafterFirst $=$ off
TimeShower:pTmaxMatch $=0$
//Hadron Level w MPI (added)
SpaceShower:QEDshowerByQ = off
SpaceShower:QEDshowerByL = off
TimeShower:QEDshowerByQ $=$ off
TimeShower:QEDshowerByL $=$ off
//Hadron Level w/o MPI (added)
PartonLevel:MI = off

```
//Shower Level (added)
HadronLevel:All = off
//Parton Level (added)
PartonLevel:ISR = off
PartonLevel:FSR = off
PartonLevel:Remnants = on
```

and, most important, we have vetoed shower emissions with a transverse momentum greater than the value of SCALUP read from the Les Houches event file for the corresponding event.

### 18.74 MADGRAPH + PYTHIA

For this study MADGRAPH/MADEVENT 5.1.1.0 and Pythia 6.4.2.4 is used. The LHE files are generated for events with a $W$ and up to four additional partons, i.e. for the process:

```
pp>w- -> l-vl~ ; l-vl~~j ; l-vl~~jj ;l-vl~~jjj ; l-vl~~jjjj ;
l-vl~ ; l-vl~j ; l-vl~jj ;
l-vl~jjj ; l-vl~ jjjj ()
```

The mass of the b quark is set to zero. The strong constant $\alpha_{s}\left(M_{Z}^{2}\right)$ is set to 0.1300 both in the matrix element calculation and in the proton PDF, that is the CTEQ6L1.

Pythia is used for the parton shower and the hadronisation with the following parameters modified according to tune Z 2 .

```
MSTU(21)=1 ! Check on possible errors during program execution
MSTJ(22)=2 ! Decay those unstable particles
PARJ (71)=10 . ! for which ctau 10 mm
MSTP(33)=0 ! no K factors in hard cross sections
MSTP(2)=1 ! which order running alphaS
MSTP(51)=10042 ! structure function chosen (external PDF CTEQ6L1)
MSTP(52)=2 ! work with LHAPDF
PARP(82)=1.832 ! pt cutoff for multiparton interactions
PARP(89)=1800. ! sqrts for which PARP82 is set
PARP(90)=0.275 ! Multiple interactions: rescaling power
MSTP(95)=6 ! CR (color reconnection parameters)
PARP (77)=1.016 ! CR
PARP (78)=0.538 ! CR
PARP (80)=0.1 ! Prob. colored parton from BBR
PARP(83)=0.356 ! Multiple interactions: matter distribution para...
PARP(84)=0.651 ! Multiple interactions: matter distribution para...
PARP (62)=1.025 ! ISR cutoff
MSTP(91)=1 ! Gaussian primordial kT
PARP(93)=10.0 ! primordial kT-max
MSTP(81)=21 ! multiple parton interactions 1 is Pythia default
MSTP (82)=4 ! Defines the multi-parton model
PMAS (5,1)=4.8 ! b quark mass
PMAS (6,1)=172.5 ! t quark mass
MSTJ(1)=1 ! Fragmentation/hadronization on
MSTP(61)=1 ! Parton showering on
```

For additional studies, we set

```
MSTJ(41)=3 ! switch off lepton FSR
MSTP(81)=20 ! switch off MPI
MSTJ(1)=0 ! Fragmentation/hadronization off
```

to switch off, respectively, final state QED radiation, multi-particle interactions, and hadronisation.

## Part V

## EXPERIMENTAL DEFINITIONS AND CORRECTIONS

## 19. PHOTON ISOLATION AND FRAGMENTATION CONTRIBUTION ${ }^{43}$

#### Abstract

Photon isolation and its link with the fragmentation contribution is explored via NLO matrix-element generator and parton-shower Monte-Carlo.

Firstly the dependence of the inclusive photon and di-photon NLO cross sections to the choice of isolation criteria are investigated. The isolation criteria used is the discretized version of the Frixione isolation, with parameters chosen for those most practical at an experimental level. As an extention, a more generalized version of the standard Frixione isolation is also studied. The selection of scale is also investigated in search of the 'saddle point', which would give the optimal scale choice. In addition the choice of jet algorithm is investigated for the photon with associated jet cross section. Secondly, properties of the fragmentation contribution in parton-shower Monte-Carlos are investigated. The distance profile of the photon to the other generator level particles in the event is explored in the case of neutral mesons, fragmentation photons and direct photons. Next the impact of a "hollow" or "crown" isolation criterion, expected to enhance the fragmentation contribution, is explored. Then, to complement the NLO inclusive studies, the impact of typical Frixione isolation criteria on the fragmentation component are investigated in the parton-shower Monte-Carlos.

Finally conclusions are made comparing the properties of the fragmentation contribution in NLO generators and parton-shower generators.

### 19.1 INTRODUCTION

Experimental measurements of single photons and di-photons require the application of isolation cuts to reduce the copious backgrounds arising from jet fragmentation. Such cuts also have the impact of reducing the fragmentation contributions of photon production. On the theoretical side, including fragmentation contributions of photon production can greatly increase the complexity of the calculations, while the application of appropriate isolation cuts can effectively remove those fragmentation contributions.

[^152]
### 19.11 Frixione isolation

In the following we will study the Frixione isolation criterion [471], which was designed to suppress the fragmentation contribution. It has been shown to reduce the fragmentation contribution in NLO generators [18]. The question is to know whether or not the behavior is still applicable using parton shower Monte-Carlo and if it can be used experimentally.

We consider the following function for the isolation criterion :

$$
\begin{equation*}
E_{T}^{i s o}(R)<f(R)=\epsilon \cdot p_{T, \gamma} \cdot\left(\frac{1-\cos (R)}{1-\cos \left(R_{0}\right)}\right)^{n} \tag{19.1.1}
\end{equation*}
$$

where $E_{T}^{i s o}(R)$ is the isolation sum of all particles inside a cone of $R=\sqrt{\Delta \phi^{2}+\Delta \eta^{2}}$ around the photon, $\epsilon$ is the strength or the scale of the isolation criterion, $p_{T, \gamma}$ is the transverse energy of the photon, $R_{0}$ is the first considered cone and $n$ the power of the isolation criterion. This formula can be altered by replacing $p_{T, \gamma}$ with a fixed threshold. Functional forms $f(R)$ for different $\epsilon$ and $n$ are shown Fig. 96

Fig. 96: Examples of Frixione functional form for different parameters.

The Frixione isolation is tighter and tighter when decreasing the $R$ cone size. With matrix element NLO generators (as in Jetphox [472, 473] and Diphox [474]), the only contribution possible at a given $R \neq 0$ is the one coming from the suplementary hard jets in the event, while the fragmentation debris are emitted colinearly to the photon at $R=0$ (angle information is lost due to the fragmentation function which is integrated over the angle). With parton-shower generator, fragmentation photons are emitted off quarks at a non-zero angle during the showering process. In the following sections we will study the link between isolation and fragmentation in NLO generators, then with parton-shower Monte-Carlo.

### 19.12 Experimental complications

There are various mismatches between isolation cuts applied to theoretical calculations and isolation cuts applied to data (or to Monte Carlo). First of all, we wish to apply the isolation cut only to energy related to the hard scatter. Experimentally, most of the energy inside an isolation cone is due to the underlying event associated with the hard scatter, or the remnants of additional interactions in the same crossing. Techniques such as jet area subtraction [475, 476] can be used to remove an amount of energy from the isolation cone roughly equal to the expected contamination from underlying event/pileup, leaving only energy related to the hard scatter and specifically to fragmentation processes. Since there is no underlying event/pileup in partonic level theory calculations, only the isolation cut needs to be applied to the theory.

Full details of the use of this correction within the ATLAS collaboration can be found in the inclusive cross section measurement [477]. The ATLAS isolation definition uses a cone around the cluster of cells that are identified as a photon. These photon cluster cells are not included in the sum, so there is first a correction for any leakage of the photon shower into the surrounding cells (typically a few percent of the photon $p_{T}$ ). The pile-up/underlying event correction is then applied by calculating per event the ambient energy from the jet activity in that specific event. This follows the jet area corrections method mentioned above, where all jets are reconstructed without any minimum momentum threshold. The energy density of each jet is calculated and the median density is used for the correction. In 2010 this typically resulted in a correction of around 900 MeV .

The original Frixione isolation scheme assumed that an isolation cut could be applied continuously as a function of R (distance from the photon). Actual detectors have a finite granularity. A solution to this was the adoption of a discretized version of Frixione isolation, allowing this granularity to be taken into account [18]. However, it is not possible to place an isolation cut on the inner-most cone (typically $R \sim 0.1$ ), because of the presence of the photon itself. While the separation between the fragmentation photon and the jet remnants is finite in data (and in Monte Carlo), fragmentation is treated as a collinear process in partonic cross sections. The inability to apply the isolation cut down to $R=0$, results in a greatly reduced ability to discriminate against fragmentation processes in the partonic level theory.

To rectify this the Frixione calculation could be modified into a 'crown' isolation, whereby the last cone is missed from the calculation. Unfortunately as most of the radiation is collinear in the fragmentation events, it is likely to reduce its effect of removing these events. Other studies [478] have shown that the photon quality cuts applied by the experiments will reduce the fraction of fragmentation photons accepted, where substantial fragmentation energy is collinear with the photon. However, the rejection is not $100 \%$, so we are still left with a smaller reduction of fragmentation contributions in the partonic level theory than are actually (presumably) present in the data. In these proceedings, we will discuss how to more properly incorporate the correct level of rejection in the theory.

### 19.13 Choice of fragmentation scale

In addition to the experimental difficulties with applying the isolation criteria there are also difficulties in choosing appropriate scales for the theoretical calculation. This is discussed in the following text, along with other considerations for applying Frixione isolation at a theoretical level.

Fragmentation is treated as a collinear process in partonic calculations. In this framework, the original "continuous" Frixione criterion [471] was designed to inhibit the appearance of final state photonparton collinear singularities which otherwise require absorption in a fragmentation function $D\left(z, M_{F}\right)$. Thus, cross sections for the production of prompt photons isolated with this criterion involve no fragmentation contribution. Discretized variants of this criterion have been proposed which aim at matching better what can be actually implemented experimentally [18]. They consist in a limited number of nested cones $\mathcal{C}_{j=1, \cdots, n}$ with respective radii $R_{1}=R_{\min }<R_{2}<\cdots<R_{n}=R_{\max }$ defined in the azimuthal and rapidity differences with respect to the photon direction, and requiring recursively that the accompanying hadronic transverse energies inside every successive cone $\mathcal{C}_{j}$ be less than an ordered sequence of maximum values ${ }^{44} E_{T j}^{i s o}$ such that $0<E_{T 1}^{i s o}<\cdots<E_{T n}^{i s o}$. However, in contrast with the continuous criterion, such discretized variants still involve a fragmentation contribution, though the latter is expected to be small, since the situation in the innermost cone shares some similarity with the standard cone criterion. When quantifying the magnitude of the fragmentation contribution with such discretized criteria, a potentially tricky issue concerns the fragmentation scale dependence and the "best choice" of scale.

This issue matters for isolation with the standard cone criterion when the radius $R$ of the cone is $\ll 1$ while $E_{T}^{i s o}$ is kept fixed. Whereas the natural fragmentation scale $M_{F}$ in the non-isolated case

[^153]is $\sim p_{T}^{\gamma}$, this choice can lead to very poor theoretical estimates at Next to Leading Order (NLO) in perturbative QCD when $R \ll 1$ [472]. The scale dependence near the choice $M_{F} \sim p_{T}^{\gamma}$ is then large and, worse, the theoretical prediction may eventually exhibit an unphysical violation of unitarity whereby the predicted NLO cross section for photons becomes larger than the inclusive one, so that even for only moderately small $R$ the reliability of the prediction is questionable. On the other hand, as ${ }^{45} D\left(z, M_{F}\right) \sim$ $\log \left(M_{F} / \Lambda_{Q C D}\right)$, with the choice $M_{F} \sim R p_{T}^{\gamma}$ the fragmentation contribution is suppressed compared with $M_{F} \sim p_{T}^{\gamma}$. The situation is improved regarding both scale dependence and unitarity, although it does not solve the problem completely. One actually faces a multiscale problem: $\Lambda_{Q C D} \ll R p_{T}^{\gamma} \ll p_{T}^{\gamma}$, and a one-scale compromise is possibly insufficient depending on the kinematical regime explored. The atypical choice $M_{F} \sim R p_{T}^{\gamma}$ has in principle to be supplemented by a resummation of the logarithmic $R$ dependence coming form outside the cone, if at all possible. At leading-log $R$ (LLR) accuracy at least, such a resummation is actually feasible, which furthermore allows to solve the apparent puzzle why scale choices should be very different in the cases with isolation in a narrow cone vs. broad cone or without isolation.

The concern about the discretized Frixione criteria is that the innermost cone size is quite small. The choice for the fragmentation scale $M_{F}$ shall then arguably be $M_{F} \sim \mathcal{O}\left(R_{\min } p_{T}^{\gamma}\right)$. On the other hand, as the allowed transverse energy deposit $E_{T}^{i s o}\left(R_{\text {min }}\right)$ inside this cone is correspondingly small, the width of the interval in the fragmentation variable on which the fragmentation function is convoluted with the partonic cross section is restricted to a rather narrow range $0<1-z<E_{T}^{i s o}\left(R_{\min }\right) / p_{T}^{\gamma} \sim$ $\epsilon\left(R_{\min } / R_{\max }\right)^{n}$. This leads to a quite suppressed fragmentation contribution. The combination of the two effects: a low fragmentation scale and a narrow $z$-range, is the discrete counterpart of the inhibition of fragmentation by the continuous criterion. We may thus expect that the issue of the narrow cone is less worrying for the reliability of the NLO calculation in this case than if only $R$ were taken small while keeping $E_{T}^{i s o}$ fixed. In order to assess the uncertainty on the fragmentation contribution we may perform the calculation for the "arguably better" scale $M_{F} \sim R_{\min } p_{T}^{\gamma}$ and compare it to the expectedly larger result for the standard choice $M_{F} \sim p_{T}^{\gamma} / 2$.

### 19.2 ISOLATION FOR INCLUSIVE PHOTONS AND DIPHOTONS AT NLO

The study at NLO uses the Jetphox generator to calculate the inclusive photon cross section and Diphox for the di-photon cross section. Details of how to use the software and to obtain predictions with errors can be found in [480] and the selection criteria used are listed in the appendix. Previous results from Les Houches [18] showed that the discretized Frixione isolation criteria did manage to reduce the fragmentation contribution, here we extend that study in several ways. Firstly the cross section returned has been compared to that calculated from using the standard cone isolation, as used in current measurements. A generalized form of the Frixione isolation is discussed, aimed to satisfy both the experimental and the theoretical requirements on the isolation cut for different $p_{T}$ regimes. In addition the effects of changing the number of cones used in the calculation and of choosing an $E_{T}$ cut, rather than relating it to the photon $p_{T}$, are investigated. In addition, further complications to comparing theoretical and experimental isolation calculations are discussed. Finally there are further brief studies using Jetphox to look at scale and jet algorithm choices.

### 19.21 Discretized prescription

The parameters used to define different selections, according to Eq. 19.1.1, were:

$$
\begin{array}{llll}
a: \epsilon=0.05 n=0.2 & b: \epsilon=1 n=0.2 & c: \epsilon=1 n=1 & d: \epsilon=0.5 n=1 \\
e: \epsilon=0.05 n=1 & f: \epsilon=1 n=0.1 & g: \epsilon=1 n=0.5 &
\end{array}
$$

[^154]

Fig. 97: Left: Fragmentation fraction for the cone and Frixione isolation criteria. Right: The applied $E_{T}$ cut on the isolation sum as a function of $p_{T}$ for the 0.4 cone or 0.1 cone in the Frixione criteria.
where all but the last two were based on the previous study. In all cases $R_{0}$ was chosen to be 0.4 , with $R$ being set to either: $0.4,0.3,0.2,0.1$ or $0.4,0.35,0.3,0.25,0.2,0.15,0.1$.

The comparison to the cone isolation in Fig. 97 shows that out of the chosen parameters only 1 set removes the fragmentation contribution more than what is removed by the cone algorithm, although two are lower until high $p_{T}$. It also shows that criteria $b$ and $f$ are not much better than applying no isolation criteria at all. When altering Eq. 19.1 .1 to use a fixed $E_{T}=4 \mathrm{GeV}$ instead of $p_{T, \gamma}$ the results are more promising but this is because it applies a cut in the 0.1 cone that is below the experimental accuracy (of the order 100 MeV due to detector resolution/noise). Unfortunately Fig. 97 also shows that this is also the case for the $p_{T}$ requirements, as case $e$ (the only criteria to perform better than the standard cone) also applies a cut that is not viable experimentally in the 0.1 cone.

There are some positive outcomes from these studies, firstly the Frixione criteria $b$ and $d$ maybe useful criteria to use experimentally as they keep the fragmentation contribution similar and low in all bins, which could help with understanding of the systematic errors/correlation between bins. Secondly the comparison of the number of cones used in the Frixione criteria resulted in a difference of around $1 \%$ on the total cross section and almost no effect on the fragmentation fraction. This means that it is fine to use the lower number of cones case, and that the discrete Frixione criteria is most likely very similar to that of the continuous version.

### 19.22 Generalized prescription

As seen previously, to remove the fragmentation contribution in the theory, a small value of $\varepsilon$ is needed. However, given the effects of finite resolution and granularity on the experimental description of the isolation energy, a minimum threshold has to be allowed in the isolation cone, especially at low $p_{T}$. A typical value of $2-4 \mathrm{GeV}$ is used as experimental cut, to optimize the rejection of hadronic background coming from the decay of light mesons. Now, at high $p_{T}$ this cut might result too tight, particularly on the theoretical side given that an isolation cut much smaller than the photon $p_{T}$ can cause large logs in the calculations, this effect was not observed in the previous Les Houches study.

As a good compromise of these two requirements, it has been proposed [481] to extend the original

Fig. 98: Effect of the two terms in the modified Frixione isolation prescription effects of the different pieces of the generalized Frixione isolation prescription on the isolation cut as a function of $p_{T}$ (left) and the cone radius R (right).

Frixione prescription (Eq. 19.1.1) to a more general form:

$$
\begin{equation*}
E_{T}^{i s o}<\left(\left(E_{0}\right)^{k}+\left(\varepsilon \cdot p_{T}\right)^{k}\right)^{1 / k}\left(\frac{1-\cos R}{1-\cos R_{0}}\right)^{n} \tag{19.2.1}
\end{equation*}
$$

where:
$R_{0}$ is the maximum cone size
$E_{0}$ is the minimum energy pedestal allowed in a cone of size $R_{0}$
$\varepsilon$ is the fraction of the photon $p_{T}$ allowed in the cone of size $R_{0}$
$k$ determines the shape of the isolation profile in $p_{T}$
$n$ determines the shape of the isolation profile in R (see Fig. 98 right])
The extra parameters give enough flexibility to ensure a (finite) tight cut at low $p_{T}\left(\sim E_{0}\right)$ and, at the same time, a loose cut at high end of the spectrum driven by the photon $p_{T}$. The $k$ parameter controls how quickly/smoothly is the transition from one regime to the other (see Fig. 98 left]).

This generalized prescriptior ${ }^{[46}$ has been implemented in Jetphox recently and some possible configurations are explored here. The studied configurations vary $\varepsilon(=0.05,1)$ and $k(=2,5,10)$, and have a fixed value for $E_{0}=4 \mathrm{GeV}$ (the typical cut applied in ATLAS) and $n=0.5$ (given the linear behaviour of isolation distribution width observed for direct photons in ATLAS [482]).

The high- $\varepsilon$ configurations ( $\varepsilon=1$ ), show a worse performance at removing the fragmentation contribution with respect to the fixed cone approach and are practically insensitive to the value of $k$ in the formula. The remaining fragmentation fraction is $\sim 25 \%$ at 45 GeV decreasing to $20 \%$ in the highest $p_{T}$ bin. On the other hand, as seen in Fig. 99, all the configurations for a low value of $\varepsilon(=0.05)$ show an improvement in fragmentation rejection compared to both the no isolation and fixed cone cases, in the whole $p_{T}$ region ( $45 \mathrm{GeV}<\mathrm{p}_{\mathrm{T}}<600 \mathrm{GeV}$ ). The $p_{T}$ profile for the smaller cone ( $R=0.1$ ) in this case (Fig. 99[right]) looks also more promising in terms of its applicability at the experimental level.

[^155]

### 19.23 Continuous and discretized Frixione criteria in di-photon events

Following the previous studies with inclusive photons, we now consider the production of photon pairs. The aims of this study are i) to assess the effect on the magnitude of the fragmentation contribution by comparing results from using the continuous Frixione criterion with those using several variants of the discretized version, implemented in the NLO programme Diphox, thereby providing a NLO assessment of how much fragmentation may be missing in the NNLO calculation of Catani et al. [78] which includes no fragmentation and therefore uses the continuous criterion; ii) to probe the dependence of the prediction with respect to the fragmentation scale choice. It supplements a similar comparison which had been performed for inclusive photon production in [18].

Fig. 100 provides a comparison of the original continuous criterion to the discretized version of the criterion based on four nested cones with respective radii $R_{\text {min }}=0.1, R_{2}=0.2, R_{3}=0.3$ and $R_{\max }=0.4$. Four variants of the energy profile $E_{T}^{\text {iso }}(R)$ as defined in Eq. 19.1.1 have been considered: $(\epsilon, n)=(0.05,0.2),(0.05,1),(0.5,1)$ and $(1,1)$. Fig. 100 (left) presents the distribution in invariant mass of photon pairs in the range $40 \mathrm{GeV} \leq m_{\gamma \gamma} \leq 300 \mathrm{GeV}$. The discretized criterion $(0.05,1)$ suppresses fragmentation so much that there is practically no difference between the discretized and continuous versions. With the criterion $(1,1)$, the discretized version leads to a distribution $O(10-12 \%)$ larger than the continuous one. The choice $(0.5,1)$ displays a similar feature, though quantitatively less important. The energy profile of the fourth choice is not suited for an efficient isolation unless $\epsilon$ is chosen very small. A similar comparison is shown on Fig. 100 (right) for the distribution in the difference in azimuthal angle $\Delta \phi$ between the two photons. Whereas the distribution in invariant mass is dominated by the direct contribution, the tail of the distribution in $\Delta \phi$ tail at low $\Delta \phi$ is more sensitive to the fragmentation contribution. Therefore, the conclusions are qualitatively similar to the one drawn for the distribution in invariant mass, yet the effects are quantitatively larger.

Fig. 101 assesses the dependence on the fragmentation scale $M_{F}$, for the distributions in invariant mass (left) and in $\Delta \phi$ (right) respectively. Two choices were considered: $M_{F}=R_{\min } \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}=$ $0.1 \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}$ vs. $M_{F}=R_{\max } \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}=0.4 \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}$ closer to a standard choice ${ }^{47}$. As expected, the distribution in invariant mass, which is not very sensitive to the fragmen-

[^156]

Fig. 100: Comparing continuous and discretized Frixione criterions for the distributions in $m_{\gamma \gamma}$ (left) and $\Delta \phi$ (right) of photon pairs, for four variants of the criterion.

Fig. 101: Fragmentation scale dependence of the distribution in $m_{\gamma \gamma}$ (left) and $\Delta \phi$ (right) of photon pairs, for four variants of the discretized Frixione criterion.
tation contribution, is practically not impacted by the choice. The distribution in $\Delta \phi$ is more sensitive to the fragmentation component and the sensitivity to the fragmentation scale choice is larger than for the distribution in invariant mass. The sensitivity to the fragmentation scale choice is the largest in the case of the criterion $(\epsilon, n)=(1,1)$, for which the predictions are $5-7 \%$ smaller, rather uniformly, with the lower scale choice than with the more standard one.

In conclusion this preliminary study shows that the impact of the fragmentation contribution passing the discretized criterion seems to be almost negligible on the distribution in invariant mass, and remains small even on the tail of the distribution in azimuthal angle. Notwithstanding, the conclusions shall have limited use depending on how isolation is actually implemented experimentally in the innermost cone. We here stick to a discretized version of the Frixione criterion which respects the original idea of a transverse energy deposit decreasing towards zero with the cone radius. If instead any experimental constraint would allow a more permissive condition in the innermost cone, a dedicated study would be mandatory.

### 19.24 Additional studies at NLO

In addition to the isolation studies with Jetphox, we present here two brief studies as an attempt to reduce the theoretical errors from the NLO calculation. These study the choice of renormalizaion and factorization scale parameter and secondly the jet algorithm parameters.

As studied in [480], the scale choice is set to a fraction of the photon $p_{T}$. By altering this fraction around the central value of 1.0 , it is hoped to gain an uncertainty on the terms missed in the NLO calculation. The best selection for this central value would be to be at a 'saddle point', where moving in any direction from this point gives similar changes in the cross section. However, it is found that as the scale is reduced (in steps: $2.0,1.0,0.5,0.25,0.1,0.05$ and 0.01 ) the cross section increases, when moving the two scales coherently or independantly. One difference in this result to the previous study was that it was carried out in three $p_{T}$ bins, but the result remained the same for all (only the highest bin was able to be calculated with a scale of 0.01 ). Similarly the addition of using Frixione isolation instead of the standard cone isolation also resulted in the same cross section behaviour. The summary of this is that there must be large contributions needed from NNLO. However, on the positive side, in all $3 p_{T}$ bins, the variation between 0.5-1.0-2.0 resulted in differences of similar magnitude around 1.0 , so this is likely a safe estimate of the uncertainty.

After the inclusive photon measurements, the next step experimentally is to require the addition of at least one jet. Using a jet of 10 GeV the cross section was calculated for two algorithms each for multiple sizes:

- Kt algorithm with $\Delta R=0.3,0.4,0.5$ or 0.6
- Cone with $\Delta R=0.4,0.5$ or 0.6

These choices had an affect of $<1 \%$ on the cross section computed in 3 photon $p_{T}$ bins, suggesting that this will not increase the error for the NLO calculation when moving from the inclusive cross section to that with an additional jet.

### 19.3 FRAGMENTATION PHOTONS IN PARTON-SHOWER MONTE-CARLO

The second part of this study continues to investigate photon isolation, but now in di-photon events using parton-shower Monte-Carlo generators; again the selection used is listed in the appendix. The study begins by investigating the distance between the photon and other particles. It then moves into studying several different styles of isolation criteria, including Frixione criteria as done in the inclusive NLO studies.
encodes the two photons in a symmetrized way.

### 19.31 Topology of fragmentation photons

We consider three sets of parton-shower Monte-Carlo samples for the $\gamma \gamma+\mathrm{X}$ process:

- Pythia [400] $\gamma \gamma$ Born and Box direct processes, plus the Pythia $\gamma+$ jet process with the jet fragmenting into a photon ( 20 million events were generated for the $\gamma+$ jet sample and 1000 times more would have been needed for the dijet fragmenting to two photons due to the low $q \rightarrow \gamma$ branching ratio for isolated photons).
- Pythia $\gamma \gamma$ Born and Box direct processes, plus the Pythia $\gamma+$ jet process with the jet fragmenting into a photon and the Pythia dijet process with the two jets fragmenting into photons. Both Pythia $\gamma+$ jet and dijet samples were generated with a filter which enhances the presence of events with isolated electromagnetic particles.
- Madgraph [165] $\gamma \gamma+$ up to two supplementary hard jets, with fragmentation/hadronization done with Pythia.
The fragmentation contribution is included as a bremsstrahlung contribution in Madgraph at matrix element level, while it is included as a showering contribution in Pythia $\gamma+$ jet and dijet (in the PYTHIA samples we identify fragmentation photons as those having a quark or gluor ${ }^{48}$ as parent). The fragmentation fraction found is compatible with ref [483]. We consider additionally the case where the two jets fragment into boosted neutral mesons ( $\pi^{0}, \eta, \rho$ and $\omega$ ) that can experimentally mimic direct or fragmentation photons at reconstructed level because of the finite granularity of the detector. These samples include an underlying event but were generated without pile-up.

Fig. 102: $\Delta R$ distance distribution between the photon and the other generator-level particle candidates in the event, for neutral mesons, fragmentation photons and partonic photons.

Fig. 102 shows the $\Delta R$ distance between the photon or neutral mesons and the other particle candidates in the event. Partonic photons, fragmentation photons and neutral mesons have different properties as a function of $\Delta R$. Partonic photons in Pythia have a linear behavior, which is expected because the only contribution that can enter in the isolation sum is the underlying event and pile-up (with also a small contribution from QCD radiation at the shower level) which is expected to be uniform in space. As each bin consists of an annulus with radius growing linearly as a function of $R$, the quantity

[^157]of particles grows linearly with $R$ in the area of the annulus. Neutral mesons have a radically different profile, with a peak of the $\Delta R$ distribution close to 0 . The peak is caused by the decay of particles resulting from jet fragmentation close to the neutral meson direction. Pythia fragmentation photons have a behavior somehow in between that of neutral mesons and partonic photons. The peak at low $\Delta R$ is still present but much reduced with respect to that of neutral mesons. Madgraph partonic photons exhibit a modulation of the Pythia partonic photon $\Delta R$ distribution, probably because Madgraph includes fragmentation as a bremsstrahlung contribution.

From this we can expect that the smaller the $\Delta R$ cone used in Frixione isolation (until $\Delta R \simeq 0.1$ ), the higher the discrimination against the neutral mesons and fragmentation photons. The discrimination against neutral mesons is higher than that against fragmentation photons (as is well-known experimentally). This can be seen in Fig. 103, which shows the isolation sum profile divided by the transverse energy of the photon for different cone sizes.

Fig. 103: Isolation sum normalized to the photon energy computed in cones of size $\Delta R<0.1$ (top left), $\Delta R<0.2$ (top right), $\Delta R<0.3$ (bottom left), $\Delta R<0.4$ (bottom right), for neutral mesons, fragmentation photons and partonic photons.

Table 14: Fraction represented by the 1-fragmentation and 2-fragmentation contributions for various Frixione isolation criteria in Pythia two-prompt photon samples (with electromagnetic enrichment filter).

### 19.32 Impact of hollow cones on the fragmentation contribution

In NLO generators, the products of the quark fragmentation are along the fragmentation photon direction. In parton-shower generators we have seen that this is not necessarily true. In NLO generators, the "hollow" or "crown" isolation, where the energy sum has to be below a fixed threshold in a region $R_{1}<\Delta R<R_{2}$ while in the region $R<R_{1}$ any arbitrary amount of energy is admitted, has been shown to enhance the fragmentation contribution with respect to the usual "solid" isolation. This "hollow" isolation is interesting also because this criterion is closer than the "solid" cone to what is used experimentally (it allows to exclude from the isolation sum the energy deposited by the photon itself). The first two lines of Tables 14 and 15 show that in general the fragmentation fraction does not increase significantly when moving from solid to hollow cone isolation, for the PYTHIA samples.

### 19.33 Impact of Frixione isolation on the fragmentation contribution

Tables 14 and 15 report the fragmentation fraction inside the Pythia two-prompt sample for different Frixione isolation criteria. Eight isolation cones were used : $\Delta R<0.05, \Delta R<0.1, \Delta R<0.15$, $\Delta R<0.2, \Delta R<0.25, \Delta R<0.3, \Delta R<0.35, \Delta R<0.4$. The results are almost identical if instead four cones are used ( $0.1,0.2,0.3,0.4$ ), as found at NLO. The tables show that in both the electromagnetically-enriched samples and non-enriched samples, the discrete Frixione isolation with the usual functional form $f(R)$ does not reduce the fragmentation contribution with respect to the standard isolation criterion (with a cone $\Delta R<0.4$ ) except when the parameter $\epsilon$ is at its smallest value, $\epsilon=$ 0.05 , for which modest reductions of between 5 and $8 \%$ can be achieved. The cause of this apparent non-optimal behavior can be explained by the non-collinearity of the fragmentation debris around the fragmentation photon in PYTHIA. Frixione isolation is designed to apply tighter and tighter isolation criteria $E_{T}^{i s o}<f(R) \rightarrow 0$ as $\Delta R \rightarrow 0$, assuming that most of the fragmentation debris are around $\Delta R \simeq 0$. As it is seemingly not the case in the parton-shower Monte-Carlo studied here, the criterion loses most of its discrimination power.

The previous study suggests that the previous working points studied with the Frixione functional form $f(R)$ might not be optimal for the rejection of fragmentation debris. In figure 104 we compare the performance of three different sets of criteria: 1) non-Frixione isolation in a single cone $\Delta R<0.4,2$ ) optimized working points for the parameters in the Frixione functional form (four cones $0.1,0.2,0.3,0.4$ were used to make the algorithm converge faster), 3) re-optimized 'Frixione' isolation criteria on cones $\Delta R<0.1,0.2,0.3,0.4$ without using the explicit functional form (we no longer constrain the events to satisfy $E_{T}^{i s o}<f(R)$ and let $f(R)$ free). In the second case, an optimization procedure is performed scanning over the parameters $\epsilon$ and $n$ to find the best working points (corresponding to a maximum

Table 15: Fraction represented by the 1 -fragmentation contribution for various Frixione isolation criteria in Pythia two-prompt photon samples (without enrichment filter).

| Criteria | 1-frag fraction |
| :---: | :---: |
| Solid $\Delta R<0.4, E_{T}^{i s o}<5 \mathrm{GeV}$ | 0.455 |
| Hollow $0.1<\Delta R<0.4, E_{T}^{i s o}<4 \mathrm{GeV}$ | 0.458 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=0.05, n=1.0$ | 0.420 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=0.05, n=0.2$ | 0.419 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=0.2$ | 0.514 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=0.1$ | 0.519 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=1.0$ | 0.489 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=0.5$ | 0.503 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=0.5, n=1.0$ | 0.465 |

efficiency for a given $s / b$ ). In the last case, an optimization code is used to find the best selection criteria to be applied on $E_{T}^{i s o}$ for each $\Delta R$ cone. The optimization takes as input the target value of $s / b$ (partonic signal over fragmentation background ratio), then relaxes and tightens each cut separately with an iterative procedure to find the best signal efficiency for this $s / b$ target. The procedure was performed to find the working points corresponding to the $s / b$ obtained with the first Frixione criterion.

Figure 104 shows that the optimized working points for the Frixione functional form perform slightly better than the standard isolation for a given photon efficiency, and that optimization using no functional form in turn performs slightly better than the Frixione functional form; for the same value of single-photon efficiency, lower values of fragmentation fraction are attainable. It should be noted that this optimisation leads to a looser cut on the first cone, $\Delta R<0.1$, than the usual functional form. Nevertheless, to obtain reductions in the fragmentation fraction of more than $10 \%$, increasingly significant reductions in single photon efficiency are required, since the fragmentation reduction becomes nearly flat.

All in all, with the definition of the isolation in a cone of $\Delta R$ used here, which is a usual way of defining isolation at the experimental level (where one has however to remove the footprint of the photon from the isolation sum and to cope with pile-up), rejecting fragmentation photons can be done only at a cost of a lowered signal efficiency. With this optimization procedure it was found that to decrease the fragmentation fraction by $10 \%$, a signal loss of about $60 \%$ has to be achieved, leading to extremely tight cuts probably not applicable in experimental analysis.

## CONCLUSIONS

Firstly for the NLO cross sections, it was found that only one of the Frixione isolation criteria suggested in [18] actually performs better at removing the fragmentation contribution in the inclusive case than that of the standard cone, although potentially too tight to use experimentally. However, it is useful to see that the results are independent of the number of cones used. This is also the case for the di-photon cross section where it compares well to the continuous criteria. A more promising result in the inclusive case is that the generalized version of Frixione isolation, with small values of $\epsilon$, do significantly reduce the fragmentation fraction without applying too tight a cut in the smallest cone. In addition it is confirmed that the 'saddle point' can not be found when altering the scale choice for the inclusive cross-section, suggesting more corrections needed at NNLO. Finally when moving to the photon with associated jet cross section, from the inclusive cross section, it is reported that the jet algorithm (or size) used at NLO makes little difference to the cross section.

In the study at the parton-shower level it was shown that the isolation profile of fragmentation

Fig. 104: The fraction of the 1 -fragmentation contribution vs single $\gamma$ efficiency for various sets of criteria. Blue : tested working points reported on table 15. Black : selection criteria on isolation in $\Delta R<0.4$. Green : Optimized Frixione isolation using the usual functional form. Red : Re-optimized isolation criteria on cones $\Delta R<0.1,0.2,0.3,0.4$ without using the functional form.
photons is no longer collinear anymore, whereas the modelization of the fragmentation function in NLO generators leads the quark/gluon debris to be collinear to the photon. Furthermore, the hadronization process of the quark/gluon that emitted the photon leads to a $\Delta R$ profile which is no longer peaked at zero (but close to zero). In parton-shower programs isolation still has increasing discriminating power when going lower in $\Delta R$. However, it was found that a $10 \%$ decrease in fragmentation fraction in diphoton events with respect to standard isolation leads to a drop in single photon signal efficiency to approximately $60 \%$ of the initial value. The usual functional form for Frixione isolation was shown to be not completely optimal for suppressing the fragmentation contribution while preserving high signal efficiency. This can be mitigated by re-optimizing the cuts for each $\Delta R$ of the discrete Frixione prescription, which allows a looser cut in the innermost cone. Further studies using other fragmentation modelizations in parton-shower programs like SHERPA [427] (LO matrix-element where photons and jets in the shower are matched to matrix element level) or POWHEG [484] (NLO matrix-element with consistent fragmentation photon matching) would need to be investigated.

In conclusion the results from the two studies show there are differences and similarities at the two levels. Regarding the fragmentation fraction, this is far more reduced at the NLO level than at the parton-shower level. However, the two levels show agreement that the results from Frixione isolation are independant of the number of cones used and that similar shape cuts can be obtained by retuning cuts at the parton-shower level and by using the generalized prescription at NLO.

## ACKNOWLEDGEMENTS

Thanks to the whole of the Les Houches photon subgroup, especially to J.P. Guillet and E. Pilon for their expert input.

## APPENDIX: Selection details

All of the studies are carried out for $p p$ collisions at $\sqrt{S}=7 \mathrm{TeV}$. For simplicity the the inclusive studies are carried out for the region where the photon lies in $|\eta|<0.6$. When calculating the cone isolation around the photon a cone of 0.4 is used with the requirement that the energy in the cone is less than 4 GeV . The renormalization scale $\mu$ and initial state factorization scale $M$ are set to the photon $p_{T}$,
unless stated otherwise, and the CTEQ6.6 PDF[256] is used and the photon fragmentation functions are BFG set II [479]. For the generalized Frixione isolation case, the cones used are: $\mathrm{R}=0.4,0.35,0.3,0.25$, $0.2,0.15$ and 0.1.

In the NLO di-photon studies, the photons have: $p_{T}^{\gamma 1} \leq 25 \mathrm{GeV}, p_{T}^{\gamma 2} \geq 22 \mathrm{GeV}$, in the rapidity range $\left|\eta^{\gamma}\right| \leq 2.5$ for both photons, and a separation $\Delta R_{\gamma \gamma} \geq 0.4$ is required between the two photons. The mass range considered is $40 \mathrm{GeV} \leq m_{\gamma \gamma} \leq 300 \mathrm{GeV}$. In this case the scales $\mu$ and $M$ are chosen equal to $\min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}$.

In the parton shower di-photon studies, the photons are selected with: $M_{\gamma \gamma}>80 \mathrm{GeV}, p_{T}>21,20$ $\mathrm{GeV},|\eta|<2.5$ and $E_{T}^{i s o}<5 \mathrm{GeV}$.

## 20. EVENT-BY-EVENT PILEUP SUBTRACTION USING JET AREAS 49

#### Abstract

In these proceedings, we compare the efficiency of several jet-area-based subtraction methods to correct for pile-up contamination at hadronic colliders. We study the dependence on various variables like the $p_{t}$ and rapidity of the jets, the number of pile-up vertices or the Monte-Carlo generator variations. We conclude that estimations of the pile-up density using a median computed over grid-cell patches, including a rescaling to correct for the rapidity dependence, perform particularly well, though alternative methods are possible.

### 20.1 Introduction

With the LHC running at larger and larger luminosities, hard $p p$ interactions are accompanied by an increasing number of pile-up (PU) collisions: from a few PU events per bunch crossing in spring 2011, operation with $\sim 20 \mathrm{PU}$ events is now routine. Considering only in-time PU , this would lead to an extra transverse momentum of $\sim 750 \mathrm{GeV}$ deposited in the event, and a jet of a typical radius $R=0.5$ would see its transverse momentum shifted by $\sim 10 \mathrm{GeV}$. In order to obtain a good energy resolution for the jets it is therefore mandatory to correct for this contamination.

In these proceedings, we review several methods - both existing methods and new refinements - to subtract the contamination due to PU and provide a systematic study of their efficiency.

It is important to note already now that PU has not only the effect to shift the momentum of the jets: it also smears their momentum. Indeed, the number of PU vertices varies from one collision to the next (following a Poisson distribution varying with the beam conditions), all PU interactions, i.e. minimum bias collisions, do not lead to the same energy deposit, and finally, the energy produced in a minimum bias collision is not deposited uniformly across the detector. Altogether, on top of an average shift, PU will add two sources of resolution smearing: event-to-event and in-event fluctuations corresponding respectively to variations of the PU activity from one event to another and from one point to another in a single event.

Here we shall primarily study in-time $P U$, that is the effects coming from multiple $p p$ interactions that occur in the same bunch crossing as the hard interaction one triggers on. Because of the response time inherent to each detector this would come with a second effect, out-of-time $P U$, corresponding to the PU activity in the few bunch crossings preceding the one with the hard interaction. Since these heavily depend on the details of each individual detector - and even varies from one sub-detector to another - it goes beyond the scope of this theoretical study. However, as we shall discuss in further detail later on, the PU subtraction methods proposed here do not make any assumption about a distinction between in-time and out-of-time PU and thus should be robust enough in more complex cases.

[^158]
### 20.2 Subtraction method(s)

We are interested in the situation where a hard event is contaminated by a background coming from additional pileup interactions. A reconstructed jet in that full event (hard event + background), which we shall call a full jet, differs from the hard jet in the original hard event because of the presence of the background. By background subtraction, we mean correcting the full jet in such as to recover the momentum of the original hard jet, i.e. subtract the pileup contamination from the jet's momentum.

### 20.21 Background effects

Our starting point is to realise [485] that a uniform background affects the momentum of a jet in two ways: it shifts its momentum because of the background particles clustered with the jet, and it modifies the way the hard particles themselves are clustered because the background particles are not infinitely soft.

This means that the reconstructed momentum has the form 50

$$
\begin{equation*}
p_{t, \text { full }}=p_{t, \text { hard }}+\rho A \pm \sigma \sqrt{A}+\Delta p_{t}^{B R} \tag{20.2.1}
\end{equation*}
$$

where $p_{t}$ denotes the transverse momentum of the reconstructed jet, $p_{t, \text { hard }}$ the momentum of the original hard jet (in the absence of PU), $A$ the jet area, $\rho$ the background density per unit area within a given event, $\sigma$ the fluctuations of that background (per unit area) from place to place within the event, and $\Delta p_{t}^{B R}$ the back-reaction describing the effect of the background particles on the clustering of the hard ones.

If the background has a positional dependence (e.g. depends on rapidity) then $\rho$ and $\sigma$ will depend on the position of the jet one tries to subtract.

Eq. 20.2.1) characterises the fact that the background has the effects of shifting the transverse momentum of the jet and to degrade its resolution. The shift comes from the " $\rho$ " term in 20.2.1) and from potential back-reaction systematic effects. Using the anti- $k_{t}$ jet algorithm the shift due to backreaction is negligibl ${ }^{51}$. Resolution smearing effects come from various sources: the fluctuations of the background from within an event, i.e. the " $\sigma$ " term in 20.2.1, fluctuations of the background from one event to another, that is the fact that $\rho$ is not the same in every event, and the fluctuations in the back-reaction.

### 20.22 Central subtraction formula

From (20.2.1], the natural way to subtract the background contamination is to define the subtracted jet as [485]

$$
\begin{equation*}
p_{t, \text { sub }}=p_{t}-\rho_{\mathrm{est}} A \tag{20.2.2}
\end{equation*}
$$

where $\rho_{\text {est }}$ is the estimated value for the background density per unit area.
To apply this subtraction we need to compute the jet area and find an estimation $\rho_{\text {est }}$ for the background density per unit area. The jet areas are readily available using FastJet, so we just need to focus on $\rho_{\text {est }}$. The main goal of these proceedings is to investigate various methods of obtaining $\rho_{\text {est }}$ which are listed below. In all cases, it is primordial to realise that the determination of $\rho_{\text {est }}$ is performed event-by-event, and even jet-by-jet when the positional dependence of the background is taken into account.

As we shall see later on, the fact that $\rho$ is estimated for each individual event is crucial: it corrects for the fluctuations of the background from one event to another. If instead one uses an averaged value for $\rho_{\text {est }}$ (over many events), one would get an extra resolution smearing due to the fluctuations of $\rho$ across different events. Similarly, the jet area $A$ in 20.2.2) has to be computed for each individual jet. Using an average area would lead to an additional source of fluctuations of the form $\rho \sqrt{\left\langle A^{2}\right\rangle-\langle A\rangle^{2}}$.

[^159]Using seen vertices Since experimentally it might be possible - within some level of accuracy that goes beyond the scope of this discussion - to count the number of pileup vertices using charged track reconstruction, one appealing way to estimate the background density in a given event would be to count these vertices and subtract a pre-determined number for each of them:

$$
\begin{equation*}
\rho_{\mathrm{est}}^{(n \mathrm{PU})}(y)=f(y) n_{\mathrm{PU}, \text { seen }}, \tag{20.2.3}
\end{equation*}
$$

where we have made explicit the fact that the proportionality constant $f(y)$ can carry a rapidity dependence. $f(y)$ can be studied from minimum bias collisions (see Section 20.32 below) and can take into account the fact that only a fraction of the PU vertices will be reconstructed.

Median subtraction This technique divides the rapidity-azimuthal angle plane in patches and estimates $\rho$ for each event using

$$
\begin{equation*}
\rho_{\text {est }}^{(\text {global })}=\operatorname{median}_{i \in \text { patches }}\left\{\frac{p_{t, i}}{A_{i}}\right\} \tag{20.2.4}
\end{equation*}
$$

This is motivated by the observation that many regions in the event are populated just by the background. In these regions, $p_{t} / A$ is an estimate of $\rho$ and the use of the median, rather than the average, which ensures reduced bias from the hard jets.

This method was originally proposed in [485] using jets (from a $k_{t}$ or Cambridge/Aachen clustering) as patches. Here, we shall also test a new option where the $y-\phi$ plane is simply subdivided into grid cells that we use as patches.

Using a local range Eq. 20.2.4 provides a unique, global, estimate of $\rho$ for the event but does not take into account the positional-dependence of the background. One option, assuming one wants to estimate $\rho$ at the location of a jet $j$, is to limit the computation of the median to the jets in the vicinity of $j$, that i. 5

$$
\begin{equation*}
\rho_{\text {est }}^{(\text {local })}(j)=\underset{\text { jets } i \in \mathcal{R}(j)}{\operatorname{median}}\left\{\frac{p_{t, i}}{A_{i}}\right\} \tag{20.2.5}
\end{equation*}
$$

where $\mathcal{R}(j)$ is a local range around $j$. A typical example, that we shall study later on, is the case of a strip range where only the jets with $\left|y-y_{j}\right|<\Delta$ are included. This option was already proven to be powerful in [486].

Using rescaling Another option to correct for the rapidity dependence of the background ${ }^{53}$ is to introduce a pre-computed rapidity-reshaping function $f(y)$ (see Section 20.32) and use

$$
\begin{equation*}
\rho_{\text {est }}^{(\text {resc. })}(y)=f(y) \operatorname{median}_{i \in \text { patches }}\left\{\frac{p_{t, i}}{A_{i} f\left(y_{i}\right)}\right\} \tag{20.2.6}
\end{equation*}
$$

where now all patches (jets or grid cells) are included in the computation of the median.

### 20.3 Performance tests

### 20.31 Testing framework

The remainder of these proceedings will be devoted to an in-depth comparison of the subtraction methods proposed in Section 20.2. Our testing framework will be very similar to the one used in [486]: we embed a hard event into a pileup background (see again Section 20.2, we reconstruct and subtract the jets in

[^160]both the hard and full event $s^{54}$. for each jet in the hard event, we find the matching jet in the full event and compute the shift
\[

$$
\begin{equation*}
\Delta p_{t}=p_{t}^{\mathrm{full}, \mathrm{sub}}-p_{t}^{\mathrm{hard}, \mathrm{sub}}, \tag{20.3.1}
\end{equation*}
$$

\]

i.e. the difference between the reconstructed-and-subtracted jet with and without pileup. A positive (resp. negative) $\Delta p_{t}$ would mean that the PU contamination has been underestimated (resp. overestimated).

Though in principle there is some genuine information in the complete $\Delta p_{t}$ distribution - e.g. it could be useful to deconvolute the extra smearing brought by the pileup, see e.g. [486] and [487] - we shall focus on two simpler quantities: the average shift $\left\langle\Delta p_{t}\right\rangle$ and the dispersion $\sigma_{\Delta p_{t}}$. While the first one is a direct measure of how well one succeeds at subtracting the pileup contamination on average, the second quantifies the remaining effects on the resolution. One thus wishes to have $\left\langle\Delta p_{t}\right\rangle$ close to 0 and $\sigma_{\Delta p_{t}}$ as small as possible. Note that these two quantities can be studied as a function of variables like the rapidity and transverse momentum of the jets or the number of pileup interactions. In all cases, a flat behaviour would indicate a robust subtraction method.

The robustness of our conclusions can be checked by varying many ingredients:

- one can study various hard processes with the hope that the PU subtraction is not biased by the hard event. In what follows we shall study dijets with $p_{t}$ ranging from 50 GeV to 1 TeV , as well as fully hadronic $t \bar{t}$ events as a representative of busier final states.
- The Monte-Carlo used to generate the hard event and PU can be varied. For the hard event, we have used Pythia 6.4.24 [400] with the Perugia 2011 tune, Pythia 8.150 with tune 4C [348] and Herwig 6.5.10 [488] with the ATLAS tune and we have switched multiple interactions on (our default) or off. For the minimum bias sample used to generate PU, we have used Pythia 8, tune 4C, and checked that our conclusions remain unchanged when using Herwig++ [489] (tune LHC-UE7-2).

Additional details of the analysis For the sake of completeness, we list here the many other details of how the $\Delta p_{t}$ analysis has been conducted: we have considered particles with $|y| \leq 5$ with no $p_{t}$ cut or detector effect; jets have been reconstructed with the anti- $k_{t}$ algorithm with $R=0.5$ keeping jets with $|y| \leq 4$; for area computations, we have used active areas with explicit ghosts with ghosts placed ${ }^{55}$ up to $|y|=5$; for jet-based background estimations, we have used the $k_{t}$ algorithm with $R=0.4$ though other options will be discussed (and the 2 hardest jets in the set have been excluded from the median computation to reduce the bias from the hard event); for grid-based estimations the grid extends up to $|y|=5$ with cells of edge-size 0.56 (other sizes will be investigated); for estimations using a local range, a strip range of half-width 1.5 has been used and we refer to the Section 20.32 below for more information about the rapidity rescaling. Jet reconstruction, area computation and background estimation have all been carried out using FastJet (v3) [361, 435]. Pile-up is generated as a superposition of a Poissondistributed number of minimum bias events and we will vary the average number of pileup interactions. We shall always assume $p p$ collisions with $\sqrt{s}=7 \mathrm{TeV}$. Finally, the matching of a full jet to a hard jet is made by requiring that their common constituents contribute for at least $50 \%$ of the transverse momentum of the hard jet. We shall not discuss matching efficiencies here but they are extremely good: for a reconstructed (full) jet of 50 GeV and 20 PU events, the matching efficiency is $99.9 \%$ and this increases to $99.98 \%$ for $p_{t} \geq 50 \mathrm{GeV}$ and 5 PU events and $99.995 \%$ for $p_{t} \geq 100 \mathrm{GeV}$ and 20 PU events.

### 20.32 Minimum bias and rapidity shape

Before discussing the performances of the subtraction methods described in Section 20.2, there is still a building block that has to be discussed, namely the rapidity dependence of the background $f(y)$ that

[^161]

Fig. 105: Rapidity dependence of the transverse energy per unit area deposited in minimum bias events (obtained from Pythia 8, tune 4C). The normalisation of the fit is such that $f_{\text {seen }}$ is the fraction of seen minimum bias events i.e. the fraction of events which have at least 2 charged tracks with $|y| \leq 2.5$ and $p_{t} \geq 100 \mathrm{MeV}$.
enters in Eqs. 20.2.3) and 20.2.6). Letting aside the question of in-time vs. out-of-time PU and nonlinear effects in the detectors, the shape $f(y)$ can be obtained directly from minimum bias events.

In our case, we have generated minimum bias events with Pythia 8 (tune 4C) and studied the rapidity dependence of the transverse momentum deposited per unit area. The result is shown on Fig. 105 together with a quartic fit. If $f(y)$ is used to rescale median-based estimates of $\rho$, Eq. 20.2.6, any global normalisation factor would cancel, but in the case of Eq. 20.2.3) i.e. for the "seen vertices" method, the normalisation has to match what we mean by a seen PU vertex. In what follows, we shall define that as a minimum bias interaction that has at least 2 charged tracks with $|y| \leq 2.5$ and $p_{t} \geq 100$ MeV , which corresponds to $69.7 \%$ of the event ${ }^{56}$. In these conditions, we have found that the rapidity dependence is well reproduced by

$$
\begin{equation*}
f(y)=1.051141-0.023608 y^{2}+0.000026 y^{4} . \tag{20.3.2}
\end{equation*}
$$

### 20.33 Generic performance and rapidity dependence

Let us begin our performance benchmarks by the study of the rapidity dependence of PU subtraction. First of all, Fig. 106 shows the residual average shift $\left(\left\langle\Delta p_{t}\right\rangle\right)$ as a function of the rapidity of the hard jet. These results are presented for different hard processes, generated with Pythia 8 and assuming an average of 10 PU events per hard interaction. Robustness w.r.t. that choice will be discussed in the next Section but does not play any significant role for the moment.

The first observation is that the subtraction based on the number of seen PU vertices does a very good job in all 3 cases. Then, global median-based (using jets or grid cells) estimations of $\rho$, i.e. the (red) square symbols, do a fair job on average but, as expected, fail to correct for the rapidity dependence of the PU contamination. If one now restricts the median to a rapidity strip around the jet, the (blue) triangles, or if one uses rapidity rescaling, the (black) circles, the residual shift is very close to 0 , typically a few hundreds of MeV , and flat in rapidity.

Note that the strip-range approach seems to have a small residual rapidity dependence and overall offset for high- $p_{t}$ processes or multi-jet situations. That last point, more clearly observed with some

[^162]

Fig. 106: Residual average shift as a function of the jet rapidity for all the considered subtraction methods. For the left (resp. centre, right) plot, the hard event sample consists of dijets with $p_{t} \geq 50 \mathrm{GeV}$ (resp. dijets with $p_{t} \geq 400 \mathrm{GeV}$, and jets above $p_{t} \geq 50 \mathrm{GeV}$ in $t \bar{t}$ events), generated with Pythia 8 (tune 4 C ) in all cases. The typical PU contamination (for unsubtracted jets) is around 5 GeV .

Monte-Carlo generators like Pythia 6 than with others, may be due to the fact that smaller ranges tend to be more affected by the presence of the hard jets (see e.g. Appendix A. 2 of [486]), an effect which is reinforced for multi-jet events. The fact that the residual shift seems a bit smaller for grid-based estimates will be discussed more extensively in the next Section.

Next, we turn to the dispersion of $\Delta p_{t}$, a direct measure of the impact of PU fluctuations on the $p_{t}$ resolution of the jets. Our results are plotted in Fig. 107 as a function of the rapidity of the hard jet (left panel), the number of PU vertices (central panel) and the transverse momentum of the hard jet (right panel). All subtraction methods have been included as well as the dispersion one would observe if no subtraction were performed.

The results show a clear trend: first, a subtraction based on the number of seen PU vertices bring an improvement compared to not doing any subtraction; second, median-based estimations of $\rho$ give a more significant improvement; and third, all median-based approaches perform similarly well.

The reason why median-based estimations of $\rho$ outperform the estimation based on the number of seen PU vertices is simply because minimum bias events do not all yield the same energy deposit and this leads to an additional source of fluctuations in the "seen vertices" estimation compared to all median-based ones. This is the main motivation for using an event-by-event determination of $\rho$ based on the energy deposited in the event. This motivation is further strengthened by the fact that additional issues like vertex resolution or out-of-time PU would affect both $\left\langle\Delta p_{t}\right\rangle$ and $\sigma_{\Delta p_{t}}$ if estimated simply from the number of seen vertices while median-based approaches are more robust.

Note finally that even though local ranges and rapidity rescaling do correct for the rapidity dependence of the PU on average, the dispersion still depends on rapidity. The increase with the number of PU vertices is in agreement with the expected $\sqrt{n_{\mathrm{PU}}}$ behaviour and the increase with the $p_{t}$ of the hard process can be associated with back-reaction, see [486]. These numbers can also be compared to the typical detector resolutions which would be $\sim 10 \mathrm{GeV}$ for 100 GeV jets and $\sim 20 \mathrm{GeV}$ at $p_{t}=400 \mathrm{GeV}$ [490, 491].

### 20.34 Robustness and Monte-Carlo dependence

The last series of results we want to present addresses the stability and robustness of the median-based estimation of the PU density per unit area.

To do that, the first thing we shall discuss is the Monte-Carlo dependence of our results. In Fig.

Fig. 107: Dispersion $\sigma_{\Delta p_{t}}$. Each curve corresponds to a different subtraction method and the results are presented as a function of different kinematic variables: left, as a function of the rapidity of the hard jet for a sample of jets with $p_{t} \geq 100 \mathrm{GeV}$ and assuming an average of 10 PU events; centre: as a function of the number of PU events for a sample of jets with $p_{t} \geq 100$; right: as a function of the $p_{t}$ of the hard jet, assuming an average of 10 PU events

Fig. 108: Dependence of the average $p_{t}$ shift as a function of the number of PU vertices for various Monte-Carlo generators. For the left plot, the hard sample is made of dijets with $p_{t} \geq 100 \mathrm{GeV}$ while for the right plot, we have used a hadronic $t \bar{t}$ sample. For each generator, we have considered both the case with the Underlying Event switched on (filled symbols) and off (open symbols). All results have been obtained using a grid-based median estimation of $\rho$ using rapidity rescaling.

Fig. 109: Average residual shift after PU subtraction. $\left\langle\Delta p_{t}\right\rangle$ is plotted as a function of the $p_{t}$ of the jet for an average of 10 PU events (left panel), or as a function of the number of PU vertices for dijets with $p_{t} \geq 100 \mathrm{GeV}$ (central panel) and for $t \bar{t}$ events (right panel). In all cases, we compare 3 methods: the rapidity-strip range, (red) triangles, the jet-based approach with $y$-rescaling, (blue) circles, and the gridbased approach with $y$ rescaling, (black) squares. Each curve is the result of averaging over the various Monte-Carlo generator options and the dispersion between them is represented both as error bars on the top row and directly on the bottom row.

108 we compare the different Monte-Carlo predictions for the $\left\langle\Delta p_{t}\right\rangle$ dependence on the number of PU vertices in the case of a grid-based median estimate of $\rho$ with rapidity rescaling. For each of the three considered Monte-Carlos, we have repeated the analysis with and without Underlying Event (UE) in the hard event. The first observation is that all the results span a range of $300-400 \mathrm{MeV}$ in $\Delta p_{t}$ and have a similar dependence on the number of PU vertices. The dependence on $n_{\mathrm{PU}}$ is flat for dijet events but shows a small decrease for the busier $t \bar{t}$ events. The $300-400 \mathrm{MeV}$ shift splits into a $100-200 \mathrm{MeV}$ effect when changing the generator, which is likely due to the small but non-zero effect of the hard event on the median computation, and a $100-200 \mathrm{MeV}$ effect coming from the switching on/off of the UE.

This question of subtracting the UE deserves a discussion: since the UE is also a soft background which is relatively uniform, it contributes to the median estimate and, therefore, one expects the UE, or at least a part of it, to be subtracted together with the PU. Precisely for that reason, when we compute $\Delta p_{t}$, our subtraction procedure is not applied only on the "full jet" (hard jet+PU) but also on the hard jet, see Eq. 20.3.1. The $100-200 \mathrm{MeV}$ negative shift observed in Fig. 108 thus means that, when switching on the UE, one subtracts a bit more of the UE in the full event (with PU) than in the hard event alone (without PU). This could be due to the fact (see [492] for details) that for sparse events, as is typically the case with UE but no PU, the median tends to slightly underestimate the "real" $\rho$, e.g. if half of the event is empty, the median estimate would be 0 . This is in agreement with the fact that for $t \bar{t}$ events, where the hard event is busier, switching on the UE tends to have a smaller effect. Note finally that as far as the size of the effect is concerned, this $100-200 \mathrm{GeV}$ shift has to be compared with the $\sim 1 \mathrm{GeV}$ contamination of the UE in the hard jets.

Finally, we wish to compare the robustness of our various subtraction methods for various processes i.e. hard events and PU conditions. In order to avoid multiplying the number of plots, we shall treat the Monte-Carlo (including the switching on/off of the UE) as an error estimate. That is, an average measure and an uncertainty will be extracted by taking the average and dispersion of the 6 Monte-Carlo setups. The results of this combination are presented on Fig. 109 for various situations and subtraction

Fig. 110: Left: relative difference between the reconstructed jet and the reconstructed $Z$ boson transverse momenta. Right: at a given $p_{t}$ of the reconstructed $Z$ boson, difference between the reconstructed $p_{t}$ of the jet and the ideal $p_{t}$ with no UE or PU, i.e. $p_{t}$ shift w.r.t. the "noUE" curve, the (black) triangles, on the left panel. See the text for the details of the analysis.
methods. For example, the 6 curves from the left plot of Fig. 108 have been combined into the (black) squares of the central panel in Fig. 109 .

Two pieces of information can be extracted from these results. First of all, for dijets, the quality of PU subtraction is, to a large extent, flat as a function of the $p_{t}$ of the jets and the number of PU vertices. When moving to multi-jet situations, we observe an additional residual shift in the $100-300 \mathrm{MeV}$ range, extending to $\sim 500 \mathrm{MeV}$ for the rapidity-strip-range method. This slightly increased sensitivity of the rapidity-strip-range method also depends on the Monte-Carlo. While in all other cases, our estimates vary by $\sim 100 \mathrm{MeV}$ when changing the details of the generator, for multi-jet events and the rapidity-strip-range approach this is increased to $\sim 200 \mathrm{MeV}$.

Overall, the quality of the subtraction is globally very good. Methods involving rapidity rescaling tends to perform a bit better than the estimate using a rapidity strip range, mainly a consequence of the latter's greater sensitivity to multi-jet events. In comparing grid-based to jet-based estimations of $\rho$, one sees that the former gives slightly better results, though the differences remain small.

Since the grid-based approach is considerably faster than the jet-based one, as it does not require an additional clustering of the even ${ }^{57}$, the estimation of $\rho$ using a grid-based median with rapidity rescaling comes out as a very good default for PU subtraction. One should however keep in mind local-range approaches for the case where the rapidity rescaling function cannot easily be obtained.

### 20.4 PU v. UE subtraction: an analysis on $Z+j e t$ events

To give further insight on the question of what fraction of the Underlying Event gets subtracted together with the pileup, we have performed an additional study of $Z+$ jet events. We look at events where the $Z$ boson decays into a pair of muons. We have considered 5 different situations: events without PU or UE, events with UE but no PU subtracted or not, and events with both UE and PU again subtracted or not. Except for the study of events without UE, this analysis could also be carried out directly on data.

Practically, we impose that both muons have a transverse momentum of at least 20 GeV and have $|y| \leq 2.5$, and we require that their reconstructed invariant mass is within 10 GeV of the nominal $Z$

[^163]mass. As previously, jets are reconstructed using the anti- $k_{t}$ jet algorithm and the pileup subtraction is performed using the grid-based-median approach with rapidity rescaling and a grid size of 0.55 . All events have been generated with Pythia 8 (tune 4C) and we have assumed an average PU multiplicity of 20 events.

In Fig. 110, we have plotted the ratio $p_{t, \text { jet }} / p_{t, Z}-1$, with $p_{t, \text { jet }}$ the transverse momentum of the leading jet, for the various situations under considerations. Compared to the ideal situation with no PU and no UE, the (black) triangles, one clearly sees the expected effect of switching on the UE, the empty (green) circles, or adding PU, the empty (red) squares: the UE and PU add to the jet $\sim 1.2$ and 13 GeV respectively.

We now turn to the cases where the soft background is subtracted, i.e. the filled (blue) squares and (magenta) circles, for the cases with and without PU respectively. There are two main observations:

- with or without PU, the UE is never fully subtracted: from the original $1-1.5 \mathrm{GeV}$ shift, we do subtract about 800 MeV to be left with a $0-500 \mathrm{MeV}$ effect from the UE. That effect becomes smaller and smaller when going to large $p_{t}$.
- in the presence of PU, the subtraction produces results very close to the corresponding results without PU and where only the UE is subtracted. This nearly perfect agreement at large $p_{t, \text { jet }}$ slightly degrades into an additional offset of a few hundreds of MeV when going to smaller scales. This comes about for the following reason: the non-zero $p_{t}$ resolution induced by pileup (even after subtraction) means that in events in which the two hardest jets have similar $p_{t}$, the one that is hardest in the event with pileup may not correspond to the one that is hardest in the event without pileup. This introduces a positive bias on the hardest jet $p_{t}$ (a similar bias would be present in real data even without pileup, simply due to detector resolution). The "matched" curve in Fig. 110 (right) shows that if, in a given hard event supplemented with pileup, we explicitly use the jet that is closest to the hardest jet in that same event without pileup, then the offset disappears, confirming its origin as due to resolution-related jet mismatching.

### 20.5 Conclusions and discussion

In these proceedings, we have investigated several methods to correct for the pile-up contamination to jets. They are all based on the observation that the average PU contribution to a jet is on average proportional to its area, which directly leads to eq. 20.2.2. The various methods then differ by the method used to estimate the PU activity per unit area, $\rho$. The subtraction efficiency has been studied by embedding hard events into PU backgrounds and investigating how jet reconstruction was affected by measuring the remaining $p_{t}$ shift after subtraction $\left(\left\langle\Delta p_{t}\right\rangle\right)$ as well as the impact on resolution ( $\sigma_{\Delta p_{t}}$ ).

There are 3 broad approaches to the estimation of $\rho$ : (a) using an average contamination per PU vertex, the seen vertices approach, (b) using an event-by-event estimation and, the median approach with jets or grid cells as patches, and (c) using an event-by-event and jet-by-jet method, the local range or rescaling approaches.

The first important message is that, though all methods give a very good overall subtraction $\left(\left\langle\Delta p_{t}\right\rangle \approx 0\right.$ ), event-by-event methods should be preferred because their smaller PU impact on the $p_{t}$ resolution (see Fig. 107). This is mostly because the "seen vertices" method has an additional smearing coming from the fluctuations between different minimum bias collisions. This does not happen in event-by event methods that are only affected by point-to-point fluctuations in an event. Note also that event-by-event methods are very likely more robust than methods based on identifying secondary vertices when effects like vertex identification and out-of-time PU are taken into account.

The next observation is that event-by-event and jet-by-jet methods have the additional advantage that they correct for positional-dependence of the background like its rapidity dependence (see Fig. 106). The median approach using a local range (with jets as patches) or rapidity rescaling (using jets or grid cells as patches) all give an average offset in the $0-300 \mathrm{MeV}$ range, independently of the rapidity of
the jet, its $p_{t}$ or the number of PU vertices, see Fig. 109 and are thus very suitable methods for PU subtraction at the LHC. Pushing the analysis a bit further one may argue that the local-range method has a slightly larger offset when applied to situations with large jet multiplicity like $t \bar{t}$ events (the right panel of Fig. (109) though this argument seems to depend on the Monte-Carlo used to generate the hard-event sample. Also, since it avoids clustering the event a second time, the grid-based method has the advantage of being faster than the jet-based approach.

At the end of the day, we can recommend the median-based subtraction method with rapidity rescaling and using grid cells as patches as a powerful default PU subtraction method at the LHC. But one should keep in mind that the use of jets instead of grid cells also does a very good job and that local-ranges can be a good alternative to rapidity rescaling if the rescaling function cannot be computed. Also, though we have not discussed that in detail, a grid cell size of 0.55 is a good default as is the use of $k_{t}$ jets with $R=0.4$.

To conclude, let us make a few general remarks. First, our suggested method involves relatively few assumptions, which helps ensure its robustness. Effects like in-time v. out-of-time PU or detector response should not have a big impact. Many of the studies performed here can be repeated with "real data" rather than Monte-Carlo simulations. The best example is certainly the $Z+$ jet study of Section 20.4 which could be done using data samples with different PU activity from 2010 and 2011. Also, the rapidity rescaling function can likely be obtained from minimum bias collision data and the embedding of a hard event into pure PU events could help quantifying the remaining $\mathcal{O}(100 \mathrm{MeV})$ bias. Experimentally, it would also be interesting to investigate hybrid techniques where one would discard the charged tracks that do not point to the primary vertex and apply the subtraction technique described here to the rest of the event. This would have the advantage to further reduce fluctuation effects (roughly by a factor $\sim \sqrt{1 /\left(1-f_{\mathrm{chg}}\right)} \approx 1.6$, where $f_{\mathrm{chg}} \approx 0.61$ is the fraction of charged particles in an event). Finally, all the facilities to compute jet areas and background estimation - including jets or grid-cells as patches, local ranges and rescaling functions - are readily available from FastJet (v3.0.0 onward) using e.g. the GridMedianBackgroundEstimator or Subtractor tools.

## Part VI

## MC TUNING AND OUTPUT FORMATS

## 21. TUNE KILLING: QUANTITATIVE COMPARISONS OF MC GENERATORS AND TUNES ${ }^{58}$

#### Abstract

We summarise the implementation, status, and scope of the "tune killing" project, which classifies MC generator codes and tunes according to their quality of data description across a range of LHC-relevant observables. The primary aim of the project is to provide sufficiently clear information about generator performance that the current large collection of available tunes may be objectively reduced to a more manageable standard set for common use by LHC experiments and phenomenologists. We make final recommendations as

[^164]to which generators and tunes are in rude health, and those which are obvious candidates for retirement from active service.

### 21.1 INTRODUCTION

Popular MC generators are nowadays associated with a bewildering array of standard parameter configurations, called "tunes". This proliferation of tunes is due to the ongoing project to provide optimised descriptions of LEP, Tevatron and LHC data: as new data and techniques have become available, new tunes have been created, usually but not always with increasing quality of data description. This process looks set to continue, and hence there is a need for agreement on which tunes are of most common interest at a given time.
The PYTHIA6 [400] event generator in particular has been the de facto testbed for tuning due to the wealth of community expertise and its ubiquity of tuning parameters for physical processes. At the time of writing there are 77 tunes available via the built-in PYTUNE routine, and a further 10 or more presented by the ATLAS experiment alone (this counting of ATLAS tunes includes equivalently weighted tunes for multiple PDFs, but not systematic variation tunes, of which there are many more). With such a profligacy of configuration options, it is difficult to objectively decide which are to be preferred for LHC simulation without manually cross-referencing hundreds of plots. It is hence not uncommon for different experimental or phenomenological studies to use entirely disjoint MC generator setups, making comparison difficult. Ideally we would have a much smaller set of agreed-upon generator setups, but choosing such a privileged subset requires clear information on which to base our preferences.
As a first step to addressing this issue, we present here a comparative study of event generator codes and tunes across a range of observables, particularly those of relevance for LHC physics. The study is based on analyses from the Rivet [360] toolkit, and the resulting data descriptions are quantitatively scored based on measures of deviation from the data values, including $\chi^{2}$ and median/maximum binwise deviations (in units of combined experimental, statistical, and theoretical uncertainties). The results are presented as a series of Web pages, using colour coded tables which are hyperlinked to provide the necessary information in a compact, hierarchical form.

### 21.2 Analysis system

The data analysed for this project was produced by individual runs of various generator/tune configurations into the Rivet analysis system. A choice of Rivet analyses was made, intended to cover a number of core QCD modelling aspects for LHC physics: these are documented in Table 16. In some cases only the most relevant range in the distribution is included, as indicated in the Table. The generators and tunes used are documented in Table 17
Note that not all observables are suitable for all generators. For example, AlpGen has not been used for LEP fragmentation, although in a future iteration we will extend the AlpGen coverage to include underlying event observables, where the hard jets could interfere with those from the multiple parton interaction (MPI) mechanism. Several observables, notably hard photon physics, minimum bias observables, and fragmentation/strangeness from RHIC and LHC have not yet been included: this is envisaged as a future extension of the project.
A Python program was written to load the histogram files for each generator/tune combination from a hierarchical directory structure, and to perform some basic statistical characterisation on each bin, histogram, and semantic group of histograms. At the histogram level, specifications are used to determine which bins are to be considered in the statistical comparisons, and to add a nominal "theoretical uncertainty". In this study a $10 \%$ theoretical uncertainty was added to the underlying event and fragmentation observables and a $5 \%$ theoretical uncertainty on the rest. The combined uncertainty for each bin $b$ is then computed from the sum in quadrature of the reference data error, the MC statistical error and the theoretical uncertainty, and is used to compute a MC-data deviation for that bin, expressed in units of

the total bin error, $\operatorname{dev}_{b}=\left(\mathrm{MC}_{b}-\operatorname{data}_{b}\right) / \operatorname{err}_{b}$.
For each active histogram, the system then reports the $\chi^{2} / N_{\text {bin }}$, and the median, mean, and maximum bin-wise deviation. A total "metric" value for each histogram is reported as the maximum bin-wise deviation if that is greater than $10 \sigma$, otherwise the greater of the median and mean deviations. This hybrid treatment of the metric allows the system to flag up histograms in which there are either widespread moderate deviations or a small number of very discrepant bins which might be missed with a pure median or mean deviation treatment. An HTML table and set of histograms are rendered by the system for each observable, with a continuous colour coding scheme used to highlight the relative quality of data description from ideal (green) to very poor (red).
The histograms are grouped to collect together observables from different sources which reflect related aspects of QCD modelling. The current groups are "Underlying Event (UE)", "Dijets", "Multijets", "Jet shapes", "W and Z", "Fragmentation", and " $B$ fragmentation". In these groups, the same $\chi^{2} / N_{\text {bin }}$, and mean/median/maximum deviation statistics are calculated as before. For visual compactness of classification we again use a hybrid performance metric for each histogram group: again this is the maximum bin-wise deviation found in the contained histograms if that is greater than $10 \sigma$, otherwise the maximum histogram-wise deviation metric in the group if that is greater than $5 \sigma$, otherwise the maximum of the median/mean bin-wise deviation.
The Web pages generated to present this data in a compact way consist of a single top level page containing a colour-coded table of tune performance metrics for each histogram group. Each cell in the table is hyperlinked to a more detailed table for that tune/group where the various $\chi^{2} / N$, max/mean/median deviation and hybrid metric are presented, again colour-coded, for each histogram in the group. The table rows are then hyperlinked to a plot page showing explicitly the tune/generator behaviour for each histogram and indicating the active range of the histograms where appropriate. These pages are shown in Figures 111 to 113 . This form of presentation allows a rapid assessment of generator/tune performance, while still permitting detailed investigation of any flagged-up issues with a few mouse clicks. The system is easily extensible to more observables, groups, and different theory uncertainty / visual classification thresholds.
The classification colours for each performance figure are generated in HSB colour space as a linear variation in deviation $x$ between green (120) and red (0) in the Hue parameter, i.e. $H=120(1-$ $\left.\min \left(x / x_{\text {bad }}, 1.0\right)\right)$, with fixed Saturation and Brightness parameters. The visual threshold $x_{\text {bad }}$ was chosen to be different for each metric type: $5 \sigma$ for maximum deviations, $4 \sigma$ for $\chi^{2} / N$, and $2 \sigma$ for mean and median deviations, and for the hybrid performance metrics. These thresholds were iterated from initial suggestions to the point where distinctions could be made between the models: similar iteration of the discriminating criteria are envisaged while significant model/tune variations exist as the motivation of this study is model discrimination rather than passing or failing a natural performance figure.

### 21.3 Results

As the central theme of this project has been to provide a comprehensible visualisation of the relative performance of generators and tunes, and hierarchical presentation via Web pages was key to achieving this, it would be self-defeating to attempt to present the same information in this summary. Additionally, the nature of tune comparison is that it evolves as new data, tunes, and generator versions become available. Hence, for up-to-date status information we refer the reader to the persistent "tune killing" web page at http:/ /projects.hepforge.org/rivet/tunecmp/.
However, it is worth mentioning some of the most striking features of generators which have been made more evident by this collating of data-MC comparisons:

- The general quality of jet and W/Z data description is in fact better than expected: among PYTHIA tunes in particular there is sufficient variation in parton shower parameters that significant deviations in jet observables would reasonably be expected, but in fact the majority of tunes describe

data fairly well.

- The UE in particular has been a focus of tuning activity and this is evident in the consistency of UE data description. The worst performance in this group is from the DW tune of PYTHIA, but even this pre-LHC tune with the "old" PYTHIA MPI model achieves a deviation metric of less than $1 \sigma$ on LHC UE observables.
- PYTHIA D6T outperforms PYTHIA DW - an unexpected result since the MPI energy evolution of D6T is fixed to the default and disfavoured form $p_{\perp}^{0}(s) \sim(\sqrt{s} / 1800 \mathrm{GeV})^{0.16}$, whereas the exponent in DW is closer to the tuned consensus of $\sim 0.25$. This may be a lucky behaviour at 7 TeV , and hence care is needed with extrapolation of D6T to 8,10 , or 14 TeV , but it is clear that the PYTHIA $Q^{2}$-ordered parton shower is not yet dead on purely physics grounds. The best tune of this PYTHIA configuration, however, is Prof- $Q^{2}$, which in addition to general small improvements, is significantly better than DW or D6T at describing the vector boson $p_{\perp}$ distribution.
- Pythia8 is generally seen to perform very well, and provides significant improvements over PYTHIA6 for jet shapes and $B$ fragmentation. Tuning focus is accordingly beginning to shift towards Pythia8, also for minimum bias observables not yet considered here.
- AlpGen interacts strongly with tunes on jet shape and vector boson data descriptions. In particular there appears to be little motivation to use AlpGen with the D6T or Perugia 2010 tunes of PYTHIA6. AlpGen+HERWIG also has significant problems with jet shapes in particular, and the indication of this study is that AlpGen+PYTHIA Perugia 2011 is the most performant configuration, closely followed by AlpGen+PYTHIA Z2. Notably, the Perugia 2011 tune of PYTHIA was specifically developed to minimise ME/PS merging artefacts when used with AlpGen.
- Both HERWIG and Herwig++ have problems describing LEP fragmentation data, but Herwig++ is a very significant improvement over its Fortran cousin. The identified hadron rates are in particular much improved, although $K^{ \pm}$and $\Sigma^{0}$ remain anomalous. However, a known problem with Herwig++ is the poor description of the LEP thrust distribution, which overshoots significantly in the multi-parton region.
- AlpGen seems to have difficulty describing dijet azimuthal decorrelations, even when restricted to the $2 / 3$ parton region of the plot. This is particularly surprising as AlpGen is intended to provide
the multi-parton configurations needed to describe this observable.
- $B$ fragmentation is in general quite poorly described. The best descriptions are by Pythia8, the AUET2B tunes of PYTHIA6, and Herwig++. Other generators and tunes are in decidedly dodgy shape for $B$-specific predictions at the LHC.
Insofar as it is within the scope of this project to make recommendations for canonical generator and tune choices, we note that the Perugia 2011, AUET2B, and Z 2 tunes of PYTHIA6 provide the best data descriptions currently available with that generator and that the Prof- $Q^{2}$ tune is the best available configuration using the $Q^{2}$-ordered PYTHIA parton shower. We hence recommend these 4 PYTHIA tunes as the current minimal set of PYTHIA tunes for general use at the LHC, particularly once an update of the ATLAS AUET2B tune has fixed the tuning issue with the $Z p_{\perp}$.
Among the other generators, where there is not such a proliferation of tunes, we note again the apparent performance issues with AlpGen - this is clearly in need of further pursuit. However, to reduce the amount of comparison needed, we note that Perugia 2011 is the only PYTHIA6 tune now optimised for use with AlpGen with avoidance of the worst effects of ME/PS coupling mismatches: hence future studies can quite happily restrict themselves to this AlpGen+PYTHIA configuration. As AlpGen+HERWIG has several problems with jet description, HERWIG itself has serious problems with both light and $B$ fragmentation, and no further tuning of the JIMMY MPI model is envisaged, the HERWIG generator cannot be recommended for future use in any capacity where an alternative exists.
The "new" C++ generators Herwig++, Pythia8, and Sherpa all perform well, with the exception of Sherpa's $B$ fragmentation and the Herwig++ light fragmentation. Pythia8 generally behaves well but some tuning or development may be needed to improve inter-jet observables and the $Z p_{\perp}$ spectrum. In general, the $\mathrm{C}++$ generators are in good health, and we anticipate further improvements as the focus of tuning studies shifts to them.

### 21.4 Outlook

This project has put in place a system and a set of classification criteria which have proven useful for summarising and investigating MC generator model and tune predictivity for a variety of QCD phenomena. While we claim no mandate to truly "kill" certain tunes or generators, and wish to emphasise that a poor performance in a single observable type (in particular $B$ fragmentation) certainly does not render that generator useless, the results from these comparisons do provide strong arguments for deprecation of at least several PYTHIA6 tunes and of the Fortran HERWIG generator in general.
It is the nature of a project like this that results are continually being updated, and there are many natural avenues for extension which we wish to pursue, in particular:

- Extra observables, e.g. minimum bias and $E_{\perp}$ flow, LHC and Tevatron photon physics, LHC $W / Z$ $p_{\perp}$ data, strangeness data from LHC and RHIC, explicit multijet observables, etc..
- Extra generators and tunes, in particular POWHEG+PYTHIA/HERWIG/Pythia8/Herwig++, MadGraph+PYTHIA/Pythia8, MC@NLO+HERWIG/Herwig++. Comparison between Sherpa with the CTEQ6.6 and CTEQ6L1 PDFs. New Pythia8 and PYTHIA6 tunes from ATLAS.
Greater automation of the data generation will be important, as finding resources (human rather than $\mathrm{CPU}!$ ) to produce and run combinatoric numbers of generator/tune/PDF/observable combinations has been troublesome. We suggest that this project can make use of the output of the CERN LPCC MCplots system (also Rivet-based) for future extension. We also look forward to a forthcoming major upgrade of the Rivet histogramming system which will greatly simplify the treatment of multi-leg generators for which the $n$-parton samples must be explicitly merged, e.g. AlpGen, MadGraph, etc.

## 22. COMPACT ASCII OUTPUT FORMAT FOR HEPMC 59

## Abstract

[^165]We discuss the possibility of reducing the footprint of HepMC event files. Different compression options are discussed, and a suggestion for an update of the HepMC ASCII file format is presented.

### 22.1 Introduction

The HepMC [509] event record has become the de-facto standard for communicating events between event generators and different kinds of analysis programs. HepMC also provides an ASCII-based file format for storing and retrieving events to and from disk, which has also become the standard. This file format is not at all optimized for size, and although disk space today is fairly cheap, there are still problems associated with handling very large files.
A typical minimum-bias 7 TeV LHC HepMC event occupies around 50 kB when written on disk. More interesting events are usually bigger than this and one would typically want to store many events to get anywhere near the statistics collected by any of the LHC experiments; it is clear that such event files will become very large and difficult to handle. Even with standard compression algorithms such as gzip and bzip2, where these file sizes can be reduced by a factor 3 or more, the problem is still substantial.
One could imagine using a binary output format to reduce the event size. Writing a 4 byte floating point number in an ASCII file typically takes 10-12 characters, so here one could expect to reduce file sizes up to a factor 3 . However, standard compression algorithms are rather good at identifying strings of numbers and compressing them, so there is normally not much to be gained by using a compressed binary format compared to a compressed ASCII one. In addition one would lose the advantage of ASCII files that they are (somewhat) readable to the human eye.
Instead the key to reducing file sizes is to remove redundant and unnecessary information stored in the files. This could involve completely reversible operations such as removing the information about the momentum of an intermediate particle, as this can be reconstructed from its decay products. It could also involve irreversible operations such as reducing the precision on the momenta. In the following we describe a number of such operations, which allows us to reduce the file sizes by almost a factor 30 .

### 22.2 The Benchmarking procedure

We started out by generating 1000 non-diffractive QCD events with Pythia 6.425[400] using the AGILe [360] interface. The resulting file size was 48 MB , which can be reduced to 16 MB or 13 MB using gzip or bzip2 respectively. We then investigated several ways of reducing this size.

Removing irrelevant particles The HepMC format contains quite a lot of information about how the event was generated, such as intermediate particles in the hard sub process, which may be generatordependent (and often unphysical) and is not relevant when comparing to experimental data. In principle one could argue that the only thing that should be written out is final-state stable particles (with HepMC status code 1). However, there are circumstances where information about intermediate unstable hadrons (status code 2) is relevant. The AGILe event generator interface already includes facilities for keeping only particle entries with status code 1 or 2.

Reconstructible information Some information in the HepMC file is redundant in the sense that it can be reconstructed from other information in the file. Here are some examples.

- Both energy, momentum and invariant mass of each particle is written out. Clearly, we can eg. reconstruct the energy given the three-momentum and mas $5^{60}$.

[^166]| Format | Status codes | no comp. <br> (MB) | gzip <br> (MB) | bzip2 <br> (MB) |
| :--- | ---: | ---: | ---: | ---: |
| Standard | All | 48 | 16 | 13 |
|  | $1 \& 2$ | 43 | 15 | 13 |
|  | 1 | 17 | 6.0 | 4.8 |
| Compact | All | 18 | 3.3 | 2.1 |
|  | $1 \& 2$ | 13 | 2.9 | 1.9 |
|  | 1 | 4.0 | 1.9 | 1.6 |
| Compact binary | 1 | 1.8 | 1.7 | 1.7 |

Table 18: Size of the benchmark file after applying different compression methods.

- The three-momenta of decayed hadrons (status code 2 ) can be reconstructed from the sum of the momenta of the decay products.
- The mass of a stable particle can be deduced from the particle ID.
- The position of a vertex can be deduced from the previous vertex position and the life-time and momentum direction of the connecting particle.
- Each particle in a HepMC event has a unique bar code, which is an otherwise arbitrary integer. No loss of information would result from renumbering the particles, simply inferring their bar code from the order in which they appear in the event.

Precision Clearly, having 8 byte floating point numbers is not very relevant for many of the numbers in an event file. When comparing with experimental data, there is no point in having much larger precision than what is achievable in the experiment, and it makes sense to match the the information in the HepMC file to the precision of the actually measured variables in the experiments.
A possible example is to store masses and transverse momenta as integers in units of 0.1 MeV , azimuthal angles as integers in units of $0.00002 \times \pi$, pseudorapidities as integers in units of 0.00001 and vertex positions as integers in units of 0.001 mm .

### 22.3 Benchmark Results

We have investigated several of the options listed in the previous section, and the resulting file sizes when applied to the benchmark file is presented in table 18 . Firstly we see the size reduction using the standard format and simply reducing the number of particles, keeping only those with status code 2 and 1 or only 1 . Next we present the same results, but using a compact format which keeps the structure of the HepMC ASCII file but applies all optimizations discussed above. Finally, for reference, we present an aggressively compacted Binary format which uses the following optimizations for each particle: stores 1 float for transverse and 1 float for longitudinal momentum, a 3-byte integer for phi, and 1 byte for PDG IDs (rare PDG IDs are written out with 4 full bytes). This format loses the HepMC structure of the event and in some sense this represents the target size, below which it is difficult to go.
It is clear that one does not gain much by using a binary format provided one uses the optimizations presented above together with bzip2 compression algorithm.

### 22.4 Outlook

Given the results above, the work to include a more efficient file format for the HepMC has begun. The suggestion is to keep the current structure of the file format, but to add options to exclude all particles except those with status code 1 (or 2). Furthermore options for the representation and precision of momenta and vertex positions will be included as well as options for excluding (simply replacing with a single exclamation mark for easy parsing) information which can be reconstructed. The new format will be included in a forthcoming HepMC version during 2012.

In this report we have not looked carefully at the time it takes to read the different formats. With the default HepMC format this can be many times larger than the time taken for typical particle-level analyses, while for minimal binary formats it is of the same order. We defer detailed study of this question to future work.

(Received May 14, 2012)
We compute the structure functions $F_{2}$ and $F_{\mathrm{L}}$ in the ACOT scheme for heavy quark production. We use the complete ACOT results to NLO, and make use of the $\overline{\mathrm{MS}}$ massless results at NNLO and $\mathrm{N}^{3} \mathrm{LO}$ to estimate the higher order mass-dependent corrections. We show numerically that the dominant heavy quark mass effects can be taken into account using massless Wilson coefficients together with an appropriate rescaling prescription. Combining the exact NLO ACOT scheme with these expressions should provide a good approximation to the full calculation in the ACOT scheme at NNLO and $\mathrm{N}^{3} \mathrm{LO}$.

## 1. Introduction

The production of heavy quarks in high energy processes has become an increasingly important subject of study both theoretically and experimentally. The theory of heavy quark production in perturbative Quantum Chromodynamics (pQCD) is more challenging than that of light parton (jet) production because of the new physics issues brought about by the additional heavy quark mass scale. The correct theory must properly take into account the changing role of the heavy quark over the full kinematic range of the relevant process from the threshold region (where the quark behaves like

[^167]a typical "heavy particle") to the asymptotic region (where the same quark behaves effectively like a parton, similar to the well known light quarks $\{u, d, s\}$ ).

With the ever-increasing precision of experimental data and the progression of theoretical calculations and parton distribution function (PDF) evolution to next-to-next-to-leading order (NNLO) of QCD, there is a clear need to formulate and also implement the heavy quark schemes at this order and beyond. The most important case is arguably the heavy quark treatment in inclusive deep-inelastic scattering (DIS) since the very precise HERA data for DIS structure functions and cross sections form the backbone of any modern global analysis of PDFs. Here, the heavy quarks contribute up to $30 \%$ or $40 \%$ to the structure functions at small momentum fractions $x$. Extending the heavy quark schemes to higher orders is, therefore, necessary for extracting precise PDFs , and this is a prerequisite for precise predictions of observables at the LHC. However, we would like to also stress the theoretical importance of having a general pQCD framework that includes heavy quarks and is valid to all orders in perturbation theory over a wide range of hard energy scales.

An example, where higher order corrections are particularly important is the structure function $F_{\mathrm{L}}$ in DIS. The leading order $\left(\mathcal{O}\left(\alpha_{\mathrm{S}}^{0}\right)\right)$ contribution to this structure function vanishes for massless quarks due to helicity conservation (Callan-Gross relation). This has several consequences: (1) $F_{\mathrm{L}}$ is useful for constraining the gluon PDF via the dominant subprocess $\gamma^{*} g \rightarrow q \bar{q}$. (2) The heavy quark mass effects of order $\mathcal{O}\left(\frac{m^{2}}{Q^{2}}\right)$ are relatively more pronounced ${ }^{1}$. (3) Since the first non-vanishing contribution to $F_{\mathrm{L}}$ is next-to-leading order (up to mass effects), the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ corrections are more important than for $F_{2}$. In Fig. 1, we show a comparison of different theoretical calculations of $F_{\mathrm{L}}$ with preliminary HERA data [2]. As can be seen, in particular at small $Q^{2}$ (i.e. small $x$ ), there are considerable differences between the predictions.

The purpose of this paper is to calculate the leading twist neutral current DIS structure functions $F_{2}$ and $F_{\mathrm{L}}$ in the ACOT factorization scheme up to order $\mathcal{O}\left(\alpha_{\mathrm{S}}^{3}\right)\left(\mathrm{N}^{3} \mathrm{LO}\right)$ and to estimate the error due to approximating the heavy quark mass terms $\mathcal{O}\left(\alpha_{\mathrm{S}}^{2} \times \frac{m^{2}}{Q^{2}}\right)$ and $\mathcal{O}\left(\alpha_{\mathrm{S}}^{3} \times \frac{m^{2}}{Q^{2}}\right)$ in the higher order corrections. The results of this study form the basis for using the ACOT scheme in NNLO global analyses and for future comparisons with precision data for DIS structure functions.

[^168]

Fig. 1. $F_{\mathrm{L}}$ vs. $Q$ from combined HERA-I inclusive deep inelastic cross sections measured by the H1 and ZEUS collaborations. Figure taken from Ref. [2].

This paper is organized as follows. In Sec. 2, we review theoretical approaches to include heavy flavors in QCD calculations. Particular emphasis is put on the ACOT scheme which is a minimal extension of the $\overline{\mathrm{MS}}$ scheme. In Sec. 3, we present the prescription for constructing the approximate DIS structure functions in the ACOT scheme up to $\mathcal{O}\left(\alpha_{S}^{3}\right)$ order. The corresponding numerical results are presented in Sec. 4. Finally, in Sec. 5 we summarize the main results. This work is based on Ref. [3], and further details can be found therein.

## 2. Review of theoretical methods

We review theoretical methods which have been advanced to improve existing QCD calculations of heavy quark production, and the impact on recent experimental results.

### 2.1. ACOT Scheme

The ACOT renormalization scheme $[4,5]$ provides a mechanism to incorporate the heavy quark mass into the theoretical calculation of heavy quark production both kinematically and dynamically. In 1998, Collins [6] extended the factorization theorem to address the case of heavy quarks; this work provided the theoretical foundation that allows us to reliably compute heavy quark processes throughout the full kinematic realm.

If we consider the DIS production of heavy quarks at $\mathcal{O}\left(\alpha_{\mathrm{S}}^{1}\right)$ this involves the LO $Q V \rightarrow Q$ process and the NLO $g V \rightarrow Q \bar{Q}$ process $^{2}$. The key ingredient provided by the ACOT scheme is the subtraction term (SUB) which removes the "double counting" arising from the regions of phase space, where the LO and NLO contributions overlap. Specifically, at NLO order, we can express the total result as a sum of

$$
\begin{equation*}
\sigma_{\mathrm{TOT}}=\sigma_{\mathrm{LO}}+\left\{\sigma_{\mathrm{NLO}}-\sigma_{\mathrm{SUB}}\right\}, \tag{1}
\end{equation*}
$$

where the subtraction term for the gluon-initiated processes is

$$
\begin{equation*}
\sigma_{\mathrm{SUB}}=f_{g} \otimes \tilde{P}_{g \rightarrow Q} \otimes \sigma_{Q V \rightarrow Q} \tag{2}
\end{equation*}
$$

$\sigma_{\text {SUB }}$ represents a gluon emitted from a proton $\left(f_{g}\right)$ which undergoes a collinear splitting to a heavy quark $\left(\tilde{P}_{g \rightarrow Q}\right)$ convoluted with the LO quarkboson scattering $\sigma_{Q V \rightarrow Q}$. Here, $\tilde{P}_{g \rightarrow Q}(x, \mu)=\frac{\alpha_{\mathrm{S}}}{2 \pi} \ln \left(\mu^{2} / m^{2}\right) P_{g \rightarrow Q}(x)$, where $P_{g \rightarrow Q}(x)$ is the usual $\overline{\text { MS }}$ splitting kernel, $m$ is the quark mass and $\mu$ is the renormalization scale which we typically choose to be $\mu=Q$.

An important feature of the ACOT scheme is that it reduces to the appropriate limit both as $m \rightarrow 0$ and $m \rightarrow \infty$ as we illustrate below. Specifically, in the limit where the quark $Q$ is relatively heavy compared to the characteristic energy scale $(\mu \lesssim m)$, we find $\sigma_{\mathrm{LO}} \sim \sigma_{\mathrm{SUB}}$ such that $\sigma_{\mathrm{TOT}} \sim \sigma_{\mathrm{NLO}}$. In this limit, the ACOT result naturally reduces to the Fixed-Flavor-NumberScheme (FFNS) result. In the FFNS, the heavy quark is treated as being extrinsic to the hadron, and there is no corresponding heavy quark PDF ( $f_{Q} \sim 0$ ); thus $\sigma_{\mathrm{LO}} \sim 0$. We also have $\sigma_{\mathrm{SUB}} \sim 0$ because this is proportional to $\ln \left(\mu^{2} / m^{2}\right)$. Thus, when the quark $Q$ is heavy relative to the characteristic energy scale $\mu$, the ACOT result reduces to $\sigma_{\text {TOT }} \sim \sigma_{\text {NLO }}$.

Conversely, in the limit where the quark $Q$ is relatively light compared to the characteristic energy scale ( $\mu \gtrsim m$ ), we find that $\sigma_{\text {LO }}$ yields the dominant part of the result, and the "formal" $\mathrm{NLO} \mathcal{O}\left(\alpha_{\mathrm{S}}\right)$ contribution $\left\{\sigma_{\mathrm{NLO}}-\sigma_{\mathrm{SUB}}\right\}$ is an $\mathcal{O}\left(\alpha_{\mathrm{S}}\right)$ correction. In this limit, the ACOT result will reduce to the MS Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS) limit exactly without any finite renormalizations. The quark mass $m$ no longer plays any dynamical role and purely serves as a regulator. The $\sigma_{\text {NLO }}$ term diverges due to the internal exchange of the quark $Q$, and this singularity is canceled by $\sigma_{\text {SUB }}$.

We illustrate the versatile role of the quark mass in Fig. 2 (a), where we display $F_{2}^{c}$ as a function of $Q$ calculated in the ZM-VFNS, FFNS, ACOT, and S-ACOT schemes. We see that the ACOT scheme coincides with the

[^169]FFNS for small $Q$, and the ZM-VFNS for large $Q$. In Fig. $2(\mathrm{~b})$, we plot $F_{2}^{c}$ as a function of the quark mass $m$ for a fixed $Q=10 \mathrm{GeV}$ for the MS ZM-VFNS and ACOT schemes. We observe that when $m$ is within a decade or two of $\mu$, the quark mass plays a dynamic role; however, for $m \ll \mu$, the quark mass purely serves as a regulator and the specific value is not important. Operationally, it means we can obtain the $\overline{\mathrm{MS}} \mathrm{ZM}-V F N S$ result either by (i) computing the terms using dimensional regularization and setting the regulator to zero, or (ii) by computing the terms using the quark mass as the regulator and then setting this to zero.

Fig. 2. (a) $F_{2}^{c}$ for $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable Flavor Number Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical. (b) Comparison of $F_{2}^{c}(x, Q)$ (scaled by $10^{4}$ ) vs. the quark mass $m$ in GeV for fixed $x=0.1$ and $Q=10 \mathrm{GeV}$. The full (red) dots are the full ACOT result, and the solid (blue) line is the massless $\overline{\mathrm{MS}}$ result.

The ACOT scheme is minimal in the sense that the construction of the massive short distance cross sections does not need any observabledependent extra contributions or any regulators to smooth the transition between the high and low scale regions. The ACOT prescription is: (a) calculate the massive partonic cross sections, and (b) perform the factorization using the quark mass as regulator.

It is in this sense that we claim the ACOT scheme is the minimal massive extension of the $\overline{\mathrm{MS}}$ ZM-VFNS. In the limit $m / \mu \rightarrow 0$ it reduces exactly to the $\overline{\mathrm{MS}} \mathrm{ZM}-V F N S$, in the limit $m / \mu \gtrsim 1$ the heavy quark decouples from the PDFs and we obtain exactly the FFNS for $m / \mu \gg 1$ and no finite renormalizations are needed.

### 2.2. S-ACOT

In a corresponding application, it was observed that the heavy quark mass could be set to zero in certain pieces of the hard scattering terms without any loss of accuracy. This modification of the ACOT scheme goes by the name Simplified-ACOT (S-ACOT) and can be summarized as follows [8].

S-ACOT: For hard-scattering processes with incoming heavy quarks or with internal on-shell cuts on a heavy quark line, the heavy quark mass can be set to zero $(m=0)$ for these pieces.

If we consider the case of NLO DIS heavy quark production, this means we can set $m=0$ for the LO terms $\sigma_{Q V \rightarrow Q}$ (incoming heavy quark), and for the SUB terms (on-shell cut on an internal heavy quark line). Hence, the only contribution which requires calculation with $m$ retained is the NLO $g V \rightarrow Q \bar{Q}$ process. Figure 2 (a) displays a comparison of a calculation using the ACOT scheme with all masses retained vs. the S-ACOT scheme; as expected, these two results match throughout the full kinematic region.

It is important to note that the S-ACOT scheme is not an approximation; this is an exact renormalization scheme, extensible to all orders.

### 2.3. ACOT and $\chi$-rescaling

As we have illustrated in Sec. 2.1, in the limit $Q^{2} \gg m^{2}$ the mass simply plays the role of a regulator. In contrast, for $Q^{2} \sim m^{2}$ the value of the mass is of consequence for the physics. The mass can enter dynamically in the hard-scattering matrix element, and can enter kinematically in the phase space of the process.

We will demonstrate that for the processes of interest the primary role of the mass is kinematic and not dynamic. It was this idea which was behind the original slow-rescaling prescription of [9] which considered DIS charm production (e.g., $\gamma c \rightarrow c$ ) introducing the shift $x \rightarrow \chi=x\left[1+\left(m_{c} / Q\right)^{2}\right]$. This prescription accounted for the charm quark mass by effectively reducing the phase space for the final state by an amount proportional to $\left(m_{c} / Q\right)^{2}$.

This idea was extended in the $\chi$-scheme by realizing that (in most cases) in addition to the observed final-state charm quark, there is also an anticharm quark in the beam fragments since all the charm quarks are ultimately produced by gluon splitting $(g \rightarrow c \bar{c})$ into a charm pair. For this case, the scaling variable becomes $\chi=x\left[1+\left(2 m_{c} / Q\right)^{2}\right]$. This rescaling is implemented in the $\mathrm{ACOT}_{\chi}$ scheme, for example $[10,11,12]^{3}$. The factor $\left(1+\left(2 m_{c}\right)^{2} / Q^{2}\right)$ represents a kinematic suppression factor which will suppress the charm process relative to the lighter quarks. Additionally, the $\chi$-scaling ensures the threshold kinematics ( $W^{2}>4 m^{2}+M^{2}$ ) is satisfied; while it is important to satisfy this condition for large $x$, this may prove too restrictive at small $x$, where the HERA data are especially precise.

[^170]To encompass all the above results, we can define a general scaling variable $\chi(n)$ as

$$
\begin{equation*}
\chi(n)=x\left[1+\left(\frac{n m_{c}}{Q}\right)^{2}\right] \tag{3}
\end{equation*}
$$

where $n=\{0,1,2\}$. Here, $n=0$ corresponds to the massless result without rescaling, $n=1$ corresponds to the original Barnett slow-rescaling, and $n=2$ corresponds to the $\chi$-rescaling.

### 2.4. Phase space (kinematic) and dynamic mass

We now investigate the effects of separately varying the mass entering the $\chi(n)$ variable taking into account the phase space constraints and the mass value entering the hard scattering cross section $\widehat{\sigma}(m)$. We call the former mass parameter "phase space (kinematic) mass" and the latter "dynamic mass".

Fig. 3. Comparison of phase space (kinematic) and dynamic mass effects. (a) Comparison of $F_{2}^{c}(x, Q)$ vs. $Q$ for the NLO ACOT calculation for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) using zero dynamic mass $[\widehat{\sigma}(m=0)]$ to show the effect of $n$ scaling; from top to bottom $n=\{0,1,2\}$ (pink, black, purple). (b) Comparison of $F_{2}^{c}(x, Q)$ vs. $Q$ for the NLO ACOT calculation for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). Here we keep the scaling fixed $n=2$ and compare the effect of varying the dynamic mass in the Wilson coefficient. The upper (cyan) curve uses a non-zero dynamic mass $[\widehat{\sigma}(m=1.3)]$ and the lower (purple) curve uses a zero dynamic mass $[\widehat{\sigma}(m=0)]$.

In Fig. $3(\mathrm{a})$, we display $F_{2}^{c}(x, Q)$ vs. $Q$. The family of 3 curves shows the NLO ACOT calculation with $\chi(n)$ scaling using a zero dynamic mass for the hard scattering. We compare this with Fig. 3 (b) which shows $F_{2}^{c}(x, Q)$ in the NLO ACOT scheme using a fixed $n=2$ scaling, but varying the mass used in the hard-scattering cross section. The upper (cyan) curves use a nonzero dynamic mass $\left[\widehat{\sigma}\left(m_{c}=1.3\right)\right]$ and the lower (purple) curves have been obtained with a vanishing dynamic mass $\left[\widehat{\sigma}\left(m_{c}=0\right)\right]$. We observe that the effect of the "dynamic mass" in $\widehat{\sigma}\left(m_{c}\right)$ is only of consequence in the limited region $Q \gtrsim m$, and even in this region the effect is minimal. In contrast, the influence of the phase space (kinematic) mass shown in Fig. 3 (a) is larger than the dynamic mass shown in Fig. 3 (b).

In conclusion, we have shown that (up to $\mathcal{O}\left(\alpha_{\mathrm{S}}\right)$ ) the phase space mass dependence is generally the dominant contribution to the DIS structure functions. Assuming that this observation remains true at higher orders, it is possible to obtain a good approximation of the structure functions in the ACOT scheme at NNLO and $\mathrm{N}^{3} \mathrm{LO}$ using the massless Wilson coefficients together with a non-zero phase space mass entering via the $\chi(n)$-prescription.

### 2.5. Other massive schemes

There are a number of other schemes for incorporating the heavy quark mass terms, and we briefly note a few examples. The Thorne-Roberts (TR) scheme $[14,15]$ and its derivatives (TR') are designed to provide a smooth threshold behavior, and this is implemented by including pieces of the higher order contributions. The FONLL scheme [16] was originally developed to match fixed order calculations with resumed ones in the case of heavy quark hadroproduction; this approach has been generalized and applied to other applications including DIS structure functions [17]. Details and comparisons of these approached is outlined in the 2009 Les Houches Workshop report [18].

## 3. ACOT scheme beyond NLO

In Sec. 2.4, we have shown using the NLO full ACOT scheme that the dominant mass effects are those coming from the phase space which can be taken into account via a generalized slow-rescaling $\chi(n)$-prescription. Assuming that a similar relation remains true at higher orders one can construct the following approximation to the full ACOT result up to $\mathrm{N}^{3} \mathrm{LO}\left(\mathcal{O}\left(\alpha_{\mathrm{S}}^{3}\right)\right)$

$$
\begin{equation*}
\operatorname{ACOT}\left[\mathcal{O}\left(\alpha_{\mathrm{S}}^{0+1+2+3}\right)\right] \simeq \operatorname{ACOT}\left[\mathcal{O}\left(\alpha_{\mathrm{S}}^{0+1}\right)\right]+\mathrm{ZM}^{-\operatorname{VFNS}_{\chi}}\left[\mathcal{O}\left(\alpha_{\mathrm{S}}^{2+3}\right)\right] \tag{4}
\end{equation*}
$$

Here, the massless Wilson coefficients at $\mathcal{O}\left(\alpha \alpha_{\mathrm{S}}^{2}\right)$ and $\mathcal{O}\left(\alpha \alpha_{\mathrm{S}}^{3}\right)$ are substituted for the Wilson coefficients in the ACOT scheme as the corresponding massive coefficients have not yet been computed.

There has been a calculation of neutral current electroproduction (equal quark masses, vector coupling) of heavy quarks at this order by Smith and van Neerven [19] in the FFNS which could be used to obtain the massive Wilson coefficients in the S-ACOT scheme by applying appropriate collinear subtraction terms ${ }^{4}$; however, this is beyond the scope of this paper. For charge current case massive calculations are available at order $\mathcal{O}\left(\alpha \alpha_{\mathrm{S}}\right)$ [21, 22, 23] and partial results at order $\mathcal{O}\left(\alpha \alpha_{\mathrm{S}}^{2}\right)$ [24].

Here, we argue that the massless Wilson coefficients at $\mathcal{O}\left(\alpha \alpha_{\mathrm{S}}^{2}\right)$ together with a $\chi(n)$-prescription provide a very good approximation of the exact result. At worst, the maximum error would be of order $\mathcal{O}\left(\alpha \alpha_{S}^{2} \times\left[\mathrm{m}^{2} / Q^{2}\right]\right)$. However, based on the arguments of Sec. 2.4 we expect the inclusion of the phase space mass effects to contain the dominant higher order contributions so that the actual error should be substantially smaller.

The massless higher order coefficient functions for the DIS structure function $F_{2}$ via photon exchange can be found in Refs. [25, 26, 27, 28, 29, $30,31,32,33,34]$. The expressions for the structure function $F_{\mathrm{L}}$ have been calculated in Refs. [35, 29, 31, 36, 33].

We now consider our choice for the appropriate generalized $\chi(n)$-rescaling variable. For the purposes of this study, we will vary the phase space mass using the $\chi(n)$ rescaling with $n=\{0,1,2\}$. While $n=0$ corresponds to the massless case (no rescaling), it is not obvious whether $n=1$ or $n=2$ is the preferred rescaling choice for higher orders. Thus, we will use the range between $n=1$ and $n=2$ as a measure of our theoretical uncertainty arising from this ambiguity.

## 4. Results

We now present our results for the $F_{2}$ and $F_{\mathrm{L}}$ structure functions calculated at $\mathrm{N}^{3} \mathrm{LO}$ in the extended ACOT scheme. The initial PDFs, based on the Les Houches benchmark set [37] are evolved using the QCDNUM program [38]. In the calculation we set $m_{c}=1.3 \mathrm{GeV}, m_{b}=4.5 \mathrm{GeV}$ and $\alpha_{\mathrm{S}}\left(M_{Z}\right)=0.118$.

In figures 4 (a) and $4(\mathrm{~b})$, we display the structure functions $F_{2}$ and $F_{\mathrm{L}}$, respectively, for selected $x$ values as a function of $Q$. Each plot has three curves which are computed using $n$-scalings of $\{0,1,2\}$. We observe that the effect of the $n$-scaling is negligible except for very small $Q$ values. This result is in part because the heavy quarks are only a fraction of the total structure function, and the effects of the $n$-scaling are reduced at larger $Q$ values.

[^171]

Fig. 4. $F_{2, \mathrm{~L}}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). The three lines show the scaling variable: $n=\{0,1,2\}$ (red, green, blue). We observe the effect of the $n$-scaling is negligible except for very small $Q$ values. (a) $F_{2}$ vs. $Q$. (b) $F_{\mathrm{L}}$ vs. $Q$.

In Ref. [3] we magnify the small $Q$ region of $F_{\mathrm{L}}$ of Fig. 4 (b) for $x=10^{-5}$, where the effects of using different scalings are largest. We can see that for inclusive observables, the $n=1$ and $n=2$ scalings give nearly identical results, but they differ from the massless case $(n=0)$. This result, together with the observation that at NLO kinematic mass effects are dominant, suggests that the error we have in our approach is relatively small and approximated by the band between $n=1$ and $n=2$ results.

We can investigate the effects of the $\chi(n)$-scaling in more details by examining the flavor decomposition of the structure functions. In figures 5 (a) and $5(\mathrm{~b})$, we display the fractional contributions of quark flavors to the structure functions $F_{2, \mathrm{~L}}$ for selected $n$-scaling values as a function of $Q$. We observe the $n$-scaling reduces the relative contributions of charm and bottom at low $Q$ scales. For example, without any $n$-scaling $(n=0)$ we find the charm and bottom quarks contribute an unusually large fraction at very low scales $\left(Q \sim m_{c}\right)$ as they are (incorrectly) treated as massless partons in this region. The result of the different $n$-scalings $(n=1,2)$ is to introduce a kinematic penalty which properly suppresses the contribution of these heavy quarks in the low $Q$ region. In the following, we will generally use the $n=2$ scaling for our comparisons.

Fig. 5. Effect of $\chi(n)$-scaling for $n=\{0,1,2\}$ (left to right) at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-3}\right\}$. Reading from the bottom, we have fractional contribution for each (final-state) quark flavor to $F_{2, \mathrm{~L}}^{j} / F_{2, \mathrm{~L}}$ vs. $Q$ from $\{u, d, s, c, b\}$ (green, blue, cyan, magenta, pink). (a) $F_{2}^{j} / F_{2}$ vs. $Q$. (b) $F_{\mathrm{L}}^{j} / F_{\mathrm{L}}$ vs. $Q$.

In figures 6 (a) and 6 (b), we display the fractional contributions for the initial-state quarks $(i)$ to the structure functions $F_{2}$ and $F_{\mathrm{L}}$, respectively, for selected $x$ values as a function of $Q$; here we have used $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{g, u, d, s, c, b\}$. We observe that for large $x$ and low $Q$ the heavy flavor contributions are minimal. For example, for $x=10^{-1}$ we see the contribution of the $u$ quark comprises $\sim 80 \%$ of the $F_{2}$ structure function at low $Q$. In contrast, at $x=10^{-5}$ and large $Q$, we see the $F_{2}$ contributions of the $u$ quark and $c$ quark are comparable (as they both couple with a factor $4 / 9$ ), and the $d$ quark and $s$ quark are comparable (as they both couple with a factor $1 / 9$ ). It is notable that the gluon contribution to $F_{\mathrm{L}}$ is significant. For $x=10^{-1}$ this is roughly $40 \%$ throughout the $Q$ range, and can be even larger for smaller $x$ values.

In figures 7 (a) and 7 (b), we display the fractional contributions for the final-state quarks $(j)$ to the structure functions $F_{2}$ and $F_{\mathrm{L}}$, respectively, for selected $x$ values as a function of $Q$; here we have used $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{u, d, s, c, b\}$. Again, we observe that for large $x$ and low $Q$ the heavy flavor contributions are minimal, but these can grow quickly as we move to smaller $x$ and larger $Q$.

Fig. 6. Fractional flavor decomposition of "initial-state" $F_{2, \mathrm{~L}}^{i} / F_{2, \mathrm{~L}}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for $n=2$ scaling. Reading from the bottom, we plot the cumulative contributions to $F_{2, \mathrm{~L}}$ from $\{g, u, d, s, c, b\}$, (red, green, blue, cyan, magenta, pink). (a) $F_{2}^{i} / F_{2}$ vs. $Q$. (b) $F_{\mathrm{L}}^{i} / F_{\mathrm{L}}$ vs. $Q$.

Fig. 7. Fractional contribution for each quark flavor to $F_{2, \mathrm{~L}}^{j} / F_{2, \mathrm{~L}}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). Results are displayed for $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{u, d, s, c, b\}$ (green, blue, cyan, magenta, pink). (a) $F_{2}^{j} / F_{2} v s . Q$. (b) $F_{\mathrm{L}}^{j} / F_{\mathrm{L}} v s . Q$.

In figure $8(\mathrm{a})$, we display the results for $F_{2}$ vs. $Q$ computed at various orders. For large $x(c f . \quad x=0.1)$ we find the perturbative calculation is particularly stable; we see that the LO result is within $20 \%$ of the others at small $Q$, and within $5 \%$ at large $Q$. The NLO is within $2 \%$ at small $Q$, and indistinguishable from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ for $Q$ values above $\sim 10 \mathrm{GeV}$. The NNLO and $\mathrm{N}^{3} \mathrm{LO}$ results are essentially identical throughout the kinematic range. For smaller $x$ values $\left(10^{-3}, 10^{-5}\right)$, the contribution of the higher order terms increases. Here, the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ coincide for $Q$ values above $\sim 5 \mathrm{GeV}$, but the NLO result can differ by $\sim 5 \%$.

Fig. 8. $F_{2, \mathrm{~L}}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$ (red, green, blue, cyan) for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for $n=2$ scaling. (a) $F_{2}$ vs. $Q$. (b) $F_{\mathrm{L}}$ vs. $Q$.

In Figure $8(\mathrm{~b})$, we display the results for $F_{\mathrm{L}}$ vs. $Q$ computed at various orders. In contrast to $F_{2}$, we find the NLO corrections are large for $F_{\mathrm{L}}$; this is because the $\mathrm{LO} F_{\mathrm{L}}$ contribution (which violates the Callan-Gross relation) is suppressed by $\left(m^{2} / Q^{2}\right)$ compared to the dominant gluon contributions which enter at NLO. Consequently, we observe (as expected) that the LO result for $F_{\mathrm{L}}$ receives large contributions from the higher order terms. Essentially, the NLO is the first non-trivial order for $F_{\mathrm{L}}$, and the subsequent contributions then converge. For example, at large $x(c f . x=0.1)$ for $Q \sim 10 \mathrm{GeV}$ we find the NLO result yields $\sim 60$ to $80 \%$ of the total, the NNLO is a $\sim 20 \%$ correction, and the $\mathrm{N}^{3} \mathrm{LO}$ is a $\sim 10 \%$ correction. For lower $x$ values $\left(10^{-3}\right.$, $10^{-5}$ ), the convergence of the perturbative series improves, and the NLO results is within $\sim 10 \%$ of the $\mathrm{N}^{3} \mathrm{LO}$ result. Curiously, for $x=10^{-5}$ the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ roughly compensate each other so that the NLO and the $\mathrm{N}^{3} \mathrm{LO}$ match quite closely for $Q \geq 2 \mathrm{GeV}$.

While the calculation of $F_{\mathrm{L}}$ is certainly more challenging, examining Fig. 1 we see that for most of the relevant kinematic range probed by HERA the theoretical calculation is quite stable. For example, in the high $Q^{2}$ region where HERA is probing intermediate $x$ values $\left(x \sim 10^{-3}\right)$ the spread of the $\chi(n)$ scalings is small. The challenge arises in the low $Q$ region $(Q \sim 2 \mathrm{GeV})$, where the $x$ values are $\sim 10^{-4}$; in this region, there is some spread between the various curves at the lowest $x$ value $\left(\sim 10^{-5}\right)$, but for $x \sim 10^{-3}$ this is greatly reduced.

## 5. Conclusions

We extended the ACOT calculation for DIS structure functions to $\mathrm{N}^{3} \mathrm{LO}$ by combining the exact ACOT scheme at NLO with a $\chi(n)$-rescaling which allows us to include the leading mass dependence at NNLO and $\mathrm{N}^{3} \mathrm{LO}$. Using the full ACOT calculation at NLO, we demonstrated that the heavy quarks mass dependence for the DIS structure functions is dominated by the kinematic mass contributions, and this can be implemented via a generalized $\chi(n)$-rescaling prescription.

We studied the $F_{2}$ and $F_{\mathrm{L}}$ structure functions as a function of $x$ and $Q$. We examined the flavor decomposition of these structure functions, and verified that the heavy quarks were appropriately suppressed in the low $Q$ region. We found the results for $F_{2}$ were very stable across the full kinematic range for $\{x, Q\}$, and the contributions from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ terms were small. For $F_{\mathrm{L}}$, the higher order terms gave a proportionally larger contribution (due to the suppression of the LO term from the Callan-Gross relation); nevertheless, the contributions from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ terms were generally small in the region probed by HERA.

The result of this calculation was to obtain precise predictions for the inclusive $F_{2}$ and $F_{\mathrm{L}}$ structure functions which can be used to analyze the HERA data.

#### Abstract

We compute the structure functions $F_{2}$ and $F_{L}$ in the ACOT scheme for heavy quark production. We use the complete ACOT results to NLO, and make use of the $\overline{M S}$ massless results at NNLO and $\mathrm{N}^{3} \mathrm{LO}$ to estimate the higher order mass-dependent corrections. We show numerically that the dominant heavy quark mass effects can be taken into account using massless Wilson coefficients together with an appropriate rescaling prescription. Combining the exact NLO ACOT scheme with these expressions should provide a good approximation to the full calculation in the ACOT scheme at NNLO and $\mathrm{N}^{3} \mathrm{LO}$.

## 1. Introduction

The production of heavy quarks in high energy processes has become an increasingly important subject of study both theoretically and experimentally. The theory of heavy quark production in perturbative Quantum Chromodynamics (pQCD) is more challenging than that of light parton (jet) production because of the new physics issues brought about by the additional heavy quark mass scale. The correct theory must properly take into account the changing role of the heavy quark over the full kinematic range of the relevant process from the threshold region (where the quark behaves like a typical "heavy particle") to the asymptotic region (where the

[^172]same quark behaves effectively like a parton, similar to the well known light quarks $\{u, d, s\}$ ).

With the ever-increasing precision of experimental data and the progression of theoretical calculations and parton distribution function (PDF) evolution to next-to-next-to-leading order (NNLO) of QCD there is a clear need to formulate and also implement the heavy quark schemes at this order and beyond. The most important case is arguably the heavy quark treatment in inclusive deep-inelastic scattering (DIS) since the very precise HERA data for DIS structure functions and cross sections form the backbone of any modern global analysis of PDFs. Here, the heavy quarks contribute up to $30 \%$ or $40 \%$ to the structure functions at small momentum fractions $x$. Extending the heavy quark schemes to higher orders is therefore necessary for extracting precise PDFs, and this is a prerequisite for precise predictions of observables at the LHC. However, we would like to also stress the theoretical importance of having a general pQCD framework that includes heavy quarks and is valid to all orders in perturbation theory over a wide range of hard energy scales.

An example, where higher order corrections are particularly important is the structure function $F_{L}$ in DIS. The leading order $\left(\mathcal{O}\left(\alpha_{S}^{0}\right)\right)$ contribution to this structure function vanishes for massless quarks due to helicity conservation (Callan-Gross relation). This has several consequences: 1) $F_{L}$ is useful for constraining the gluon PDF via the dominant subprocess $\gamma^{*} g \rightarrow q \bar{q}$. 2) The heavy quark mass effects of order $\mathcal{O}\left(\frac{m^{2}}{Q^{2}}\right)$ are relatively more pronounced 3) Since the first non-vanishing contribution to $F_{L}$ is next-to-leading order (up to mass effects), the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ corrections are more important than for $F_{2}$. In Fig. ⿴囗 we show a comparison of different theoretical calculations of $F_{L}$ with preliminary HERA data [2]. As can be seen, in particular at small $Q^{2}$ (i.e. small $x$ ), there are considerable differences between the predictions.

The purpose of this paper is to calculate the leading twist neutral current DIS structure functions $F_{2}$ and $F_{L}$ in the ACOT factorization scheme up to order $\mathcal{O}\left(\alpha_{S}^{3}\right)\left(\mathrm{N}^{3} \mathrm{LO}\right)$ and to estimate the error due to approximating the heavy quark mass terms $\mathcal{O}\left(\alpha_{S}^{2} \times \frac{m^{2}}{Q^{2}}\right)$ and $\mathcal{O}\left(\alpha_{S}^{3} \times \frac{m^{2}}{Q^{2}}\right)$ in the higher order corrections. The results of this study form the basis for using the ACOT scheme in NNLO global analyses and for future comparisons with precision data for DIS structure functions.

This paper is organized as follows. In Sec. 2 we review theoretical approaches to include heavy flavors in QCD calculations. Particular emphasis

[^173]

Fig. 1: $F_{L}$ vs. $Q$ from combined HERA-I inclusive deep inelastic cross sections measured by the H1 and ZEUS collaborations. Figure taken from Ref. [2].
is put on the ACOT scheme which is a minimal extension of the $\overline{M S}$ scheme. In Sec. 3 we present the prescription for constructing the approximate DIS structure functions in the ACOT scheme up to $\mathcal{O}\left(\alpha_{S}^{3}\right)$ order. The corresponding numerical results are presented in Sec. 4. Finally, in Sec. 5 we summarize the main results. This work is based on Ref. [3], and further details can be found therein.

## 2. Review of Theoretical Methods

We review theoretical methods which have been advanced to improve existing QCD calculations of heavy quark production, and the impact on recent experimental results.

### 2.1. ACOT Scheme

The ACOT renormalization scheme [4, 5] provides a mechanism to incorporate the heavy quark mass into the theoretical calculation of heavy quark production both kinematically and dynamically. In 1998 Collins [6] extended the factorization theorem to address the case of heavy quarks; this work provided the theoretical foundation that allows us to reliably compute heavy quark processes throughout the full kinematic realm.

If we consider the DIS production of heavy quarks at $\mathcal{O}\left(\alpha_{S}^{1}\right)$ this involves the $\mathrm{LO} Q V \rightarrow Q$ process and the NLO $g V \rightarrow Q \bar{Q}$ process ${ }^{2}$ The key ingredient provided by the ACOT scheme is the subtraction term (SUB)

[^174]which removes the "double counting" arising from the regions of phase space where the LO and NLO contributions overlap. Specifically, at NLO order, we can express the total result as a sum of
\[

$$
\begin{equation*}
\sigma_{T O T}=\sigma_{L O}+\left\{\sigma_{N L O}-\sigma_{S U B}\right\} \tag{1}
\end{equation*}
$$

\]

where the subtraction term for the gluon-initiated processes is

$$
\begin{equation*}
\sigma_{S U B}=f_{g} \otimes \tilde{P}_{g \rightarrow Q} \otimes \sigma_{Q V \rightarrow Q} . \tag{2}
\end{equation*}
$$

$\sigma_{S U B}$ represents a gluon emitted from a proton $\left(f_{g}\right)$ which undergoes a collinear splitting to a heavy quark ( $\tilde{P}_{g \rightarrow Q}$ ) convoluted with the LO quarkboson scattering $\sigma_{Q V \rightarrow Q}$. Here, $\tilde{P}_{g \rightarrow Q}(x, \mu)=\frac{\alpha_{s}}{2 \pi} \ln \left(\mu^{2} / m^{2}\right) P_{g \rightarrow Q}(x)$ where $P_{g \rightarrow Q}(x)$ is the usual $\overline{M S}$ splitting kernel, $m$ is the quark mass and $\mu$ is the renormalization scale which we typically choose to be $\mu=Q$.

An important feature of the ACOT scheme is that it reduces to the appropriate limit both as $m \rightarrow 0$ and $m \rightarrow \infty$ as we illustrate below. Specifically, in the limit where the quark $Q$ is relatively heavy compared to the characteristic energy scale ( $\mu \lesssim m$ ), we find $\sigma_{L O} \sim \sigma_{S U B}$ such that $\sigma_{T O T} \sim \sigma_{N L O}$. In this limit, the ACOT result naturally reduces to the Fixed-Flavor-Number-Scheme (FFNS) result. In the FFNS, the heavy quark is treated as being extrinsic to the hadron, and there is no corresponding heavy quark $\operatorname{PDF}\left(f_{Q} \sim 0\right)$; thus $\sigma_{L O} \sim 0$. We also have $\sigma_{S U B} \sim 0$ because this is proportional to $\ln \left(\mu^{2} / m^{2}\right)$. Thus, when the quark $Q$ is heavy relative to the characteristic energy scale $\mu$, the ACOT result reduces to $\sigma_{T O T} \sim \sigma_{N L O}$.

Conversely, in the limit where the quark $Q$ is relatively light compared to the characteristic energy scale $\left(\mu \gtrsim m\right.$ ), we find that $\sigma_{L O}$ yields the dominant part of the result, and the "formal" $\mathrm{NLO} \mathcal{O}\left(\alpha_{S}\right)$ contribution $\left\{\sigma_{N L O}-\sigma_{S U B}\right\}$ is an $\mathcal{O}\left(\alpha_{S}\right)$ correction. In this limit, the ACOT result will reduce to the $\overline{M S}$ Zero-Mass Variable-Flavor-Number-Scheme (ZMVFNS) limit exactly without any finite renormalizations. The quark mass $m$ no longer plays any dynamical role and purely serves as a regulator. The $\sigma_{N L O}$ term diverges due to the internal exchange of the quark $Q$, and this singularity is canceled by $\sigma_{S U B}$.

We illustrate the versatile role of the quark mass in Fig. 2a where we display $F_{2}^{c}$ as a function of $Q$ calculated in the ZM-VFNS, FFNS, ACOT, and S-ACOT schemes. We see that the ACOT scheme coincides with the FFNS for small $Q$, and the ZM-VFNS for large $Q$. In Fig. 2b we plot $F_{2}^{c}$ as a function of the quark mass $m$ for a fixed $Q=10 \mathrm{GeV}$ for the $\overline{M S}$ ZM-VFNS and ACOT schemes. We observe that when $m$ is within a decade or two of $\mu$, the quark mass plays a dynamic role; however, for $m \ll \mu$, the quark mass purely serves as a regulator and the specific value is not important.

Fig. 2: a) $F_{2}^{c}$ for $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable Flavor Number Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical.
b) Comparison of $F_{2}^{c}(x, Q)$ (scaled by $10^{4}$ ) vs. the quark mass $m$ in GeV for fixed $x=0.1$ and $Q=10 \mathrm{GeV}$. The red dots are the full ACOT result, and the blue line is the massless $\overline{M S}$ result.

Operationally, it means we can obtain the $\overline{M S}$ ZM-VFNS result either by i) computing the terms using dimensional regularization and setting the regulator to zero, or ii) by computing the terms using the quark mass as the regulator and then setting this to zero.

The ACOT scheme is minimal in the sense that the construction of the massive short distance cross sections does not need any observabledependent extra contributions or any regulators to smooth the transition between the high and low scale regions. The ACOT prescription is: a) calculate the massive partonic cross sections, and b) perform the factorization using the quark mass as regulator.

It is in this sense that we claim the ACOT scheme is the minimal massive extension of the $\overline{M S}$ ZM-VFNS. In the limit $m / \mu \rightarrow 0$ it reduces exactly to the $\overline{M S}$ ZM-VFNS, in the limit $m / \mu \gtrsim 1$ the heavy quark decouples from the PDFs and we obtain exactly the FFNS for $m / \mu \gg 1$ and no finite renormalizations are needed.

## 2.2. $S$-ACOT

In a corresponding application, it was observed that the heavy quark mass could be set to zero in certain pieces of the hard scattering terms without any loss of accuracy. This modification of the ACOT scheme goes by the name Simplified-ACOT (S-ACOT) and can be summarized as follows [8].

S-ACOT: For hard-scattering processes with incoming heavy
quarks or with internal on-shell cuts on a heavy quark line, the heavy quark mass can be set to zero $(m=0)$ for these pieces.

If we consider the case of NLO DIS heavy quark production, this means we can set $m=0$ for the LO terms $\sigma_{Q V \rightarrow Q}$ (incoming heavy quark), and for the SUB terms (on-shell cut on an internal heavy quark line). Hence, the only contribution which requires calculation with $m$ retained is the NLO $g V \rightarrow Q \bar{Q}$ process. Figure 2a displays a comparison of a calculation using the ACOT scheme with all masses retained vs. the S-ACOT scheme; as expected, these two results match throughout the full kinematic region.

It is important to note that the S-ACOT scheme is not an approximation; this is an exact renormalization scheme, extensible to all orders.

### 2.3. ACOT and $\chi$-Rescaling

As we have illustrated in Sec. 2.1, in the limit $Q^{2} \gg m^{2}$ the mass simply plays the role of a regulator. In contrast, for $Q^{2} \sim m^{2}$ the value of the mass is of consequence for the physics. The mass can enter dynamically in the hard-scattering matrix element, and can enter kinematically in the phase space of the process.

We will demonstrate that for the processes of interest the primary role of the mass is kinematic and not dynamic. It was this idea which was behind the original slow-rescaling prescription of [9] which considered DIS charm production (e.g., $\gamma c \rightarrow c$ ) introducing the shift $x \rightarrow \chi=x\left[1+\left(m_{c} / Q\right)^{2}\right]$. This prescription accounted for the charm quark mass by effectively reducing the phase space for the final state by an amount proportional to $\left(m_{c} / Q\right)^{2}$.

This idea was extended in the $\chi$-scheme by realizing that (in most cases) in addition to the observed final-state charm quark, there is also an anticharm quark in the beam fragments since all the charm quarks are ultimately produced by gluon splitting $(g \rightarrow c \bar{c})$ into a charm pair. For this case the scaling variable becomes $\chi=x\left[1+\left(2 m_{c} / Q\right)^{2}\right]$. This rescaling is implemented in the $\mathrm{ACOT}_{\chi}$ scheme, for example [10-12] $]^{3}$ The factor $\left(1+\left(2 m_{c}\right)^{2} / Q^{2}\right)$ represents a kinematic suppression factor which will suppress the charm process relative to the lighter quarks. Additionally, the $\chi$-scaling ensures the threshold kinematics $\left(W^{2}>4 m^{2}+M^{2}\right)$ is satisfied; while it is important to satisfy this condition for large $x$, this may prove too restrictive at small $x$ where the HERA data are especially precise.

To encompass all the above results, we can define a general scaling variable $\chi(n)$ as

$$
\begin{equation*}
\chi(n)=x\left[1+\left(\frac{n m_{c}}{Q}\right)^{2}\right] \tag{3}
\end{equation*}
$$

[^175]
(a) Comparison of $F_{2}^{c}(x, Q)$ vs. $Q$ for the NLO ACOT calculation for $x=$ $\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) using zero dynamic mass $[\widehat{\sigma}(m=0)]$ to show the effect of $n$ scaling; from top to bottom $n=\{0,1,2\}$ (pink, black, purple).

(b) Comparison of $F_{2}^{c}(x, Q)$ vs. $Q$ for the NLO ACOT calculation for $x=$ $\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). Here we keep the scaling fixed $n=2$ and compare the effect of varying the dynamic mass in the Wilson coefficient. The upper (cyan) curve uses a non-zero dynamic mass $[\widehat{\sigma}(m=1.3)]$ and the lower (purple) curve uses a zero dynamic mass $[\widehat{\sigma}(m=0)]$.
Fig. 3: Comparison of Phase Space (Kinematic) \& Dynamic Mass Effects
where $n=\{0,1,2\}$. Here, $n=0$ corresponds to the massless result without rescaling, $n=1$ corresponds to the original Barnett slow-rescaling, and $n=2$ corresponds to the $\chi$-rescaling.

### 2.4. Phase Space (Kinematic) \& Dynamic Mass

We now investigate the effects of separately varying the mass entering the $\chi(n)$ variable taking into account the phase space constraints and the mass value entering the hard scattering cross section $\widehat{\sigma}(m)$. We call the former mass parameter "phase space (kinematic) mass" and the latter "dynamic mass".

In Fig. 3a we display $F_{2}^{c}(x, Q)$ vs. $Q$. The family of 3 curves shows the NLO ACOT calculation with $\chi(n)$ scaling using a zero dynamic mass for the hard scattering. We compare this with Fig. 3b which shows $F_{2}^{c}(x, Q)$ in the NLO ACOT scheme using a fixed $n=2$ scaling, but varying the mass used in the hard-scattering cross section. The upper (cyan) curves use a non-zero dynamic mass $\left[\widehat{\sigma}\left(m_{c}=1.3\right)\right]$ and the lower (purple) curves have been obtained with a vanishing dynamic mass $\left[\widehat{\sigma}\left(m_{c}=0\right)\right]$. We observe that the effect of the 'dynamic mass' in $\widehat{\sigma}\left(m_{c}\right)$ is only of consequence in
the limited region $Q \gtrsim m$, and even in this region the effect is minimal. In contrast, the influence of the phase space (kinematic) mass shown in Fig. 3a is larger than the dynamic mass shown in Fig. 3b,

In conclusion, we have shown that (up to $\mathcal{O}\left(\alpha_{S}\right)$ ) the phase space mass dependence is generally the dominant contribution to the DIS structure functions. Assuming that this observation remains true at higher orders, it is possible to obtain a good approximation of the structure functions in the ACOT scheme at NNLO and $\mathrm{N}^{3} \mathrm{LO}$ using the massless Wilson coefficients together with a non-zero phase space mass entering via the $\chi(n)$ prescription.

### 2.5. Other massive schemes

There are a number of other schemes for incorporating the heavy quark mass terms, and we briefly note a few examples. The Thorne-Roberts (TR) scheme [14, 15] and its derivatives (TR') are designed to provide a smooth threshold behavior, and this is implemented by including pieces of the higher order contributions. The FONLL scheme [16] was originally developed to match fixed order calculations with resumed ones in the case of heavy quark hadroproduction; this approach has been generalized and applied to other applications including DIS structure functions [17]. Details and comparisons of these approached is outlined in the 2009 Les Houches Workshop report [18].

## 3. ACOT scheme beyond NLO

In Sec. 2.4 we have shown using the NLO full ACOT scheme that the dominant mass effects are those coming from the phase space which can be taken into account via a generalized slow-rescaling $\chi(n)$-prescription. Assuming that a similar relation remains true at higher orders one can construct the following approximation to the full ACOT result up to $\mathrm{N}^{3} \mathrm{LO}$ $\left(\mathcal{O}\left(\alpha_{S}^{3}\right)\right)$ :

$$
\begin{equation*}
\operatorname{ACOT}\left[\mathcal{O}\left(\alpha_{S}^{0+1+2+3}\right)\right] \simeq \operatorname{ACOT}\left[\mathcal{O}\left(\alpha_{S}^{0+1}\right)\right]+{\mathrm{ZM}-\operatorname{VFNS}_{\chi}\left[\mathcal{O}\left(\alpha_{S}^{2+3}\right)\right] . . . ~}_{\text {. }} \tag{4}
\end{equation*}
$$

Here, the massless Wilson coefficients at $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$ and $\mathcal{O}\left(\alpha \alpha_{S}^{3}\right)$ are substituted for the Wilson coefficients in the ACOT scheme as the corresponding massive coefficients have not yet been computed.

There has been a calculation of neutral current electroproduction (equal quark masses, vector coupling) of heavy quarks at this order by Smith \& VanNeerven [19] in the FFNS which could be used to obtain the massive Wilson coefficients in the S-ACOT scheme by applying appropriate collinear
subtraction terms $\sqrt{4}^{4}$ however, this is beyond the scope of this paper. For charge current case massive calculations are available at order $\mathcal{O}\left(\alpha \alpha_{S}\right)$ [21]23] and partial results at order $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$ [24.

Here, we argue that the massless Wilson coefficients at $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$ together with a $\chi(n)$-prescription provide a very good approximation of the exact result. At worst, the maximum error would be of order $\mathcal{O}\left(\alpha \alpha_{S}^{2} \times\left[m^{2} / Q^{2}\right]\right)$. However, based on the arguments of Sec. 2.4 we expect the inclusion of the phase space mass effects to contain the dominant higher order contributions so that the actual error should be substantially smaller.

The massless higher order coefficient functions for the DIS structure function $F_{2}$ via photon exchange can be found in Refs. 25$] 34$. The expressions for the structure function $F_{L}$ have been calculated in Refs. [29, 31, 33, (35, 36.

We now consider our choice for the appropriate generalized $\chi(n)$-rescaling variable. For the purposes of this study, we will vary the phase space mass using the $\chi(n)$ rescaling with $n=\{0,1,2\}$. While $n=0$ corresponds to the massless case (no rescaling), it is not obvious whether $n=1$ or $n=2$ is the preferred rescaling choice for higher orders. Thus, we will use the range between $n=1$ and $n=2$ as a measure of our theoretical uncertainty arising from this ambiguity.

## 4. Results

We now present our results for the $F_{2}$ and $F_{L}$ structure functions calculated at $\mathrm{N}^{3} \mathrm{LO}$ in the extended ACOT scheme. The initial PDFs, based on the Les Houches benchmark set [37] are evolved using the QCDNUM program [38]. In the calculation we set $m_{c}=1.3 \mathrm{GeV}, m_{b}=4.5 \mathrm{GeV}$ and $\alpha_{s}\left(M_{Z}\right)=0.118$.

In Figures 4a and 4b we display the structure functions $F_{2}$ and $F_{L}$, respectively, for selected $x$ values as a function of $Q$. Each plot has three curves which are computed using $n$-scalings of $\{0,1,2\}$. We observe that the effect of the $n$-scaling is negligible except for very small $Q$ values. This result is in part because the heavy quarks are only a fraction of the total structure function, and the effects of the $n$-scaling are reduced at larger $Q$ values.

In Ref. [3] we magnify the small $Q$ region of $F_{L}$ of Fig. 4b for $x=10^{-5}$, where the effects of using different scalings are largest. We can see that for inclusive observables, the $n=1$ and $n=2$ scalings give nearly identical results, but they differ from the massless case $(n=0)$. This result, together

[^176]

Fig. 4: $F_{2, L}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). The three lines show the scaling variable: $n=\{0,1,2\}$ (red, green, blue). We observe the effect of the $n$-scaling is negligible except for very small $Q$ values.
with the observation that at NLO kinematic mass effects are dominant, suggests that the error we have in our approach is relatively small and approximated by the band between $n=1$ and $n=2$ results.

We can investigate the effects of the $\chi(n)$-scaling in more details by examining the flavor decomposition of the structure functions. In Figures 5 a and 5b we display the fractional contributions of quark flavors to the structure functions $F_{2, L}$ for selected $n$-scaling values as a function of $Q$. We observe the $n$-scaling reduces the relative contributions of charm and bottom at low $Q$ scales. For example, without any $n$-scaling $(n=0)$ we find the charm and bottom quarks contribute an unusually large fraction at very low scales $\left(Q \sim m_{c}\right)$ as they are (incorrectly) treated as massless partons in this region. The result of the different $n$-scalings $(n=1,2)$ is to introduce a kinematic penalty which properly suppresses the contribution of these heavy quarks in the low $Q$ region. In the following, we will generally use the $n=2$ scaling for our comparisons.

In Figures 6a and 6b we display the fractional contributions for the initial-state quarks $(i)$ to the structure functions $F_{2}$ and $F_{L}$, respectively, for selected $x$ values as a function of $Q$; here we have used $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{g, u, d, s, c, b\}$. We observe that for large $x$ and low $Q$ the heavy flavor contributions are minimal. For example, for $x=10^{-1}$ we see the contribution

Fig. 5: Effect of $\chi(n)$-scaling for $n=\{0,1,2\}$ (left to right) at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-3}\right\}$. Reading from the bottom we have fractional contribution for each (final-state) quark flavor to $F_{2, L}^{j} / F_{2, L}$ vs. $Q$ from $\{u, d, s, c, b\}$ (green, blue, cyan, magenta, pink).

Fig. 6: Fractional flavor decomposition of "initial-state" $F_{2, L}^{i} / F_{2, L}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for $n=2$ scaling. Reading from the bottom, we plot the cumulative contributions to $F_{2, L}$ from $\{g, u, d, s, c, b\}$, (red, green, blue, cyan, magenta, pink).

Fig. 7: Fractional contribution for each quark flavor to $F_{2, L}^{j} / F_{2, L}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). Results are displayed for $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{u, d, s, c, b\}$ (green, blue, cyan, magenta, pink).
of the $u$-quark comprises $\sim 80 \%$ of the $F_{2}$ structure function at low $Q$. In contrast, at $x=10^{-5}$ and large $Q$ we see the $F_{2}$ contributions of the $u$ quark and $c$-quark are comparable (as they both couple with a factor $4 / 9$ ), and the $d$-quark and $s$-quark are comparable (as they both couple with a factor $1 / 9$ ). It is notable that the gluon contribution to $F_{L}$ is significant. For $x=10^{-1}$ this is roughly $40 \%$ throughout the $Q$ range, and can be even larger for smaller $x$ values.

In Figures 7a and 7b we display the fractional contributions for the final-state quarks $(j)$ to the structure functions $F_{2}$ and $F_{L}$, respectively, for selected $x$ values as a function of $Q$; here we have used $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{u, d, s, c, b\}$. Again, we observe that for large $x$ and low $Q$ the heavy flavor contributions are minimal, but these can grow quickly as we move to smaller $x$ and larger $Q$.

In Figure we display the results for $F_{2}$ vs. $Q$ computed at various orders. For large $x$ (c.f. $x=0.1$ ) we find the perturbative calculation is particularly stable; we see that the LO result is within $20 \%$ of the others at small $Q$, and within $5 \%$ at large $Q$. The NLO is within $2 \%$ at small $Q$, and indistinguishable from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ for $Q$ values above $\sim 10 \mathrm{GeV}$. The NNLO and $\mathrm{N}^{3} \mathrm{LO}$ results are essentially identical throughout the kinematic range. For smaller $x$ values $\left(10^{-3}, 10^{-5}\right)$ the contribution of

Fig. 8: $F_{2, L}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$ (red, green, blue, cyan) for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for $n=2$ scaling.
the higher order terms increases. Here, the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ coincide for $Q$ values above $\sim 5 \mathrm{GeV}$, but the NLO result can differ by $\sim 5 \%$.

In Figure 8 b we display the results for $F_{L}$ vs. $Q$ computed at various orders. In contrast to $F_{2}$, we find the NLO corrections are large for $F_{L}$; this is because the LO $F_{L}$ contribution (which violates the Callan-Gross relation) is suppressed by $\left(m^{2} / Q^{2}\right)$ compared to the dominant gluon contributions which enter at NLO. Consequently, we observe (as expected) that the LO result for $F_{L}$ receives large contributions from the higher order terms. Essentially, the NLO is the first non-trivial order for $F_{L}$, and the subsequent contributions then converge. For example, at large $x$ (c.f. $x=0.1$ ) for $Q \sim 10 \mathrm{GeV}$ we find the NLO result yields $\sim 60$ to $80 \%$ of the total, the NNLO is a $\sim 20 \%$ correction, and the $\mathrm{N}^{3} \mathrm{LO}$ is a $\sim 10 \%$ correction. For lower $x$ values $\left(10^{-3}, 10^{-5}\right)$ the convergence of the perturbative series improves, and the NLO results is within $\sim 10 \%$ of the $\mathrm{N}^{3} \mathrm{LO}$ result. Curiously, for $x=10^{-5}$ the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ roughly compensate each other so that the NLO and the $\mathrm{N}^{3} \mathrm{LO}$ match quite closely for $Q \geq 2 \mathrm{GeV}$.

While the calculation of $F_{L}$ is certainly more challenging, examining Fig. Tiwe see that for most of the relevant kinematic range probed by HERA the theoretical calculation is quite stable. For example, in the high $Q^{2}$ region where HERA is probing intermediate $x$ values $\left(x \sim 10^{-3}\right)$ the spread of the $\chi(n)$ scalings is small. The challenge arises in the low $Q$ region ( $Q \sim 2 \mathrm{GeV}$ ) where the $x$ values are $\sim 10^{-4}$; in this region, there is some spread between the various curves at the lowest $x$ value $\left(\sim 10^{-5}\right)$, but for $x \sim 10^{-3}$ this is
greatly reduced.

## 5. Conclusions

We extended the ACOT calculation for DIS structure functions to $\mathrm{N}^{3} \mathrm{LO}$ by combining the exact ACOT scheme at NLO with a $\chi(n)$-rescaling which allows us to include the leading mass dependence at NNLO and $\mathrm{N}^{3} \mathrm{LO}$. Using the full ACOT calculation at NLO, we demonstrated that the heavy quarks mass dependence for the DIS structure functions is dominated by the kinematic mass contributions, and this can be implemented via a generalized $\chi(n)$-rescaling prescription.

We studied the $F_{2}$ and $F_{L}$ structure functions as a function of $x$ and $Q$. We examined the flavor decomposition of these structure functions, and verified that the heavy quarks were appropriately suppressed in the low $Q$ region. We found the results for $F_{2}$ were very stable across the full kinematic range for $\{x, Q\}$, and the contributions from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ terms were small. For $F_{L}$, the higher order terms gave a proportionally larger contribution (due to the suppression of the LO term from the Callan-Gross relation); nevertheless, the contributions from the NNLO and $\mathrm{N}^{3}$ LO terms were generally small in the region probed by HERA.

The result of this calculation was to obtain precise predictions for the inclusive $F_{2}$ and $F_{L}$ structure functions which can be used to analyze the HERA data.

#### Abstract

We analyze the properties of the Aivazis-Collins-Olness-Tung (ACOT) scheme for heavy quark production and make use of the $\overline{\mathrm{MS}}$ massless results at next-to-next-to-leading order and $\mathrm{N}^{3} \mathrm{LO}$ for the structure functions $F_{2}$ and $F_{L}$ in neutral current deep-inelastic scattering to estimate the higher order corrections. For this purpose we decouple the heavy quark mass entering the phase space from the one entering the dynamics of the short distance cross section. We show numerically that the phase space mass is generally more important. Therefore, the dominant heavy quark mass effects at higher orders can be taken into account using the massless Wilson coefficients together with an appropriate slow-rescaling prescription implementing the phase space constraints. Combining the exact ACOT scheme at next-toleading order with these expressions should provide a good approximation to the missing full calculation in the ACOT scheme at next-to-next-to-leading order and $\mathrm{N}^{3} \mathrm{LO}$.

## I. INTRODUCTION

## A. Motivation

The production of heavy quarks in high energy processes has become an increasingly important subject of study both theoretically and experimentally. The theory of heavy quark production in perturbative quantum chromodynamics is more challenging than that of light parton (jet) production because of the new physics issues brought about by the additional heavy quark mass scale. The correct theory must properly take into account the changing role of the heavy quark over the full kinematic range of the relevant process from the threshold region (where the quark behaves like a typical "heavy particle") to the asymptotic region (where the same quark behaves effectively like a parton, similar to the well-known light quarks $\{u, d, s\}$ ).

With the ever-increasing precision of experimental data and the progression of theoretical calculations and parton distribution function (PDF) evolution to next-to-next-toleading order (NNLO) of QCD there is a clear need to formulate and also implement the heavy quark schemes at this order and beyond. The most important case is arguably the heavy quark treatment in inclusive deep-inelastic scattering (DIS) since the very precise HERA data for DIS structure functions and cross sections form the backbone of

[^177]any modern global analysis of PDFs. Here, the heavy quarks contribute up to $30 \%$ or $40 \%$ to the structure functions at small momentum fractions $x$. Extending the heavy quark schemes to higher orders is therefore necessary for extracting precise PDFs and hence for precise predictions of observables at the LHC. However, we would like to also stress the theoretical importance of having a general perturbative quantum chromodynamic framework including heavy quarks which is valid to all orders in perturbation theory over a wide range of hard energy scales and which is also applicable to other observables than inclusive DIS in a straightforward manner.

An example, where higher order corrections are particularly important is the structure function $F_{L}$ in DIS. The leading $\operatorname{order}\left(\mathcal{O}\left(\alpha_{S}^{0}\right)\right)$ contribution to this structure function vanishes for massless quarks due to helicity conservation (Callan-Gross relation). This has several consequences:
(i) $F_{L}$ is useful for constraining the gluon PDF via the dominant subprocess $\gamma^{*} g \rightarrow q \bar{q}$.
(ii) The heavy quark mass effects of order $\mathcal{O}\left(\frac{m^{2}}{Q^{2}}\right)$ are relatively more pronounced. ${ }^{1}$
(iii) Since the first nonvanishing contribution to $F_{L}$ is next-to-leading order (up to mass effects), the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ corrections are more important than for $F_{2}$.

In Fig. 1 we show a comparison of different theoretical calculations of $F_{L}$ with preliminary HERA data [2]. As can

[^178]

FIG. 1 (color online). $\quad F_{L}$ vs $Q$ from combined HERA-I inclusive deep inelastic cross sections measured by the H1 and ZEUS collaborations. Figure taken from Ref. [2].
be seen, in particular, at small $Q^{2}$ (i.e. small $x$ ), there are considerable differences between the predictions. ${ }^{2}$

The purpose of this paper is to calculate the leading twist neutral current DIS structure functions $F_{2}$ and $F_{L}$ in the Aivazis-Collins-Olness-Tung (ACOT) factorization scheme up to order $\mathcal{O}\left(\alpha_{S}^{3}\right)\left(\mathrm{N}^{3} \mathrm{LO}\right)$ and to estimate the error due to approximating the heavy quark mass terms $\mathcal{O}\left(\alpha_{S}^{2} \times \frac{m^{2}}{Q^{2}}\right)$ and $\mathcal{O}\left(\alpha_{S}^{3} \times \frac{m^{2}}{Q^{2}}\right)$ in the higher order corrections. The results of this study form the basis for using the ACOT scheme in NNLO global analyses and for future comparisons with precision data for DIS structure functions.

## B. Outline of paper

The rest of this paper is organized as follows. In Sec. II we review theoretical approaches to include heavy flavors in QCD calculations. Particular emphasis is put on the ACOT scheme which is the minimal extension of the $\overline{\mathrm{MS}}$ scheme in the sense that the observables in the ACOT scheme reduce to the ones in the $\overline{\mathrm{MS}}$ scheme in the limit $m \rightarrow 0$ without any finite renormalizations. In this discussion we explicitly distinguish between the heavy quark/ heavy meson mass entering the final state phase space which we will call "phase space mass" and the heavy quark mass entering the dynamics of the short distance cross section denoted "dynamic mass." We show numerically using the exact ACOT scheme at $\mathcal{O}\left(\alpha_{S}\right)$ next-toleading order (NLO) that the effects of the phase space mass are more important than the ones due to the dynamic mass. We use this observation to construct in Sec. III the NC DIS structure functions in the ACOT scheme up to $\mathcal{O}\left(\alpha_{S}^{3}\right)$. The corresponding numerical results are presented in Sec. IV. Finally, in Sec. V we summarize the main results.

[^179]

FIG. 2 (color online). Characteristic Feynman graphs which contribute to DIS heavy quark production in the ACOT scheme: (a) the LO $\mathcal{O}\left(\alpha_{S}^{0}\right)$ quark-boson scattering $Q V \rightarrow Q$, (b) the NLO $\mathcal{O}\left(\alpha_{S}^{1}\right)$ gluon-boson scattering $g V \rightarrow Q \bar{Q}$, and (c) the corresponding subtraction term (SUB) $(g \rightarrow Q \bar{Q}) \otimes(Q \rightarrow g Q)$.

## II. REVIEW OF THEORETICAL METHODS

We review theoretical methods which have been advanced to improve existing QCD calculations of heavy quark production, and the impact on recent experimental results.

## A. ACOT scheme

The ACOT renormalization scheme [4] provides a mechanism to incorporate the heavy quark mass into the theoretical calculation of heavy quark production both kinematically and dynamically. In 1998 Collins [5] extended the factorization theorem to address the case of heavy quarks; this work provided the theoretical foundation that allows us to reliably compute heavy quark processes throughout the full kinematic realm.

Figure 2 displays characteristic Feynman graphs for the first two orders of DIS heavy quark production. If we consider the DIS production of heavy quarks at $\mathcal{O}\left(\alpha_{S}^{1}\right)$ this involves the leading order (LO) $Q V \rightarrow Q$ process and the NLO $g V \rightarrow Q \bar{Q}$ process. ${ }^{3}$

The key ingredient provided by the ACOT scheme is the subtraction term (SUB) which removes the "double counting" arising from the regions of phase space where the LO and NLO contributions overlap. Specifically, at NLO order, we can express the total result as a sum of

$$
\begin{equation*}
\sigma_{\mathrm{TOT}}=\sigma_{\mathrm{LO}}+\left\{\sigma_{\mathrm{NLO}}-\sigma_{\mathrm{SUB}}\right\} \tag{1}
\end{equation*}
$$

where the subtraction term for the gluon-initiated processes is

$$
\begin{equation*}
\sigma_{\mathrm{SUB}}=f_{g} \otimes \tilde{P}_{g \rightarrow Q} \otimes \sigma_{Q V \rightarrow Q} \tag{2}
\end{equation*}
$$

$\sigma_{\text {SUB }}$ represents a gluon emitted from a proton $\left(f_{g}\right)$ which undergoes a collinear splitting to a heavy quark $\left(\tilde{P}_{g \rightarrow Q}\right)$ convoluted with the LO quark-boson scattering $\sigma_{Q V \rightarrow Q}$. Here, $\tilde{P}_{g \rightarrow Q}(x, \mu)=\frac{\alpha_{s}}{2 \pi} \ln \left(\mu^{2} / m^{2}\right) P_{g \rightarrow Q}(x)$ where $P_{g \rightarrow Q}(x)$ is the usual $\overline{\mathrm{MS}}$ splitting kernel, $m$ is the quark

[^180]mass and $\mu$ is the renormalization scale ${ }^{4}$ which we typically choose to be $\mu=Q$.

An important feature of the ACOT scheme is that it reduces to the appropriate limit both as $m \rightarrow 0$ and $m \rightarrow \infty$ as we illustrate below.

## 1. Fixed-flavor-number-scheme limit

Specifically, in the limit where the quark $Q$ is relatively heavy compared to the characteristic energy scale ( $\mu \lesssim$ $m$ ), we find $\sigma_{\mathrm{LO}} \sim \sigma_{\mathrm{SUB}}$ such that $\sigma_{\mathrm{TOT}} \sim \sigma_{\mathrm{NLO}}$. In this limit, the ACOT result naturally reduces to the fixed-flavor-number-scheme (FFNS) result. In the FFNS, the heavy quark is treated as being extrinsic to the hadron, and there is no corresponding heavy quark $\operatorname{PDF}\left(f_{Q} \sim 0\right)$; thus $\sigma_{\mathrm{LO}} \sim 0$. We also have $\sigma_{\mathrm{SUB}} \sim 0$ because this is proportional to $\ln \left(\mu^{2} / m^{2}\right)$. Thus, when the quark $Q$ is heavy relative to the characteristic energy scale $\mu$, the ACOT result reduces to $\sigma_{\mathrm{TOT}} \sim \sigma_{\mathrm{NLO}}$.

## 2. Zero-mass variable-flavor-number-scheme limit

Conversely, in the limit where the quark $Q$ is relatively light compared to the characteristic energy scale ( $\mu \gtrsim m$ ), we find that $\sigma_{\text {LO }}$ yields the dominant part of the result, and the "formal" $\mathrm{NLO} \mathcal{O}\left(\alpha_{S}\right)$ contribution $\left\{\sigma_{\mathrm{NLO}}-\sigma_{\mathrm{SUB}}\right\}$ is an $\mathcal{O}\left(\alpha_{S}\right)$ correction.

In the limit $m / \mu \rightarrow 0$, the ACOT result will reduce to the $\overline{\mathrm{MS}}$ zero-mass variable-flavor-number-scheme (ZMVFNS) limit exactly without any finite renormalizations. In this limit, the quark mass $m$ no longer plays any dynamical role and purely serves as a regulator. The $\sigma_{\mathrm{NLO}}$ term diverges due to the internal exchange of the quark $Q$, and this singularity will be canceled by $\sigma_{\text {SUB }}$.

## 3. ACOT as a minimal extension of $\overline{\mathrm{MS}}$

We illustrate the versatile role of the quark mass in Fig. 3(a) where we display the $\overline{\mathrm{MS}} \mathrm{ZM}-V F N S$ and the ACOT result as a function of the quark mass $m$.

We observe that when $m$ is within a decade or two of $\mu$ that the quark mass plays a dynamic role; however, for $m \ll \mu$, the quark mass purely serves as a regulator and the specific value is not important. Operationally, it means we can obtain the $\overline{\mathrm{MS}}$ ZM-VFNS result either by i) computing the terms using dimensional regularization and setting the regulator to zero, or ii) by computing the terms using the quark mass as the regulator and then setting this to zero. ${ }^{5}$ To demonstrate this point explicitly, in Fig. 3(b) we again display the $\overline{\mathrm{MS}} \mathrm{ZM}-\mathrm{VFNS}$ and the ACOT results

[^181]

FIG. 3 (color online). Comparison of $F_{2}^{c}(x, Q)$ (scaled by $10^{4}$ ) vs the quark mass $m$ in GeV for fixed $x=0.1$ and $Q=10 \mathrm{GeV}$. The red dots are the full ACOT result, and the blue line is the massless $\overline{\mathrm{MS}}$ result. The logarithmic plot demonstrates this result holds precisely in the $m \rightarrow 0$ limit.
but this time with a logarithmic scale to highlight the small $m$ region. We clearly see that ACOT reduces the $\overline{\mathrm{MS}} \mathrm{ZM}-$ VFNS exactly in this limit without any additional finite renormalization contributions. ${ }^{6}$

The ACOT scheme is minimal in the sense that the construction of the massive short distance cross sections does not need any observable-dependent extra contributions or any regulators to smooth the transition between the high and low scale regions. The ACOT prescription is to just calculate the massive partonic cross sections and perform the factorization using the quark mass as regulator.

It is in this sense that we claim the ACOT scheme is the minimal massive extension of the $\overline{\mathrm{MS}}$ ZM-VFNS. In the limit $m / \mu \rightarrow 0$ it reduces exactly to the $\overline{\mathrm{MS}}$ ZM-VFNS, in the limit $m / \mu \gtrsim 1$ the heavy quark decouples from the PDFs and we obtain exactly the FFNS for $m / \mu \gg 1$ and no finite renormalizations or additional parameters are needed.

## 4. When do we need heavy quark PDFs

The novel ingredient in the above calculation is the inclusion of the heavy quark PDF contribution which

[^182]

FIG. 4. Comparison of the DGLAP evolved charm PDF $f_{c}(x, \mu)$ with the perturbatively computed single splitting (SUB) $\tilde{f}_{c}(x, \mu)=f_{g}(x, \mu) \otimes \tilde{P}_{g \rightarrow c}$ vs $\mu$ in GeV for two representative values of $x$.
resums logs of $\alpha_{S} \ln \left(\mu^{2} / m^{2}\right)$. An obvious question is when do we need to consider such terms, and how large are their contributions? The answer is illustrated in Fig. 4 where we compare the Dokshitzer, Gribov, Lipatov, Altarelli, Parisi (DGLAP) evolved PDF $f_{Q}(x, \mu)$ with the single splitting perturbative result $\tilde{f}_{Q}(x, \mu)$.

The DGLAP PDF evolution sums a nonperturbative infinite tower of logs which are contained in $\sigma_{\text {LO }}$ while the $\sigma_{\text {SUB }}$ contribution removes the perturbative single splitting component which is already included in the $\sigma_{\text {NLO }}$ contribution. Hence, at the PDF level the difference between the heavy quark DGLAP evolved PDF $f_{Q}$ and the single-splitting perturbative $\tilde{f}_{Q}$ will indicate the contribution of the higher order logs which are resummed into the heavy quark PDF. Here, $\tilde{f}_{Q}=f_{g} \otimes \tilde{P}_{g \rightarrow Q}$ represents the PDF of a heavy quark $Q$ generated from a single perturbative splitting.

For $\mu \sim m$ we see that $f_{Q}$ and $\tilde{f}_{Q}$ match quite closely, whereas they differ significantly for $\mu$ values a few times $m$. While the details will depend on the specific process, in general we find that for $\mu$-scales a few times $m$ the terms resummed by the heavy quark PDF can be significant. Additionally, the difference between $f_{Q}$ and $\tilde{f}_{Q}$ will be reduced at higher orders as more perturbative splittings are included in $\tilde{f}_{Q}$.

Note that these scales are much lower than one might estimate using the naive criterion $\frac{\alpha_{S}}{2 \pi} \ln \left(\mu^{2} / m^{2}\right) \sim 1$; in particular, the ACOT calculation often yields reduced $\mu$ dependence as the quark dominated $\sigma_{\text {LO }}$ contributions typically have behavior which is complementary to the gluon-initiated $\sigma_{\text {NLO }}$ terms.

## B. S-ACOT

In a corresponding application, it was observed that the heavy quark mass could be set to zero in certain pieces of the hard scattering terms without any loss of accuracy. This modification of the ACOT scheme goes by the name simplified-ACOT (S-ACOT) and can be summarized as follows [8].

S-ACOT: For hard-scattering processes with incoming heavy quarks or with internal on-shell cuts on a heavy quark line, the heavy quark mass can be set to zero $(m=0)$ for these pieces.

If we consider the case of NLO DIS heavy quark production, this means we can set $m=0$ for the LO terms $(Q V \rightarrow Q)$ as this involves an incoming heavy quark, and we can set $m=0$ for the SUB terms as this has an on-shell cut on an internal heavy quark line. Hence, the only contribution which requires calculation with $m$ retained is the NLO $g V \rightarrow Q \bar{Q}$ process. Figure 5 displays a comparison of a calculation using the ACOT scheme with all masses retained vs the S-ACOT scheme; as expected, these two results match throughout the full kinematic region.

It is important to note that the S-ACOT scheme is not an approximation; this is an exact renormalization scheme, extensible to all orders.

## C. ACOT and $\boldsymbol{\chi}$ rescaling

As we have illustrated in Sec. II A above, in the limit $Q^{2} \gg m^{2}$ the mass simply plays the role of a regulator. In contrast, for $Q^{2} \sim m^{2}$ the value of the mass is of consequence for the physics. The mass can enter dynamically

FIG. 5 (color online). $F_{2}^{c}$ for $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, FFNS, and ZM-VFNS. The ACOT and S-ACOT results are virtually identical.
in the hard-scattering matrix element, and can enter kinematically in the phase space of the process.

We will demonstrate that for the processes of interest the primary role of the mass is kinematic and not dynamic. It was this idea which was behind the original slow-rescaling prescription of [9] which considered DIS charm production (e.g., $\gamma c \rightarrow c$ ) introducing the shift

$$
\begin{equation*}
x \rightarrow \chi=x\left[1+\left(\frac{m_{c}}{Q}\right)^{2}\right] \tag{3}
\end{equation*}
$$

This prescription accounted for the charm quark mass by effectively reducing the phase space for the final state by an amount proportional to $\left(m_{c} / Q\right)^{2}$.

This idea was extended in the $\chi$-scheme by realizing that in addition to the observed final-state charm quark, if the beam has a charm-flavor quantum number of zero (such as a proton beam) then there is also an anticharm quark in the beam fragments because all the charm quarks are ultimately produced by gluon splitting ( $g \rightarrow c \bar{c}$ ) into a charm pair. ${ }^{7}$ For this case the scaling variable becomes

$$
\begin{equation*}
\chi=x\left[1+\left(\frac{2 m_{c}}{Q}\right)^{2}\right] \tag{4}
\end{equation*}
$$

This rescaling is implemented in the $\mathrm{ACOT}_{\chi}$ scheme, for example [10-12]. The factor $\left(1+\left(2 m_{c}\right)^{2} / Q^{2}\right)$ represents a kinematic suppression factor which will suppress the charm process relative to the lighter quarks. Additionally, the $\chi$ scaling ensures the threshold kinematics $\left(W^{2}>4 m_{c}^{2}+M^{2}\right)$ are satisfied; while it is important to satisfy this condition for large $x$, this may prove too restrictive at small $x$ where the HERA data are especially precise. ${ }^{8}$

To encompass all the above results, we can define a general scaling variable $\chi(n)$ as

$$
\begin{equation*}
\chi(n)=x\left[1+\left(\frac{n m_{c}}{Q}\right)^{2}\right] \tag{5}
\end{equation*}
$$

where $n=\{0,1,2\}$. Here, $n=0$ corresponds to the massless result without rescaling, $n=1$ corresponds to the original Barnett slow rescaling, and $n=2$ corresponds to the $\chi$ rescaling.

## D. Phase space (kinematic) and dynamic mass

We now investigate the effects of separately varying the mass entering the $\chi(n)$ variable taking into account the phase space constraints and the mass value entering

[^183]the hard scattering cross section $\hat{\sigma}(m)$. We call the former mass parameter "phase space (kinematic) mass" and the latter "dynamic mass". 9

In Fig. 6(a) we display $F_{2}^{c}(x, Q)$ vs $Q$. The family of 3 curves shows the NLO ACOT calculation with $\chi(n)$ scaling using a zero dynamic mass for the hard scattering. We compare this with Fig. 6(b) which shows $F_{2}^{c}(x, Q)$ in the NLO ACOT scheme using a fixed $n=2$ scaling, but varying the mass used in the hard-scattering cross section. The upper (cyan) curves use a nonzero dynamic mass [ $\left.\hat{\sigma}\left(m_{c}=1.3\right)\right]$ and the lower (purple) curves have been obtained with a vanishing dynamic mass $\left[\hat{\sigma}\left(m_{c}=0\right)\right]$. We observe that the effect of the "dynamic mass" in $\hat{\sigma}\left(m_{c}\right)$ is only of consequence in the limited region $Q \gtrsim m$, and even in this region the effect is minimal. In contrast, the influence of the phase space (kinematic) mass shown in Fig. 6(a) is larger than the dynamic mass shown in Fig. 6(b). To highlight these differences, we scale the curves in Fig. 7 by the massless $n=2$ scaling result and plot bands that represent the variation of the dynamic and kinematic masses.

In conclusion, we have shown that (up to $\mathcal{O}\left(\alpha_{S}\right)$ ) the phase space mass dependence is generally the dominant contribution to the DIS structure functions. Assuming that this observation remains true at higher orders, it is possible to obtain a good approximation of the structure functions in the ACOT scheme at NNLO and $\mathrm{N}^{3} \mathrm{LO}$ using the massless Wilson coefficients together with a nonzero phase space mass entering via the $\chi(n)$ prescription.

## III. ACOT SCHEME BEYOND NLO

We have shown using the NLO full ACOT scheme that the dominant mass effects are those coming from the phase space which can be taken into account via a generalized slow-rescaling $\chi(n)$ prescription. Assuming that a similar relation remains true at higher orders, one can construct the following approximation to the ACOT result up to $\mathrm{N}^{3} \mathrm{LO}$ $\left(\mathcal{O}\left(\alpha_{S}^{3}\right)\right)$ :

$$
\begin{align*}
\operatorname{ACOT}\left[\mathcal{O}\left(\alpha_{S}^{0+1+2+3}\right)\right] \simeq & \operatorname{ACOT}\left[\mathcal{O}\left(\alpha_{S}^{0+1}\right)\right] \\
& +\mathrm{ZM}^{-\operatorname{VFNS}_{\chi(n)}}\left[\mathcal{O}\left(\alpha_{S}^{2+3}\right)\right] \tag{6}
\end{align*}
$$

In this equation, "ACOT" generically represents any variant of the ACOT scheme (ACOT, S-ACOT, S-ACOT ${ }_{\chi}$ ); for the results presented in Sec. IV, we will use the fully massive ACOT scheme with all masses retained out to NLO. The $\mathrm{ZM}^{2}-\mathrm{VFNS}_{\chi(n)}$ term uses the massless Wilson

[^184]
(a) Comparison of $F_{2}^{c}(x, Q)$ vs. $Q$ for the NLO ACOT calculation for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) using zero dynamic mass $[\hat{\sigma}(m=0)]$ to show the effect of $n$ scaling; from top to bottom $n=\{0,1,2\}$ (pink, black, purple).

(b) Comparison of $F_{2}^{c}(x, Q)$ vs. $Q$ for the NLO ACOT calculation for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). Here we keep the scaling fixed $n=2$ and compare the effect of varying the dynamic mass in the Wilson coefficient. The upper (cyan) curve uses a non-zero dynamic mass $[\widehat{\sigma}(m=1.3)]$ and the lower (purple) curve uses a zero dynamic mass $[\widehat{\sigma}(m=0)]$.

FIG. 6 (color online). Comparison of phase space (kinematic) \& dynamic mass effects.

FIG. 7 (color online). Comparison of kinematic \& dynamic mass effects for $F_{2}^{c}(x, Q)$ vs $Q$ for the NLO ACOT calculation for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). The curves are scaled by the massless $n=2$ result. The wider (yellow) band represents the variation of the kinematic mass of Fig. 6(a); note this band extends down to a ratio of 1.0. The narrower (blue) band is overlaid on the plot and represents the variation of the dynamic mass of Fig. 6(b).
coefficients at $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$ and $\mathcal{O}\left(\alpha \alpha_{S}^{3}\right)$ with the specified $\chi(n)$ scaling. ${ }^{10}$ Sample processes which contribute at this order are displayed in Fig. 8.

We use the $\mathrm{ZM}^{-V F N S}{ }_{\chi(n)}$ result in Eq. (6) to approximate the higher-order terms because not all the necessary massive Wilson coefficients at $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$ and $\mathcal{O}\left(\alpha \alpha_{S}^{3}\right)$ have been computed. There has been a calculation of neutral current electroproduction (equal quark masses, vector coupling) of heavy quarks at this order by Smith and van Neerven [13] in the FFNS which could be used to

[^185]obtain the massive Wilson coefficients in the S-ACOT scheme by applying appropriate collinear subtraction terms. However, for the original ACOT scheme it would then still be necessary to compute the massive Wilson coefficients for the heavy quark initiated subprocess at $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$. See Refs. [12,14] for details.

Using the result of Ref. [13], Thorne and Roberts developed an NLO variable-flavor-number scheme (VFNS) [7,15], and an improved NNLO formulation was presented in Ref. [16]. The fixed-order next-to-leading logs (FONLL) formalism was outlined in Ref. [17] and this was used to construct matched expressions for structure functions to NNLO [18]; implications of these results in the context of the NNPDF analysis were presented in Ref. [19]. An

FIG. 8. Sample Feynman diagrams contributing to DIS heavy quark production (from left): LO $\mathcal{O}\left(\alpha_{S}^{0}\right)$ quark-boson scattering $Q V \rightarrow Q, \mathrm{NLO} \mathcal{O}\left(\alpha_{S}^{1}\right)$ gluon-boson scattering $g V \rightarrow Q \bar{Q}$, NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ boson-gluon scattering $g V \rightarrow g Q \bar{Q}$, and $\mathrm{N}^{3} \mathrm{LO}$ $\mathcal{O}\left(\alpha_{S}^{3}\right)$ boson-gluon scattering $g V \rightarrow g g Q \bar{Q}$.
overview and comparison of these analyses was presented in the 2009 Les Houches report [20]. More recently, an NNLO S-ACOT- $\chi$ calculation was developed in Refs. [12,14]. For charge current case massive calculations are available at order $\mathcal{O}\left(\alpha \alpha_{S}\right)$ [21-23] and partial results at order $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$ [24]. Comparative analyses of these schemes are under investigation; however, this is beyond the scope of this paper.

Here, we argue that the massless Wilson coefficients at $\mathcal{O}\left(\alpha \alpha_{S}^{2}\right)$ together with a $\chi(n)$ prescription provide a very good approximation of the exact result. At worst, the maximum error would be of order $\mathcal{O}\left(\alpha \alpha_{S}^{2} \times\left[m^{2} / Q^{2}\right]\right)$. However, based on the arguments of Sec. II D we expect the inclusion of the phase space mass effects to contain the dominant higher order contributions so that the actual error should be substantially smaller.

The massless higher order coefficient functions for the DIS structure function $F_{2}$ via photon exchange can be found in Refs. [25-27] for $\mathcal{O}\left(\alpha_{S}^{1}\right)$, Refs. [28-30] for $\mathcal{O}\left(\alpha_{S}^{2}\right)$, and Ref. [31] for $\mathcal{O}\left(\alpha_{S}^{3}\right)$. For our numerical code we have used the $x$-space parameterization provided in Refs. [32,33] for $\mathcal{O}\left(\alpha_{S}^{2}\right)$, and Refs. [31,34] for $\mathcal{O}\left(\alpha_{S}^{3}\right)$.

The expressions for the structure function $F_{L}$ have been calculated in Refs. [29,35] for $\mathcal{O}\left(\alpha_{S}^{2}\right)$, and Ref. [31] for $\mathcal{O}\left(\alpha_{S}^{3}\right)$. In our FORTRAN code we have used the $x$-space parameterization provided in Refs. [32,36] for $\mathcal{O}\left(\alpha_{S}^{2}\right)$ and Ref. [36] for $\mathcal{O}\left(\alpha_{S}^{3}\right)$.

In order to calculate the inclusive structure functions $F_{2}$ and $F_{L}$ in the ZM-VFNS $\chi_{\chi}$ using these Wilson coefficients, plus- and delta-distributions have to be evaluated which is in principle straightforward. However, for the implementation of the slow-rescaling prescription it is necessary to decompose the Wilson coefficients into the contributions from different parton flavors. This step is nontrivial at $\mathcal{O}\left(\alpha_{S}^{2}\right)$ and beyond, and we therefore provide some details of our calculation in the Appendix B.

## A. Choice of $\boldsymbol{\chi}(\boldsymbol{n})$ rescaling

We now consider our choice for the appropriate generalized $\chi(n)$-rescaling variable.

In Table I we display the various rescalings of $\xi$ for the LO $\gamma Q \rightarrow Q$ process and the NLO $\gamma g \rightarrow Q \bar{Q}$ process. The "general" result is obtained by working out the detailed kinematics for the corresponding process [37].

The factor $\eta$ is the rescaling due to the hadronic mass $M$; notice that this factors out from the partonic mass dependence as it should [1]. For details see Appendix A.

The LO case with full massive kinematics has been computed in Ref. [37]. In the limit where the initial mass is small $\left(m_{1} \rightarrow 0\right)$, we recover the Barnett [9] slowrescaling result. Additionally, we obtain the curious result that for a neutral current equal mass case ( $m_{1}=m_{2}$ ) the rescaling is this same factor.

For the NLO gluon-induced process, the interpretation of the rescaling is straightforward; the phase space is simply suppressed by the total invariant mass of the final state $\left(m_{1}+m_{2}\right)$ compared to the scale $Q$. For the charged current case where we neglect $m_{1}$, we again obtain the standard rescaling factor. However, for the neutral current case $\left(m_{1}=m_{2}\right)$ we obtain a rescaling factor which is analogous to the $\chi$-scaling factor.

For the purposes of this study, we will vary the phase space mass using the $\chi(n)$ rescaling with $n=\{0,1,2\}$. While $n=0$ corresponds to the massless case (no rescaling), it is not obvious whether $n=1$ or $n=2$ is the preferred rescaling choice for higher orders. Thus, we

TABLE I. The massive rescaling factor for the LO quark-initiated process $\left(V q_{1} \rightarrow q_{2}\right)$, and the NLO gluon-initiated process ( $V g \rightarrow q_{1} \bar{q}_{2}$ ). The quarks $q_{1,2}$ have mass $m_{1,2}$, respectively, and $V$ represents the vector boson; $\gamma / Z$ for neutral current processes ( $m_{1}=m_{2}$ ), and $W^{ \pm}$for charged current processes $\left(m_{1} \neq m_{2}\right) . \eta$ is the scaling factor which depends on the hadronic mass $M$; see Appendix A for details. The triangle-function is defined as: $\Delta[a, b, c]=$

| $\sqrt{a^{2}+b^{2}+c^{2}-2(a b+b c+c a)}$. |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| $\xi$ | General | $m_{1}=0$ | $m_{1}=m_{2}=m$ | $\chi$ scheme: |
| $w^{3}$ | $\eta\left[\frac{Q^{2}-m_{1}^{2}+m_{2}^{2}+\Delta\left[-Q^{2}, m_{1}^{2}, m_{2}^{2}\right]}{2 Q^{2}}\right]$ | $\eta\left[1+\frac{m_{2}^{2}}{Q^{2}}\right]$ | $\eta\left[1+\frac{m^{2}}{Q^{2}}\right]$ | $\eta\left[1+\frac{(2 m)^{2}}{Q^{2}}\right]$ |
|  | $\eta\left[1+\left(\frac{m_{1}+m_{2}}{Q}\right)^{2}\right]$ | $\eta\left[1+\frac{m_{2}^{2}}{Q^{2}}\right]$ | $\eta\left[1+\frac{(2 m)^{2}}{Q^{2}}\right]$ | $\eta\left[1+\frac{(2 m)^{2}}{Q^{2}}\right]$ |

FIG. 9 (color online). $\quad F_{2, L}$ vs $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). The three lines show the scaling variable: $n=\{0,1,2\}$ (red, green, blue). We observe the effect of the $n$ scaling is negligible except for very small $Q$ values.
will use the range between $n=1$ and $n=2$ as a measure of our theoretical uncertainty arising from this ambiguity.

## IV. RESULTS

We now present the results of our calculation extending the ACOT scheme to NNLO and $\mathrm{N}^{3} \mathrm{LO}$. As outlined in Eq. (6), we will use the fully massive ACOT scheme for the LO and NLO contributions, and combine this with the ZM-VFNS supplemented with the $\chi$-rescaling prescription to approximate the higher order terms. We will use the QCDNUM program [38] with the VFNS evolved with the DGLAP kernels at NNLO to generate our PDFs from an initial distribution based on the Les Houches benchmark set [39]; this ensures that our heavy quark PDFs are consistently evolved so that the heavy quark initiated LO terms properly match the corresponding SUB contribution. At NNLO the proper matching conditions across flavor thresholds introduces discontinuities in the PDFs which are incorporated in the QCDNUM program; we discuss this in detail in Appendix C. We choose $m_{c}=1.3 \mathrm{GeV}, m_{b}=$ $4.5 \mathrm{GeV}, \alpha_{S}\left(M_{Z}\right)=0.118$. We note that the QCDNUM ZM-STFN package has the massless Wilson coefficients computed up to $\mathrm{N}^{3} \mathrm{LO}$; we cross checked our implementation of ACOT in the massless limit with QCDNUM, and they agree precisely.

## A. Effect of $\boldsymbol{\chi}(\boldsymbol{n})$ scaling

In Figs. 9(a) and 9(b) we display the structure functions $F_{2}$ and $F_{L}$, respectively, for selected $x$ values as a function of $Q$. Each plot has three curves which are computed using
$n$ scalings of $\{0,1,2\}$. We observe that the effect of the $n$ scaling is negligible except for very small $Q$ values. This result is in part because the heavy quarks are only a fraction of the total structure function, and the effects of the $n$ scaling are reduced at larger $Q$ values.

In Fig. 10 we magnify the small $Q$ region of $F_{L}$ of Fig. 9 for $x=10^{-5}$, where the effects of using different scalings are largest. We can see that for inclusive observables, the $n=1$ and $n=2$ scalings give nearly identical results, but they differ from the massless case ( $n=0$ ). This result, together with the observation that at NLO kinematic mass effects are dominant, suggests that the error we have in our approach is relatively small and approximated by the band between $n=1$ and $n=2$ results.

FIG. 10 (color online). Enlargement of Fig. 9(b) for $x=10^{-5}$ showing the small $Q$ region. Here we can distinguish plots for different scalings; from top to bottom we have $n=\{0,1,2\}$ (red, green, blue).

FIG. 11 (color online). Effect of $\chi(n)$ scaling for $n=\{0,1,2\}$ (left to right) at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-3}\right\}$. Reading from the bottom we have fractional contribution for each quark flavor to $F_{2, L}^{j} / F_{2, L}$ vs $Q$ from $\{u, d, s, c, b\}$ (green, blue, cyan, magenta, pink).

## B. Flavor decomposition of $\boldsymbol{\chi}(\boldsymbol{n})$ scaling

We can investigate the effects of the $\chi(n)$ scaling in more details by examining the flavor decomposition of the structure functions.

In Figs. 11(a) and 11(b) we display the fractional contributions of quark flavors to the structure functions $F_{2, L}$ for selected $n$-scaling values as a function of $Q$. Flavor decomposition of inclusive structure functions is defined in Appendix B in Eqs. (B1) and (B2). We observe the $n$ scaling reduces the relative contributions of charm and bottom at low $Q$ scales. For example, without any $n$ scaling ( $n=0$ ) we find the charm and bottom quarks contribute an unusually large fraction at very low scales $\left(Q \sim m_{c}\right)$ as they are (incorrectly) treated as massless partons in this region. The result of the different $n$ scalings $(n=1,2)$ is to introduce a kinematic penalty which properly suppresses the contribution of these heavy quarks in the low $Q$ region. In the following, we will generally use the $n=2$ scaling for our comparisons.

## C. $\boldsymbol{F}_{\mathbf{2}, L}$ initial-state flavor decomposition

In Figs. 12(a) and 12(b) we display the fractional contributions for the initial-state quarks $(i)$ to the structure functions $F_{2}$ and $F_{L}$, ${ }^{11}$, respectively, for selected $x$ values as a function of $Q$; here we have used $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{g, u, d, s, c, b\}$. Although this decompo-

[^186]sition is not physically observable, it is instructive to see which PDFs are dominantly influencing the result. We observe that for large $x$ and low $Q$ the heavy flavor contributions are minimal. For example, for $x=10^{-1}$ we see the contribution of the $u$-quark comprises $\sim 80 \%$ of the $F_{2}$ structure function at low $Q$. In contrast, at $x=10^{-5}$ and large $Q$ we see the $F_{2}$ contributions of the $u$-quark and $c$-quark are comparable (as they both couple with a factor $4 / 9$ ), and the $d$-quark and $s$-quark are comparable (as they both couple with a factor $1 / 9$ ).

It is notable that the gluon contribution to $F_{L}$ is significant. For $x=10^{-1}$ this is roughly $40 \%$ throughout the $Q$ range, and can be even larger for smaller $x$ values.

## D. $\boldsymbol{F}_{\mathbf{2}, L}$ final-state flavor decomposition

In Figs. 13(a) and 13(b) we display the fractional contributions for the final-state quarks $(j)$ to the structure functions $F_{2}$ and $F_{L}$, respectively, for selected $x$ values as a function of $Q$; here we have used $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{u, d, s, c, b\}$. Again, we observe that for large $x$ and low $Q$ the heavy flavor contributions are minimal, but these can grow quickly as we move to smaller $x$ and larger $Q$.

## E. Comparison of LO, NLO, NNLO, $\mathrm{N}^{\mathbf{3}} \mathrm{LO}$

In Fig. 14(a) we display the results for $F_{2}$ vs $Q$ computed at various orders. For large $x$ (cf. $x=0.1$ ) we find the perturbative calculation is particularly stable; we see that the LO result is within $20 \%$ of the others at small $Q$, and

FIG. 12 (color online). Fractional flavor decomposition of "initial-state" $F_{2, L}^{i} / F_{2, L}$ vs $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for $n=2$ scaling. Reading from the bottom, we plot the cumulative contributions to $F_{2, L}$ from $\{g, u, d, s, c, b\}$, (red, green, blue, cyan, magenta, pink).

FIG. 13 (color online). Fractional contribution for each quark flavor to $F_{2, L}^{j} / F_{2, L}$ vs $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right). Results are displayed for $n=2$ scaling. Reading from the bottom, we have the cumulative contributions from the $\{u, d, s, c, b\}$ (green, blue, cyan, magenta, pink).
within $5 \%$ at large $Q$. The NLO is within $2 \%$ at small $Q$, and indistinguishable from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ for $Q$ values above $\sim 10 \mathrm{GeV}$. The NNLO and $\mathrm{N}^{3} \mathrm{LO}$ results are essentially identical throughout the kinematic range. For
smaller $x$ values $\left(10^{-3}, 10^{-5}\right)$ the contribution of the higher order terms increases. Here, the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ coincide for $Q$ values above $\sim 5 \mathrm{GeV}$, but the NLO result can differ by $\sim 5 \%$.

FIG. 14 (color online). $\quad F_{2, L}$ vs $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$ (red, green, blue, cyan) for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for $n=2$ scaling.

In Fig. 14(b) we display the results for $F_{L}$ vs $Q$ computed at various orders. In contrast to $F_{2}$, we find the NLO corrections are large for $F_{L}$; this is because the LO $F_{L}$ contribution (which violates the Callan-Gross relation) is suppressed by $\left(m^{2} / Q^{2}\right)$ compared to the dominant gluon contributions which enter at NLO. Consequently, we observe (as expected) that the LO result for $F_{L}$ receives large contributions from the higher order terms. ${ }^{12}$ Essentially, the NLO is the first nontrivial order for $F_{L}$, and the subsequent contributions then converge. For example, at large $x$ (cf. $x=0.1$ ) for $Q \sim 10 \mathrm{GeV}$ we find the NLO result yields $\sim 60$ to $80 \%$ of the total, the NNLO is a $\sim 20 \%$ correction, and the $\mathrm{N}^{3} \mathrm{LO}$ is a $\sim 10 \%$ correction. For lower $x$ values $\left(10^{-3}, 10^{-5}\right)$ the convergence of the perturbative series improves, and the NLO results is within $\sim 10 \%$ of the $\mathrm{N}^{3} \mathrm{LO}$ result. Curiously, for $x=10^{-5}$ the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ roughly compensate each other so that the NLO and the $\mathrm{N}^{3} \mathrm{LO}$ match quite closely for $Q \geq 2 \mathrm{GeV}$.

While the calculation of $F_{L}$ is certainly more challenging, examining Fig. 1 we see that for most of the relevant kinematic range probed by HERA the theoretical calculation is quite stable. For example, in the high $Q^{2}$ region where HERA is probing intermediate $x$ values $\left(x \sim 10^{-3}\right)$ the spread of the $\chi(n)$ scalings is small. The challenge

[^187]arises in the low $Q$ region $(Q \sim 2 \mathrm{GeV})$ where the $x$ values are $\sim 10^{-4}$; in this region, there is some spread between the various curves at the lowest $x$ value $\left(\sim 10^{-5}\right)$, but for $x \sim 10^{-3}$ this is greatly reduced.

## V. CONCLUSIONS

We extended the ACOT calculation for DIS structure functions to $\mathrm{N}^{3} \mathrm{LO}$ by combining the exact ACOT scheme at NLO with a $\chi(n)$ rescaling; this allows us to include the leading mass dependence at NNLO and $\mathrm{N}^{3} \mathrm{LO}$. Using the full ACOT calculation at NLO, we demonstrated that the heavy quarks mass dependence for the DIS structure functions is dominated by the kinematic mass contributions, and this can be implemented via a generalized $\chi(n)$-rescaling prescription.

We studied the $F_{2}$ and $F_{L}$ structure functions as a function of $x$ and $Q$. We examined the flavor decomposition of these structure functions, and verified that the heavy quarks were appropriately suppressed in the low $Q$ region. We found the results for $F_{2}$ were very stable across the full kinematic range for $\{x, Q\}$, and the contributions from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ terms were small. For $F_{L}$, the higher order terms gave a proportionally larger contribution (due to the suppression of the LO term from the Callan-Gross relation); nevertheless, the contributions from the NNLO and $\mathrm{N}^{3}$ LO terms were generally small in the region probed by HERA.

The result of this calculation was to obtain precise predictions for the inclusive $F_{2}$ and $F_{L}$ structure functions which can be used to analyze the HERA data.

Yu was supported by the Deutsche Forschungsgemeinschaft (DFG) through Grant No. YU 118/1-1.

## APPENDIX A: KINEMATIC RELATIONS

## 1. Target mass contributions

In the DIS process, the effect of the target mass $(M)$ on the scaling variable is a multiplicative correction factor

$$
\begin{equation*}
\eta=\frac{2 x}{1+\sqrt{1+\frac{4 x^{2} M^{2}}{Q^{2}}}} \rightarrow \underset{M \rightarrow 0}{\rightarrow} x\left[1-\left(\frac{x M}{Q}\right)^{2}\right]+\ldots \tag{Al}
\end{equation*}
$$

This is used in Table I to modify the scaling variable [1,37].

## 2. Barnett scaling

If we consider the charged-current DIS process for charm production, this takes place via the subprocess $W^{+}(q) s(\xi P) \rightarrow c(k)$. If we impose 4-momentum conservation, we have $(q+\xi P)^{2}=k^{2}=m_{c}^{2}$. Defining $q^{2}=$ $-Q^{2}$ and $x=Q^{2} /(2 p \cdot q)$, we obtain the traditional "slow rescaling" relation [9]

$$
\xi=x\left(1+\frac{m_{c}^{2}}{Q^{2}}\right)
$$

which was used in Eq. (3).

## 3. $\hat{W}$ constraints

If we compute the invariant mass $\hat{W}$ of a boson of momentum $q$ scattering from a light parton $a$ of momentum $p_{a}=\xi P$, we find [14]

$$
\begin{equation*}
\hat{W}=\left(p_{a}+q\right)^{2}=Q^{2}(\xi / x-1) . \tag{A2}
\end{equation*}
$$

If the partonic final state has a minimum invariant mass $\hat{W}_{\text {min }}=4 m^{2}$, then $\xi$ is constrained by

$$
\begin{equation*}
1 \geq \xi \geq \chi \geq x \tag{AB}
\end{equation*}
$$

where $\chi=x\left(1+4 m^{2} / Q^{2}\right)$. This is the relation used in Eq. (4). This choice will ensure $\hat{W} \geq \hat{W}_{\text {min }}$ is satisfied. While this constraint is important in the large $x$ region,
this may be too restrictive in the small $x$ region-especially as this is the region where the HERA data is very precise.

## APPENDIX B: DECOMPOSITION OF THE WILSON COEFFICIENTS

In this appendix we present the decomposition of the Wilson coefficients used to implement the scheme. We will need to decompose the structure function $F$ in terms of the individual partonic contributions,

$$
\begin{equation*}
F=\sum_{i=0}^{5} \sum_{j=1}^{6} F^{i j} \tag{Bi}
\end{equation*}
$$

where the indices $i$ and $j$ represent initial and final-state partons, respectively, (see captions of Figs. 15-24). More specifically, $i=0$ denotes a gluon and $i, j=1,2,3, \ldots$ denotes $u, d, s, \ldots$ quarks and antiquarks. A top quark PDF ( $i=6$ ) is not included in this study.

Let us consider the heavy quark structure functions $F_{2, L}^{c}$ as an example. This is obtained by requiring that there is a charm in the initial state while summing over the final-state flavors up to and including charm in Eq. (B1), or by

FIG. 15. $\mathcal{O}\left(\alpha_{S}^{0}\right)-\gamma^{*} q_{i} \rightarrow q_{i}$. Contributes to $C_{a, q}^{\mathrm{ns}}$ (and hence to $C_{a, q}^{\mathrm{s}}$ ) but not to $C_{a, q}^{\mathrm{ps}}$.

FIG. 16. $\mathcal{O}\left(\alpha_{S}^{1}\right)-\gamma^{*} q_{i} \rightarrow q_{i} g$. Contributes to $C_{a, q}^{\mathrm{ns}}$ (and hence to $C_{a, q}^{\mathrm{s}}$ ) but not to $C_{a, q}^{\mathrm{ps}}$. This contribution does not depend on $n_{f}$.

FIG. 17. $\mathcal{O}\left(\alpha_{S}^{1}\right)-\gamma^{*} g \rightarrow q_{j} \bar{q}_{j}$.

FIG. 18. $\mathcal{O}\left(\alpha_{S}^{2}\right)-\gamma^{*} q_{i} \rightarrow q_{i} g g$. Contributes to $C_{a, q}^{\mathrm{ns}}$ (and hence to $C_{a, q}^{\mathrm{s}}$ ) but not to $C_{a, q}^{\mathrm{ps}}$. This part is independent of $n_{f}$.

FIG. 19. $\mathcal{O}\left(\alpha_{S}^{2}\right) — \gamma^{*} g \rightarrow q_{j} \bar{q}_{j} g$.
requiring that there is a charm in the final-state and summing over the initial flavors up to and including charm. Thus, we obtain:

$$
\begin{equation*}
F^{c}=\sum_{i=0}^{3} F^{i 4}+\sum_{j=1}^{3} F^{4 j}+F^{44} \tag{B2}
\end{equation*}
$$

The case where the initial and final-state are both charm quarks $\left(F^{44}\right)$ has been written explicitly in the equation to avoid double counting this contribution. ${ }^{13}$ The first sum in Eq. (B2) includes cases, as in Fig. 20, where the incoming quark is a light quark while the charm quark is one of the quarks in the quark antiquark pair.

In order to obtain the required decomposition, there are some manipulations that need to be performed to transform

[^188]
(a) Contribution proportional to $n_{f}$ for $C_{a, q}^{\mathrm{ps}}$.

(b) Contribution proportional to $n_{f}$ for $C_{a, q}^{\mathrm{ns}}$.

FIG. 20. $\mathcal{O}\left(\alpha_{S}^{2}\right)-\gamma^{*} q_{i} \rightarrow q_{i} q_{j} \bar{q}_{j}$.

FIG. 21. $\mathcal{O}\left(\alpha_{S}^{3}\right)-\gamma^{*} q_{i} \rightarrow q_{i} g g g$. Contribution to $C_{a, q}^{\mathrm{ns}}$ not proportional to $n_{f}$.
from the singlet ( $s$ ), nonsinglet ( $n s$ ), and purely singlet $(p s)$ structure function combinations found in the literature into individual partonic components.

The general expression for the structure function is given by:

$$
\begin{equation*}
x^{-1} F_{a}=q_{n s} \otimes C_{a, q}^{\mathrm{ns}}+\left\langle e^{2}\right\rangle\left(q_{\mathrm{s}} \otimes C_{a, q}^{\mathrm{s}}+g \otimes C_{a, g}\right) \tag{B3}
\end{equation*}
$$

where $a=\{2, L\}$, and
$q_{\mathrm{ns}}=\sum_{i=1}^{n_{f}}\left(e_{i}^{2}-\left\langle e^{2}\right\rangle\right) q_{i}^{+}, \quad q_{\mathrm{s}}=\sum_{i=1}^{n_{f}} q_{i}^{+}$,
$q_{i}^{+}=q_{i}+\bar{q}_{i}, \quad\left\langle e^{2}\right\rangle=\left\langle e^{2}\right\rangle^{\left(n_{f}\right)}=\frac{1}{n_{f}} \sum_{i=1}^{n_{f}} e_{i}^{2}$,

FIG. 22. $\mathcal{O}\left(\alpha_{S}^{3}\right)-\gamma^{*} g \rightarrow q_{j} \bar{q}_{j} g g$.
and $C_{a, q}^{\mathrm{ns}}, C_{a, q}^{\mathrm{s}}, C_{a, g}$ are the Wilson coefficients. From Eq. (B4) one can extract the contribution from a single initial-state quark as

$$
\begin{equation*}
x^{-1} F_{a, q_{i}}=q_{i}^{+} \otimes\left[e_{i}^{2} C_{a, q}^{\mathrm{ns}}+\left\langle e^{2}\right\rangle C_{a, q}^{\mathrm{ps}}\right] \tag{B5}
\end{equation*}
$$

where $C_{a, q}^{\mathrm{ps}}$ is

$$
\begin{equation*}
C_{a, q}^{\mathrm{ps}}=C_{a, q}^{\mathrm{s}}-C_{a, q}^{\mathrm{ns}} . \tag{B6}
\end{equation*}
$$

To further decompose Eq. (B5) into the different finalstate contributions, we examine the diagrams that contribute to the nonsinglet and purely singlet coefficients. Diagrams in which the photon couples to the incoming quark contribute to $C_{a, q}^{\mathrm{ns}}$ (Figs. 15, 16, 18, and 20(b), etc.), whereas the diagrams where the photon does not couple to

(a) Contribution proportional to $n_{f}$ for $C_{a, q}^{\mathrm{ps}}$.

(b) Contribution proportional to $n_{f}$ for $C_{a, q}^{\mathrm{ns}}$.

FIG. 23. $\mathcal{O}\left(\alpha_{S}^{3}\right)-\gamma^{*} q_{i} \rightarrow q_{i} q_{j} \bar{q}_{j} g$.

FIG. 24. $\mathcal{O}\left(\alpha_{S}^{3}\right)-\gamma^{*} g \rightarrow q_{j} \bar{q}_{j} q_{k} \bar{q}_{k}$.
the incoming quark contribute to $C_{a, q}^{\mathrm{ps}}$; these contributions appear for the first time at $\mathcal{O}\left(\alpha_{S}^{2}\right)$ in Figs. 20(a) and 23(a). Separating out the final-state quark from Eq. (B5) we obtain:

$$
\begin{align*}
x^{-1} F_{a}^{i j}= & q_{i}^{+} \otimes\left\{e _ { i } ^ { 2 } \left[C_{a, q}^{\mathrm{ns}}\left(n_{f}=0\right) \delta_{i j}\right.\right. \\
& \left.+C_{a, q}^{\mathrm{ns}}(j)-C_{a, q}^{\mathrm{ns}}(j-1)\right] \\
& \left.+\left\langle e^{2}\right\rangle^{(j)} C_{a, q}^{\mathrm{ps}}(j)-\left\langle e^{2}\right\rangle^{(j-1)} C_{a, q}^{\mathrm{ps}}(j-1)\right\} . \tag{B7}
\end{align*}
$$

We have introduced $\delta_{i j}$ in the nonsinglet contribution to account for contributions in which the photon couples to the initial and final-state quark. When this is not the case, [i.e., in all purely singlet contributions and in nonsinglet contributions such as the ones in Fig. 20(a)], the difference of the coefficient functions with $n_{f}=j$ and $n_{f}=j-1$ flavors is taken.

Some comments are in order:
(i) We have verified analytically and numerically that one recovers Eq. (B5) when summing over the final state quark partons $\left(j=1, \ldots, n_{f}\right)$ in Eq. (B7).
(ii) The corresponding decomposition for the gluoninitiated subprocesses is simpler than the one in Eq. (B7) since there are only purely singlet contributions:

$$
\begin{equation*}
x^{-1} F_{a}^{0 j}=g \otimes\left\{\left\langle e^{2}\right\rangle^{(j)} C_{a, g}(j)-\left\langle e^{2}\right\rangle^{(j-1)} C_{a, g}(j-1)\right\} . \tag{B8}
\end{equation*}
$$

(iii) We remark that the decomposition in Eq. (B7) also includes the contributions from virtual diagrams to the Wilson coefficients. As has been discussed in the literature [40], such a decomposition is ambiguous at $\mathcal{O}\left(\alpha_{S}^{2}\right)$ and beyond due to the treatment of heavy quark loops contributing to the light quark structure functions. However, numerically the ambiguous terms are small and it is standard to analyze the heavy quark structure functions $F_{2, L}^{c}$
and $F_{2, L}^{b}$ in addition to the inclusive structure functions $F_{2, L}$ without any further prescription.
For the general neutral current case (including Z-boson exchange), the electromagnetic couplings should be replaced by electroweak couplings as follows:

$$
\begin{equation*}
e_{i}^{2} \rightarrow a_{q_{i}}^{+}=e_{i}^{2}-2 e_{i} v_{e} v_{q} \chi_{Z}+\left(v_{e}^{2}+a_{e}^{2}\right)\left(v_{q}^{2}+a_{q}^{2}\right) \chi_{Z}^{2} \tag{B9}
\end{equation*}
$$

where

$$
\begin{equation*}
v_{f}=T_{f}^{3}-2 Q_{f} \sin ^{2} \theta_{W}, \quad a_{f}=T_{3}^{f} \tag{B10}
\end{equation*}
$$

are the standard (axial-)vector couplings of the $Z$-boson to the leptons $(f=e)$ and quarks $(f=q)$. Furthermore, $\chi_{Z}$ is the ratio of the $Z$-boson propagator with respect to the photon propagator including additional coupling factors:

$$
\begin{equation*}
\chi_{Z}=\frac{G_{F} M_{Z}^{2}}{2 \sqrt{2} \pi \alpha_{e m}} \frac{Q^{2}}{Q^{2}+M_{Z}^{2}} . \tag{B11}
\end{equation*}
$$

Finally, the average squared charge is modified as

$$
\begin{equation*}
\left\langle e^{2}\right\rangle^{\left(n_{f}\right)} \rightarrow a^{+}\left(n_{f}\right)=\frac{1}{n_{f}} \sum_{i=1}^{n_{f}} a_{q_{i}}^{+} . \tag{B12}
\end{equation*}
$$

## APPENDIX C: MATCHING ACROSS HEAVY FLAVOR THRESHOLDS

As we compute at higher orders, we find the matching conditions of the PDFs become discontinuous at $\mathcal{O}\left(\alpha_{s}^{2}\right)$ (NNLO), and the matching of the $\overline{\mathrm{MS}} \alpha_{s}(\mu)$ becomes discontinuous at $\mathcal{O}\left(\alpha_{s}^{3}\right)\left(\mathrm{N}^{3} \mathrm{LO}\right)$.

While the discontinuities in the PDFs and $\alpha_{s}$ (which are unphysical quantities) persist at all orders, physical observables (such as cross sections and structure functions) will match across thresholds up to the computed order of the perturbation theory; for example, a physical observable in an $N$-flavor and an $(N+1)$-flavor scheme will match up to higher order terms when computed to order $\alpha_{s}^{M}$ in the perturbation expansion:

$$
\sigma^{N}=\sigma^{N+1}+\mathcal{O}\left(\alpha_{s}^{M+1}\right)
$$

As it is not immediately obvious how the discontinuities cancel order by order, we shall examine a NNLO numeric case, and also a simple analytic example.

## 1. Discontinuities across the flavor transition

To illustrate the behavior of the discontinuities, we will work at NNLO where the DGLAP evolution and the flavorthreshold boundary conditions have been computed and implemented. ${ }^{14}$ Since $\mu=m_{c}$ is often used for the initial

[^189]evolution scale, we will focus on the transition from $N_{F}=4$ to $N_{F}=5$ flavors at $\mu=m_{b}$.

The matching conditions across flavor thresholds can be summarized as [41]

$$
\begin{equation*}
f_{a}^{N+1}=A_{a b} \otimes f_{b}^{N} \tag{C1}
\end{equation*}
$$

where $f^{N}$ and $f^{N+1}$ are the PDFs for $N$ and $N+1$ flavors, and $A_{a b}$ can be expanded perturbatively. In the VFNS for $\mu<m_{b}$, the $b$-quark PDF is zero and the gluon PDF is finite and positive. Using Eq. (C1) for $\mu>m_{b}$, we find the $b$-quark is negative for $\mu \sim m_{b}$, and it becomes more negative as we move to smaller $x$. In contrast, the gluon has a positive discontinuity as it must to ensure the momentum sum rule is satisfied.

## 2. The $\boldsymbol{b}$-quark flavor transition

Although these discontinuities are too small to be noticeable in the figures of Sec. IV, in Fig. 25 we have magnified the axes so the discontinuities are visible. Here, we display $F_{2}$ and $F_{L}$ for a selection of $x$ values.

The first general feature we notice in Fig. 25 is that the size of the discontinuity generally grows as we go to smaller $x$ values. This is consistent with the fact that the discontinuity computed by Eq. (C1) also grows for smaller $x$. We display the results for a selection of $n$-scaling values; note that the uncertainty arising from the discontinuity is typically on the order of the difference due to the choice of scaling.

Another feature that is most evident for the series of $F_{L}$ plots (Fig. 25(b)) is that the discontinuity can change sign for different $x$ values. This can happen because the mix of quark and gluon initiated terms is changing as a function of $x$.

This observation is key to understanding how the (unphysical) PDFs may have a relatively large discontinuity, while the effect on the physical quantities (such as $\sigma$ and $F_{2, L}$ ) is moderated. Because physical quantities will contain a sum of gluon and quark initiated contributions, and because the discontinuity of the quark and gluon PDFs have opposite signs, the discontinuities of the quark and gluon PDFs can partially cancel so that the physical quantity may have a reduced discontinuity.

This discontinuity, in part, reflects the theoretical uncertainty of the perturbation theory at a given order. As we compute the physical observables to higher and higher orders, this discontinuity will be reduced even though the discontinuity in the PDFs and $\alpha_{s}$ remain. We will demonstrate this mechanism in the following.

## C. A "Toy" example at NLO

We now illustrate how the cancellation of the quark and gluon PDF discontinuities work analytically using a toy calculation.

(a) $F_{2}$ vs. $Q$ for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for different $n$ scalings.

(b) $F_{L}$ vs. $Q$ for $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for different $n$ scalings.

FIG. 25 (color online). Discontinuity for $F_{2}, F_{L}$ at NNLO in the region of the bottom mass, $m_{b}=4.5 \mathrm{GeV}$.

Expanding Eq. (C1) in the region of $\mu=m_{b}$ we have:

$$
\begin{align*}
& f_{b}^{5}=\left\{0+\frac{\alpha_{s}}{2 \pi} P_{q g}\left(L+a_{q g}\right)+O\left(\alpha_{s}^{2}\right)\right\} \otimes f_{g}^{4}  \tag{C2}\\
& f_{g}^{5}=\left\{1+\frac{\alpha_{s}}{2 \pi} P_{g g}\left(L+a_{g g}\right)+O\left(\alpha_{s}^{2}\right)\right\} \otimes f_{g}^{4}
\end{align*}
$$

where $L=\ln \left(\mu^{2} / m_{b}^{2}\right)$. It happens that the constant terms $a_{i j}$ in Eq. ( C 2$)$ are zero at $\mathcal{O}\left(\alpha_{s}^{1}\right)$ in the $\overline{\mathrm{MS}}$ scheme; this is not due to any underlying symmetry, and in fact at $\mathcal{O}\left(\alpha_{s}^{2}\right)$ these terms are nonzero. Because $a_{i j}$ are zero, if we perform the matching at $\mu=m_{b}$, we find that the gluon PDF is continuous $f_{b}^{5}\left(x, m_{b}\right)=f_{g}^{4}\left(x, m_{b}\right)$, and the bottom PDF starts from zero $f_{b}^{5}\left(x, m_{b}\right)=0$.

$$
\text { a. If } a_{i j} \text { was nonzero at } \mathcal{O}\left(\alpha_{s}^{1}\right)
$$

To illustrate how the discontinuities cancel in the ACOT renormalization scheme, we will suppose (for this toy calculation) that the constant terms $\left(a_{i j}\right)$ in the matching conditions are nonvanishing at order $\alpha_{s}^{1}$; thus, the gluon and bottom PDFs will now have $\mathcal{O}\left(\alpha_{s}^{1}\right)$ discontinuities, but the physical observables computed with different $N_{F}$ values will still match up to $\mathcal{O}\left(\alpha_{s}^{2}\right)$.

In the ACOT scheme, the total cross section can be decomposed as: $\sigma_{\mathrm{TOT}}=\sigma_{\mathrm{LO}}+\sigma_{\mathrm{NLO}}-\sigma_{\mathrm{SUB}}$, where $\sigma_{\mathrm{LO}}$ represents $\gamma b \rightarrow b, \sigma_{\mathrm{NLO}}$ represents $\gamma g \rightarrow b \bar{b}$, and $\sigma_{\text {SUB }}$ represents the $(g \rightarrow b) \otimes(\gamma b \rightarrow b)$ "subtraction" contribution. ${ }^{15}$ We will now perturbatively compute $\sigma_{\text {TOT }}$ in the region $\mu \sim m_{b}$ for both $N_{F}=4$ and $N_{F}=5$.

[^190]
## b. ACOT for $N_{F}=4$

For $\mu<m_{b}$, we have $N_{F}=4$ and $f_{b}=0$; thus, $\sigma_{\mathrm{LO}}$ and $\sigma_{S U B}$ vanish, and we have:

$$
\sigma_{\mathrm{TOT}}^{N_{F}=4}=\sigma_{\mathrm{NLO}}=C^{1} \otimes f_{g}^{4}+O\left(\alpha_{s}^{2}\right)
$$

where $C^{1}$ represents the $\mathcal{O}\left(\alpha_{s}^{1}\right)$ process $\gamma g \rightarrow b \bar{b}$.

$$
\text { c. ACOT for } N_{F}=5
$$

For $\mu>m_{b}$, we have $N_{F}=5$ and $f_{b} \neq 0$. For the contributions we have:

$$
\begin{aligned}
\sigma_{\mathrm{LO}}= & C^{0} \otimes f_{b}^{5} \simeq C^{0} \otimes\left\{0+\frac{\alpha_{s}}{2 \pi} P_{q g}\left(L+a_{q g}\right)\right\} \otimes f_{g}^{4} \\
\sigma_{\mathrm{NLO}}= & C^{1} \otimes f_{g}^{5} \simeq C^{1} \otimes\left\{1+\frac{\alpha_{s}}{2 \pi} P_{g g}\left(L+a_{g g}\right)\right\} \otimes f_{g}^{4} \\
\sigma_{\mathrm{SUB}}= & C^{0} \otimes \tilde{f}_{g \rightarrow q} \otimes f_{g}^{5} \simeq C^{0} \otimes\left\{\frac{\alpha_{s}}{2 \pi} P_{q g}\left(L+a_{q g}\right)\right\} \\
& \otimes\left\{1+\frac{\alpha_{s}}{2 \pi} P_{g g}\left(L+a_{g g}\right)\right\} \otimes f_{g}^{4}
\end{aligned}
$$

Keeping terms to $\mathcal{O}\left(\alpha_{s}^{1}\right)$ we have:

$$
\sigma_{\mathrm{TOT}}^{N_{F}=5}=\sigma_{\mathrm{LO}}+\sigma_{\mathrm{NLO}}-\sigma_{\mathrm{SUB}}=C^{1} \otimes f_{g}^{4}+O\left(\alpha_{s}^{2}\right)
$$

Notice that the discontinuity introduced by $a_{q g}$ in the PDFs is canceled by $a_{q g}$ from the SUB contribution. ${ }^{16}$

[^191]
## d. Comparison of $N_{F}=5$ and $N_{F}=4$

Comparing the $N_{F}=5$ and $N_{F}=4$ results, we find

$$
\sigma_{\mathrm{TOT}}^{N_{F}=5}=\sigma_{\mathrm{TOT}}^{N_{F}=4}+O\left(\alpha_{s}^{2}\right)
$$

so that the total physical results match up the order of the perturbation theory.

In the above illustration, we have retained the log terms $(L)$; the cancellation of the logs is ensured in a well defined renormalization scheme, and the $a_{i j}$ constant terms get carried along with the logs and will thus cancel order by order.

Therefore, the discontinuity of the physical quantities ( $\sigma, F_{2, L}$ ) reflects the perturbative uncertainty, and this will be systematically reduced at higher orders.

#### Abstract

The 2011 Les Houches workshop was the first to confront LHC data. In the two years since the previous workshop there have been significant advances in both soft and hard QCD, particularly in the areas of multi-leg NLO calculations, the inclusion of those NLO calculations into parton shower Monte Carlos, and the tuning of the non-perturbative parameters of those Monte Carlos. These proceedings describe the theoretical advances that have taken place, the impact of the early LHC data, and the areas for future development.

Report of the SM and NLO Multileg and SM MC Working Groups for the Workshop "Physics at TeV Colliders", Les Houches, France, 31 May-8 June, 2011.

## Part I

## INTRODUCTION

The workshop in 2011 was the first for which the long-awaited LHC data (at 7 TeV ) was available for analysis and comparison to theory. Even though of limited statistical power compared to the ultimate goals of the LHC, this data accesses a very wide kinematic range, and probes regions where multiple scales are important. The presence of large scales for some processes, on the TeV level, points to the importance of electroweak corrections, which have been calculated only for some of the important processes. The first hints of a Higgs boson have now been observed. In order to search for signs of New Physics, as well as to completely understand the Standard Model at the LHC, it is important to understand the perturbative framework at the LHC. The data taken so far provides many challenges for perturbative QCD predictions; and it is clear that New Physics, if it is present in current data, is hiding well.

On the theoretical side, there has been a great deal of productivity in the area of multi-particle calculations at next-to-leading order (NLO) and next-to-next-to-leading order (NNLO). NLO is the first order at which the normalization, and in some cases the shape, of perturbative cross sections can be considered reliable [1]. A full understanding for both Standard Model and beyond the Standard Model physics at the LHC requires the development of fast, reliable programs for the calculation of multi-parton final states at NLO. There have been many advances in the development of NLO techniques, especially in the area of automation $[2,3,4,5,6,7,8,9,10,11,12]$.

Some of these approaches also allow for relatively easy [13, 14, 12] and/or automatic [15] inclusion of the NLO matrix elements into parton shower Monte Carlo programs. For more details we refer to the individual contributions in these proceedings.

A prioritized list of NLO (and some NNLO) cross sections was assembled at Les Houches in 2005 [16] and added to in 2007 [17] and 2009 [18]. This list includes cross sections which are experimentally important, and which are theoretically feasible (if difficult) to calculate. As we stand now, basically all NLO $2 \rightarrow 3$ and $2 \rightarrow 4$ cross sections of interest have been calculated, see Tables 12 below, and even some processes which were not on the 2009 wishlist are available at NLO, see e.g. [19, 20, 21, 22, 23, 24, 25]. The success of automation techniques means that future NLO calculations of similar complexity can be completed without the man-years of labor previously required. Thus, we do not add to the NLO wish list in 2011. Instead, we comment on calculations needed at NNLO, and processes at NLO for which it is important to calculate the impact of electroweak corrections, and/or the
influence of interference effects with other processes with the same final state.
For many of the processes calculated at the LHC (such as for Higgs production), it is important either to apply a veto for the production of extra jets, or to bin the analysis results according to the jet multiplicity. While such cuts are useful for dealing with the experimental backgrounds, the exclusivity of the cross sections results in increases to the theoretical uncertainties obtained for the corresponding inclusive results, see e.g. [26]. The impact of such cuts is explored in the contribution of Stewart and Tackmann in these proceedings.

Much of the complexity for multi-parton NLO processes consists of the calculation of the nonleading color contributions. Such contributions typically contribute only at the level of a few percent and approximations to the non-leading color contributions should be accurate within a percent or so [70, 71, [51]. So it may be more time-prudent for groups carrying out such calculations to estimate the non-leading color effects before carrying out the full calculation.

To reach full utility, the codes for any of these complex NLO calculations should be made public and/or the authors should generate ROOT ntuples providing the parton level event information from which experimentalists can assemble any cross sections of interest. Where possible, decays (with spin correlations) should be included. A ROOT output option is especially useful where the creation of a user-friendly NLO program may be very time-consuming. We now have some experience with the use of ROOT ntuples with both MCFM and Blackhat+Sherpa calculations. The latter, in particular, does not exist as a public program, while ROOT tuples have been made available for NLO W/Z +n jet multiplicities (with $n$ up to 4 ) for $W / Z+$ jets, and (also for $n$ up to 4 ) for inclusive jet production. The estimation of the correct scale for use in multi-parton NLO calculations, and the proper evaluation of the uncertainty on this scale, is more complex than for simpler calculations. The use of ROOT ntuples can make these evaluations easier to carry out. A contribution describing their use has been included in these proceedings.

While NLO is sufficient for most predictions, it is also crucial to understand certain critical cross sections at NNLO. To date, NNLO calculations have been carried out primarily for processes in $e^{+} e^{-}$ annihilation [72, 73, 74], and in hadronic collisions for $2 \rightarrow 1$ processes, with the exception of VH [75, 76, 77] and $\gamma \gamma$ production [78].

To calculate a $2 \rightarrow 2$ scattering process at NNLO, the divergent contributions arising from the treelevel $2 \rightarrow 4$, the one-loop $2 \rightarrow 3$ and the two-loop $2 \rightarrow 2$ subprocesses have to be properly subtracted and cancelled, such that the finite remainders can be combined into a parton-level event generator. To combine the three contributions, an infra-red subtraction scheme for unresolved real radiation is required. Several approaches have been used and are being further developed: antenna subtraction [79], which currently is extended to hadronic and semi-hadronic initial states [80, 81, 82, 83, 84], a method based on sector decomposition appplied to real radiation [85, 86, 87] where the decomposition is guided by the physical singularity structure [88, 89], $q_{T}$-subtraction [90], which is very elegant but appplicable only to colourless final states, and the one of [91] described in these proceedings.

Further, two-loop amplitudes are interesting in their own right from a field theory point of view, for example to study asymptotic behaviour, or to gain insights into the all-order infared structure of massless field theories.

Below we construct a table of calculations needed at the LHC, and which are feasible within the next few years. Certainly, results for inclusive cross sections at NNLO will be easier to achieve than differential distributions, but most groups are working towards a partonic Monte Carlo program capable of producing fully differential distributions for measured observables.

- $t \bar{t}$ production:
needed for accurate background estimates, top mass measurement, top quark asymmetry (which is zero at tree level, so NLO is the leading non-vanishing order for this observable, and a discrepancy of theory predictions with Tevatron data needs to be understood). Several groups are already well

Table 1: The updated experimenter's wishlist for LHC processes

| Calculations beyond NLO added in 2007 |  |
| :--- | :--- |
| 13. $g g \rightarrow W^{*} W^{*} \mathcal{O}\left(\alpha^{2} \alpha_{s}^{3}\right)$ | backgrounds to Higgs |
| normalization of a benchmark process |  |
| 14. NNLO $p p \rightarrow t \bar{t}$ |  |
| 15. NNLO to VBF and $Z / \gamma+$ jet |  |
| Calculations including electroweak effects |  |
| 16. NNLO QCD+NLO EW for $W / Z$ | precision calculation of a SM benchmark |
| NLO EW to $W / Z$ | $[65,66$ |
| NLO EW to $W / Z+$ jet |  |
| NLO EW to $W H / Z H$ | $[67,6]$ |
| $[69]$ |  |

Table 2: The updated experimenter's wishlist for LHC processes continued
on the way to complete NNLO results for $t \bar{t}$ production [92, 93, 94, 95].

- $W^{+} W^{-}$production:
importand background to Higgs search. At the LHC, $g g \rightarrow W W$ is the dominant subprocess, but $g g \rightarrow W W$ is a loop-induced process, such that two loops need to be calculated to get a reliable estimate of the cross section. Advances towards the full two-loop result are reported in [96, 97].
- inclusive jet/dijet production:

NNLO parton distribution function (PDF) fits are starting to become the norm for predictions and comparisons at the LHC. Paramount in these global fits is the use of inclusive jet production to tie down the behavior of the gluon distribution, especially at high $x$. However, while the other essential processes used in the global fitting are known to NNLO, the inclusive jet production cross section is only known at NLO. Thus, it is crucial for precision predictions for the LHC for the NNLO corrections for this process to be calculated, and to be available for inclusion in the global PDF fits. First results for the real-virtual and double real corrections to gluon scattering can be found in [98, 99].

- $\mathrm{V}+1$ jet production:
$W / Z / \gamma+$ jet production form the signal channels (and backgrounds) for many key physics processes, for both SM and BSM. In addition, they also serve as calibration tools for the jet energy scale and for the crucial understanding of the missing transverse energy resolution. The two-loop amplitudes for this process are known [100, 101], therefore it can be calculated once the parts involving unresolved real radiation are available.
- $\mathrm{V}+\gamma$ production:
important signal/background processes for Higgs and New Physics searches. The two-loop helicity amplitudes for $q \bar{q} \rightarrow W^{ \pm} \gamma$ and $q \bar{q} \rightarrow Z^{0} \gamma$ recently have become available [102].
- Higgs+1 jet production:

As mentioned previously, events in many of the experimental Higgs analyses are separated by the number of additional jets accompanying the Higgs boson. In many searches, the Higgs +0 jet and Higgs +1 jet bins contribute approximately equally to the sensitivity. It is thus necessary to have the same theoretical accuracy for the Higgs +1 jet cross section as already exists for the inclusive Higgs cross section, i.e. NNLO. The two-Loop QCD Corrections to the Helicity Amplitudes for $H \rightarrow 3$ partons are already available [103].

The contributions in this document are arranged as follows. In section II various developments concerning techniques for NLO and NNLO calculations are described, in particular in view of providing
automated tools for NLO corrections. In section III, issues related to parton distribution functions are discussed. Section IV contains phenomenological studies of observables and uncertainties, based on theory input where higher order corrections obtained by different approaches are available. Section V includes phenomenological studies on the definition of experimental observables and corrections applied to data. Finally Section VI discusses issues related to the tuning of Monte Carlos and standardised Monte Carlo output formats.

## Part II

## NLO AUTOMATION AND (N)NLO TECHNIQUES

## 1. PJFRY - A C++ PACKAGE FOR TENSOR REDUCTION OF ONE-LOOP FEYNMAN INTEGRALS ${ }^{1}$

#### Abstract

The C++ package PJFry 1.0.0 [104, 105] - a one loop tensor integral library is introduced. We use an algebraic approach to tensor reduction. As a result, the tensor integrals are presented in terms of scalar one- to four-point functions, which have to be provided by an external library, e.g. QCDLoop/FF or OneLOop or LoopTools/FF. The reduction is implemented until five-point functions of rank five. A numerical example is shown, including a special treatment for small or vanishing inverse four-point Gram determinants. Future modules of PJFry might cover the treatment of $n$-point functions with $n \geq 6$; the corresponding formulae are worked out. Further, an extremely efficient approach to tensor reduction relies on evaluations of complete contractions of the tensor integrals with external momenta. For this, we worked out an algorithm for the analytical evaluation of sums over products of signed minors with scalar products of chords, i.e. differences of external momenta. As a result, the usual multiple sums over tensor coefficients are replaced for the numerical evaluation by compact combinations of the basic scalar functions.

### 1.1 PJFry

The goal of the C++ package PJFry is a stable and fast open-source implementation of one-loop tensor reduction of Feynman integrals

$$
\begin{equation*}
I_{n}^{\mu_{1} \cdots \mu_{R}}=C(\epsilon) \int \frac{d^{d} k}{i \pi^{d / 2}} \frac{\prod_{r=1}^{R} k^{\mu_{r}}}{\prod_{j=1}^{n}\left(k-q_{j}\right)^{2}-m_{j}^{2}+i \epsilon}, \tag{1}
\end{equation*}
$$

suitable for any physically relevant kinematics ${ }^{2}$ The algorithm was invented in [105]. PJFry performs the reduction of 5 -point 1 -loop tensor integrals up to rank 5 . The 4 - and 3 -point tensor integrals are obtained as a by-product. Main features are:

- Any combination of internal or external masses
- Automatic selection of optimal formula for each coefficient
- Leading ()$_{5}$ are eliminated in the reduction

[^192]- Small ()$_{4}$ are avoided using asymptotic expansions where appropriate
- Cache system for tensor coefficients and signed minors
- Interfaces for C, C++, FORTRAN and Mathematica
- Uses QCDLoop [109, 110] or OneLOop [111] for 4-dim scalar integrals
- Available from the project webpage https://github.com/Vayu/PJFry/ [104, 105]

The installation of PJFry may be performed following the instructions given at the project webpage. The project subdirectories are ./src - the library source code ./mlink - the MathLink interface
./examples - the FORTRAN examples of library use, built with make check
A build on Unix/Linux and similar systems is done in a standard way by sequential performing ./configure, make, make install. See the INSTALL file for a detailed description of the ./configure options.

The functions for tensor coefficients for up to rank $R=5$ pentagon integrals are declared in the Mathematica interface:

```
In:= Names["PJFry`*"]
Out={A0v0, B0v0, B0v1, B0v2, C0v0, C0v1, C0v2, C0v3, \
D0v0, D0v1, D0v2, D0v3, D0v4, E0v0, E0v1, E0v2, \
EOv3, EOv4, EOv5, GetMu2, SetMu2}
```

The C++ and Fortran interface syntax is very close to that of e.g. LoopTools/FF:
E0v3[i,j,k,p1s,p2s,p3s,p4s,p5s,s12,s23,s34,s45,s15,m1s,m2s,m3s,m4s,m5s,ep=0]
where 3
i, $\mathrm{j}, \mathrm{k}$ are indices of the tensor coefficient $(0<i \leq j \leq k<n)$,
$\mathrm{p} 1 \mathrm{~s}, \mathrm{p} 2 \mathrm{~s}, \ldots$ are squared external masses $p_{i}^{2}$,
s12, s23, ... are Mandelstam invariants $\left(p_{i}+p_{j}\right)^{2}$,
$\mathrm{m} 1 \mathrm{~s}, \mathrm{~m} 2 \mathrm{~s}, \ldots$ are squared internal masses $m_{i}^{2}$,
$\mathrm{ep}=0,-1,-2$ selects the coefficient of the $\epsilon$-expansion.
The average evaluation time per phase-space point on a 2 GHz Core 2 laptop for the evaluation of all 81 rank 5 tensor form-factors amounts to 2 ms .

A numerical example is shown, for a configuration as in figure 1, in figures 2 and 3 for a five-point rank $R=4$ tensor coefficient in a region, where one of the 4-point sub-Gram determinants vanishes [at $x=0]$ :
$E_{3333}\left(0,0,-6 \times 10^{4}(x+1), 0,0,10^{4},-3.5 \times 10^{4}, 2 \times 10^{4},-4 \times 10^{4}, 1.5 \times 10^{4}, 0,6550,0,0,8315\right)$
The red curve is produced with standard PJFry, and the blue one with Passarino-Veltman [PV] reduction [112]; we mention that for the case treated here $(x \rightarrow 0)$, the PV reduction is no standard option. Our expansion in terms of higher dimensional scalar 3-point functions in case of vanishing 4-point subGram determinants uses only functions $I_{3}^{d+2 l}$ [105]. These are tensor coefficients of the pure $g^{\mu \nu}$ type [113], and so our method is different from others with a mixed numerical approach [114] or with use of additional tensor coefficients [115].

Tensor reduction by PJFry is used as one option of the GoSam package [12]. An older version of the algorithm, as described in [116], has been implemented independently in [11].

[^193]

Fig. 1: Momenta definitions for PJFry.

### 1.2 POTENTIAL UPGRADES

### 1.21 Tensor reduction for higher-point functions

So far, PJFry is foreseen for 5-point functions and simpler ones. The extension to 6-point functions is known from e.g. [114, 115, [116]. In [107] we solve analytically generalized recursions for $n \geq 6$, derived in [114]:

$$
\begin{equation*}
I_{n}^{\mu_{1} \mu_{2} \ldots \mu_{R}}=-\sum_{r=1}^{n} C_{r}^{\mu_{1}}(n) I_{n-1}^{\mu_{2} \cdots \mu_{R}, r} \tag{2}
\end{equation*}
$$

where in $I_{n-1}^{\mu, \cdots, r}$ the line $r$ is scratched. The coefficients for 6-point functions are:

$$
\begin{equation*}
C_{r}^{s, \mu}(6)=\sum_{i=1}^{5} \frac{1}{\binom{0}{s}_{6}}\binom{0 r}{s i}_{6} q_{i}^{\mu_{1}}, s=0 \ldots 6, \tag{3}
\end{equation*}
$$

where the $q_{i}$ are chords, and $\binom{0 r}{s i}_{6}$ etc. are signed minors with arbitrary $s$. For the 7-point and 8-point functions, we found several representations, among them

$$
\begin{equation*}
C_{r}^{s t, \mu}(7)=\sum_{i=1}^{6} \frac{1}{\binom{(t)^{2}}{s t}_{7}}\binom{s t i}{s t r}_{7} q_{i}^{\mu} \tag{4}
\end{equation*}
$$

and

$$
\begin{equation*}
C_{r}^{s t u, \mu}(8)=\sum_{i=1}^{7} \frac{1}{\binom{s t u}{s t u}_{8}}\binom{\text { stui }}{\text { stur }}_{8} q_{i}^{\mu} \tag{5}
\end{equation*}
$$

The upper indices $s, t$ and $u$ stand for the redundancy of the solutions and can be freely chosen.

### 1.22 Evaluation of contracted tensor integrals using sums over signed minors

The contraction of a tensor integral with chords may be written as a sum over basic scalar integrals (at a stage where they are free of tensor coefficient indices), multiplied by (multiple) sums over chords times

Fig. 2: Absolute accuracy of $E_{3333}$ in the region of vanishing sub-Gram determinant. Blue curve: conventional Passarino-Veltman reduction, red curve: PJFry.
signed minors. If one may perform these sums algebraically, the method becomes very efficient. And this has been systematically worked out in [106], see also [108].

We reproduce here two 7-point examples.
The rank $R=2,3$ integrals become by contraction

$$
\begin{align*}
q_{a, \mu} q_{b, \nu} I_{7}^{\mu \nu} & =\sum_{r, t=1}^{7} K^{a b, r t} I_{5}^{r t},  \tag{6}\\
q_{a, \mu} q_{b, \nu} q_{c, \lambda} I_{7}^{\mu \nu \lambda} & =\sum_{r, t, u=1}^{7} K^{a b c, r t u} I_{4}^{r t u}, \tag{7}
\end{align*}
$$

where $I_{5}^{r t}$ and $I_{4}^{r t u}$ are scalar 5- and 4-point functions, arising from the 7-point function by scratching lines $r, t, \ldots$ In the general case, we have at this stage higher-dimensional integrals $I_{n}^{d+2 l}, n=2, \ldots, 5$, to be further reduced following the known scheme, if needed. Here, the $I_{5}^{r t}$ have to be expressed by 4 -point functions.

The expansion coefficients are factorizing here,

$$
\begin{align*}
K^{a b, r t} & =K^{a, r} K^{b, r t},  \tag{8}\\
K^{a b c, r t u} & =-K^{a, r} K^{b, r t} K^{c, r t u} \tag{9}
\end{align*}
$$

and the sums over signed minors have been performed analytically:

$$
\begin{gather*}
K^{a, r}=\frac{1}{2}\left(\delta_{a r}-\delta_{7 r}\right),  \tag{10}\\
K^{b, r t}=\sum_{j=1}^{6}\left(q_{b} q_{j}\right) \frac{\left(\begin{array}{c}
r s t \\
r s)_{7}
\end{array}\right.}{\binom{r s}{r s}_{7}} \equiv \frac{\Sigma_{b}^{1, s t u}}{\binom{r s}{r s}_{7}}=\frac{1}{2}\left(\delta_{b t}-\delta_{7 t}\right)-\frac{1}{2} \frac{\binom{r s}{t s}_{7}}{\binom{r s}{r s}}\left(\delta_{b r}-\delta_{7 r}\right), \tag{11}
\end{gather*}
$$

Fig. 3: Relative accuracy of $E_{3333}$ in the region of vanishing sub-Gram determinant. At $x \sim 0.0015$, PJFry switched to the asymptotic expansion.

$$
\begin{align*}
K^{a, s t u} & =\sum_{i=1}^{6}\left(q_{a} q_{i}\right)\binom{0 s t u}{0 s t i}_{7} \equiv \Sigma_{a}^{2, s t u}  \tag{12}\\
& =\frac{1}{2}\left\{\binom{s t u}{s t 0}_{7}\left(Y_{a 7}-Y_{77}\right)+\binom{0 s t}{0 s t}_{7}\left(\delta_{a u}-\delta_{7 u}\right)-\binom{0 s t}{0 s u}_{7}\left(\delta_{a t}-\delta_{7 t}\right)-\binom{0 t s}{0 t u}_{7}\left(\delta_{a s}-\delta_{7 s}\right)\right\}
\end{align*}
$$

with

$$
\begin{equation*}
Y_{j k}=-\left(q_{j}-q_{k}\right)^{2}+m_{j}^{2}+m_{k}^{2} \tag{13}
\end{equation*}
$$

Conventionally, $q_{7}=0$.
The sums may be found in eqns. (A.15) and (A.16) of [106]. The $s$ is redundant and fulfils $s \neq r, b, 7$ in $K^{b, r t}$. In $K_{0}^{a, s t u}$ it is $s, t, u=1, \ldots 7$ with $s \neq u, t \neq u$.

## ACKNOWLEDGEMENTS

J.F. thanks DESY for kind hospitality. Work is supported in part by Sonderforschungsbereich/Transregio SFB/TRR 9 of DFG "Computergestützte Theoretische Teilchenphysik" and European Initial Training Network LHCPHENOnet PITN-GA-2010-264564.

## 2. THE GOSAM APPROACH TO AUTOMATED ONE-LOOP CALCULATIONS ${ }^{4}$

#### Abstract

We describe the GoSAM framework for the automated computation of multiparticle scattering amplitudes at the one-loop level. The amplitudes are generated explicitly in terms of Feynman diagrams, and can be evaluated using either $d$-dimensional reduction at the integrand level or tensor decomposition. GoSAM can be used to compute one-loop QCD and EW corrections to Standard Model processes, and it is ready to link generic model files for theories Beyond the Standard Model.

[^194]
### 2.1 Introduction and General Motivations

In the last few years we observed major advances in the direction of constructing packages for fully automated one-loop calculations, which profited from the new developments in the field of NLO QCD calculations [17, 18]. The continuous improvement of the techniques for one-loop computations led to important new results for processes with many particles [51, 70, 117, 71, 53, 48, 49, 50, 54, 62, 63, 23, 118, 25, 56, 57, 21, 22, 20, 19].

Very advanced calculations have been performed with improved algebraic reduction methods based on Feynman-diagrammatic algorithms, as well as with new numerical techniques based on the idea of reconstructing one-loop amplitudes from their unitarity cuts. These theoretical developments found an ideal counterpart in the integrand-level reduction algorithm, that allows for the reduction of any scattering amplitudes to scalar master integrals, simply by evaluating numerically the integrand at given fixed values of the integration momentum. In both scenarios, to tackle the increase in the complexity and in the number of diagrams that contribute to the amplitudes, automation becomes indispensable for processes with many external legs.

The purpose of the present document is to illustrate the main features of GoSam [12], a new framework which allows the automated calculation of one-loop scattering amplitudes for multi-particle processes. This approach combines the automated algebraic generation of $d$-dimensional unintegrated amplitudes obtained via Feynman diagrams, with the numerical integrand-level reduction provided by the $d$-dimensional extension [119, 120, 6] of the OPP integrand-level reduction method [121, 122, 123] and improved tensorial techniques [124, 125].

The integrands of the one-loop amplitudes are generated via Feynman diagrams, using QGRAF [126], FORM [127], spinney [128] and haggies [129]. The only task required from the user is the preparation of an "input card" to start the generation of the source code and its compilation, without having to worry about internal details of the code generation. The individual program tasks are efficiently managed by python scripts. Concerning the reduction, the program offers the possibility to use either the $d$-dimensional extension of the OPP method, as implemented in SAMURAI [6], or tensor reduction as implemented in Golem95C [130, 131] interfaced through tensorial reconstruction at the integrand level [124].

### 2.2 Algebraic approach to Automation

There are several approaches to the automated computation of multi-particle scattering amplitudes at the one-loop level, which provide different recipes for the construction of multi-purpose tools. The goal of such tools is the evaluation of one-loop scattering amplitudes for any choice of particles in the initial and final states, in a fully automated manner.

In the algebraic approach to multi-purpose automation, amplitudes can be generated from Feynman diagrams by employing tools for algebraic manipulation: already some time ago, the idea of automating NLO calculations has been pursued by public programs like FeynArts [132] and QGRAF [126] for diagram generation and FormCalc/LoopTools [133] and GRACE [3] for the automated calculation of NLO corrections, primarily in the electroweak sector.

When we combine the algebraic generation with the integrand-level reduction, the set of algebraic operations required are quite different with respect to a traditional tensorial reduction. Since the target is to provide the numerical value of the numerator function at given values of integration momentum, we should aim at expressions for the unintegrated numerator that are easily evaluated numerically. To achieve this task, for example, expressions in terms of spinor products are particularly convenient.

We briefly list here some of the advantages of the "algebraic approach": i) the algebraic generation is executed separately from the numerical reduction, therefore algebraic manipulations are possible before starting the numerical integration; CPU-time can be spent, once for all at the beginning of the calculation, to optimize and reduce the size of the integrands that will be evaluated numerically several times
later on during the reduction; ii) the algebraic method allows us to group sets of diagrams and cache all factors that do not depend on the integration momentum; iii) easy access to sub-parts of the computation; subsets of diagrams can be easily added or removed from the final results, simplifying comparisons and tests; iv) computer algebra can be performed in dimension $d$ using alternative regularization schemes; v) the choice between different reduction algorithms can be performed at run-time, providing flexibility and internal cross-checks. In the next section we will briefly illustrate how these properties are used within GoSAM.

Important progress in a similar direction has been also recently achieved by means of FeynArts, FormCalc and LoopTools [134, 2] to provide amplitudes that can be processed using the integrand-level reduction provided by CutTools [135] and/or SAMURAI [6] or with the traditional Passarino-Veltman reduction [112].

### 2.3 A brief introduction to GoSAM

GoSAM produces in a fully automated way all the code required to perform the calculation of virtual one-loop amplitudes. The only task left to the user is the preparation of an "input card" which contains all the information related to the particular process namely initial and final particles, model, helicities, selection rules to exclude particular sets of diagrams, regularization scheme. The card also contains flags to select the preferred reduction methods and some optimization flags to adapt the diagram generation to the needs of the user.

There are three main steps that GoSAM follows in order to prepare the code for the calculation: the generation of diagrams that contribute to the process, the optimization and algebraic manipulation to simplify their expressions, and the writing of a FORTRAN code ready to be used within a phase-space integration. It is important to remember that these steps will only be performed once. After the code is generated, the reduction of unintegrated amplitudes to linear combinations of scalar (master) integrals is fully embedded in the process and can be performed with different options, all available at run-time. Only the last part, namely the reduction and evaluation of master integrals, will be repeated for all the different phase-space points that contribute to the cross-section.

### 2.31 Diagram Generation

For the diagram generation both at tree level and one-loop level we employ QGRAF [126] which we complemented by adding another filter over diagrams implemented in Python. This gives several advantages since it increases the ability of the code to distinguish certain classes of diagrams and group them according to the sets of their propagators, in order to fully optimize the reduction.

At this stage GoSAm generates three sets of output files: an expression for each diagram for FORM [127], Python code for drawing each diagram, and Python code for computing the properties of the diagram. Information about the model is either read from the built-in Standard Model of QGRAF or can be defined by the user by means of LanHEP [136] or an Universal FeynRules Output (UFO) file [137]

The Python program automatically performs several operations: diagrams whose color factor turns out to be zero are dropped; the number of propagators containing the loop momentum, the tensor rank and the kinematic invariants of the associated loop integral are computed; diagrams with a vanishing loop integral associated are detected and flagged for the diagram selection; all propagators and vertices are classified for the diagram selection; diagrams containing massive quark self-energy insertions or closed massless quark loops are specially flagged.

During this phase, GoSAM also generates a ETEX file which contains, among other useful information of the generated process, the drawings of all contributing diagrams. To achieve this task, we use our own implementation of the algorithms described in Ref. [138] and Axodraw [139] to actually draw the diagrams.

### 2.32 Lorentz Algebra

Concerning the algebraic operations performed by GoSAM to render the integral suitable for efficient numerical evaluation, one of the primary goals is to split the $(4-2 \varepsilon)$ dimensional algebra into strictly four-dimensional objects and symbols representing the higher-dimensional remainder. All external vectors (momenta and polarisation vectors) are kept in four dimensions; internal vectors, however, are kept in the $d$-dimensional vector space.

We adopt the conventions used in [128], where $\hat{k}$ denotes the four dimensional projection of an in general $d$ dimensional vector $k$. The $(d-4)$ dimensional orthogonal projection is denoted as $\tilde{k}$. For the integration momentum $q$ we introduce in addition the symbol $\mu^{2}=-\tilde{q}^{2}$, such that

$$
\begin{equation*}
q^{2}=\hat{q}^{2}+\tilde{q}^{2}=\hat{q}^{2}-\mu^{2} . \tag{14}
\end{equation*}
$$

We also introduce suitable projectors by splitting the metric tensor

$$
\begin{equation*}
g^{\mu \nu}=\hat{g}^{\mu \nu}+\tilde{g}^{\mu \nu}, \quad \hat{g}^{\mu \nu} \tilde{g}_{\nu \rho}=0, \quad \hat{g}_{\mu}^{\mu}=4, \quad \tilde{g}_{\mu}^{\mu}=d-4 \tag{15}
\end{equation*}
$$

Once all propagators and all vertices have been replaced by their corresponding expressions, according to the model file, all vector-like quantities and metric tensors are split into their four-dimensional and their orthogonal part. As we use the 't Hooft algebra, $\gamma_{5}$ is defined as a purely four-dimensional object, $\gamma_{5}=i \epsilon_{\mu \nu \rho \sigma} \hat{\gamma}^{\mu} \hat{\gamma}^{\nu} \hat{\gamma}^{\rho} \hat{\gamma}^{\sigma}$. By applying the usual anti-commutation relation for Dirac matrices we can always separate the four-dimensional and $(d-4)$-dimensional parts of Dirac traces.

While the $(d-4)$-dimensional traces are reduced completely to products of $(d-4)$-dimensional metric tensors, the four-dimensional part, which will be reduced numerically, is treated such that the number of terms in the resulting expression is kept as small as possible.

### 2.33 Treatment of rational terms $R_{2}$

Instead of relying on the construction of $R_{2}$ from specialized Feynman rules [123, 140, 141, 142, 143], we can generate the $R_{2}$ part along with all other contribution using automated algebraic manipulations. The code offers the option between the implicit and explicit construction of the $R_{2}$ terms. The implicit construction treats the $4-$ and $(d-4)$ dimensional numerators on equal grounds: they are generated algebraically and reduced numerically. The explicit construction of $R_{2}$ is based on the fact that the $(d-4)$ dimensional part of the numerator function contains expressions for the corresponding integrals that are relatively simple and known explicitly. Therefore, after separating it using the algebraic manipulation described before, the $(d-4)$ dimensional part is computed analytically whereas the purely four-dimensional part is passed to the numerical reduction. This approach also allows for an efficient calculation of the part $R_{2}$ alone.

### 2.34 Reduction to scalar (master) integrals

GoSAM allows to choose at run-time (i.e. without re-generating the code) the preferred method of reduction. Available options include the integral-level $d$-dimensional reduction, as implemented in SAMURAI, or traditional tensor reduction as implemented in Golem95C interfaced through tensorial reconstruction at the integrand level, or a combination of both. Concerning the scalar (tensorial) integrals, GoSAM allows to choose among a variety of options, including QCDLoop [109], OneLoop [111], Golem95C [130], plus the recently added P JFRY [108]. Among these codes, OneLoop and Golem95C also fully support complex masses.

### 2.4 Installation and Usage

GoSam can be used within a standard Linux/Unix environment. In order to work, it requires some programs to be installed on the system: these include a recent version of Python (version $\geq 2.6$ ), Java
( $\geq 1.5$ ), a Fortran 95 compiler, FORM (version $\geq 3.3$ ), and QGRAF. Further, at least one of the libraries SAMURAI or Golem95C needs to be present at the time the code is compiled.

To facilitate this task, we have prepared a package containing SAMURAI and Golem95C together with the libraries for the integrals: OneLOop, QCDLoop, and FF. The package, which is called gosam-contrib-1.0.tar.gz is available for download from

```
http://projects.hepforge.org/gosam/.
```

The installation procedure is facilitated by the use of Autotools.
The user can download the GoSAM code either as a tar-ball or from the subversion repository at http://projects.hepforge.org/gosam/. The installation of GoSam is controlled by Python Distutils and can be performed by simply running the command

```
python setup.py install
```

In order to generate the code for a process, the user needs to prepare an input file (process card) which contains:

- process specific information, such as a list of initial and final state particles, their helicities (optional) and the order of the coupling constants;
- scheme specific information, such as the regularisation and renormalisation schemes, the underlying model, masses and widths which are set to zero;
- system specific information, such as paths to programs and libraries or compiler options;
- optional information for optimisations within the code generation.

Assuming that the process card is called myprocess.in, the generation of the code can be started by simply running the command gosam.py myprocess.in. All further steps are controlled by makefiles which are automatically generated by GoSAM: the command make compile generates the source code and compiles all files relevant for the production of the matrix element. The code can be tested with the program test. f 90 (located in the subdirectory matrix) which provides, for a random phase-space point, the tree-level LO matrix element and the NLO result for the finite part, single and double poles. Examples of process cards for a selection of benchmark processes are provided with the main distubution.

For more details about the usage and installation of GoSAM, we refer the user to a more technical presentation [144] or to the original publication [12] and the user manual which accompanies the code.

### 2.5 Examples of Applications

The BLHA interface [145] allows to link GoSAM to a general Monte Carlo event generator, which is responsible for supplying the missing ingredients for a complete NLO calculation of a physical cross section. Among those, SHERPA [146] offers the possibility to compute the LO cross section and the real corrections with both the subtraction terms and the corresponding integrated counterparts [147]. Using the BLHA interface, we linked GoSAM with SHERPA to compute the physical cross section for $W^{ \pm}+1$-jet at NLO, which is described in Section 18 .

The codes produced by GoSam have been tested on several processes of increasing complexity, some of which are shown in Table 1. The full list of processes produced by GoSam and compared to the literature where available is given in Ref. [12].

As an example of the usage of GoSam with a model file different from the Standard Model, we calculated the QCD corrections to neutralino pair production in the MSSM. The model file has been imported using the UFO interface. In this calculation, we combined the one-loop amplitude with the real radiation corrections to obtain results for differential cross sections. For the infrared subtraction terms

| $e^{+} e^{-} \rightarrow u \bar{u}$ | $[148]$ |
| :--- | :--- |
| $e^{+} e^{-} \rightarrow t \bar{t}$ | $[149,150]$, own analytic calculation |
| $u \bar{u} \rightarrow d \bar{d}$ | $[15$, 8] |
| $g g \rightarrow g g$ | $[152]$ |
| $g g \rightarrow g Z$ | $[153]$ |
| $b g \rightarrow H b$ | $[154,8]$ |
| $\gamma \gamma \rightarrow \gamma \gamma(\mathrm{W}$ loop) | $[15]$ |
| $\gamma \gamma \rightarrow \gamma \gamma \gamma \gamma$ (fermion loop) | $[156]$ |
| $p p \rightarrow t \bar{t}$ | $[8]$, MCFM [157, 158] |
| $p p \rightarrow W^{ \pm} j$ (QCD corr.) | $[157,158]$ |
| $p p \rightarrow W^{ \pm} j$ (EW corr.) | for IR poles: [65, 159] |
| $p p \rightarrow W^{ \pm} t$ | $[157,158]$ |
| $p p \rightarrow W^{ \pm} j j$ | $[157,158]$ |
| $p p \rightarrow W^{ \pm} b \bar{b}$ (massive b) | $[157,158$ |
| $e^{+} e^{-} \rightarrow e^{+} e^{-} \gamma(\mathrm{QED})$ | $[160]$ |
| $p p \rightarrow H t t \bar{t}$ | $[8]$ |
| $p p \rightarrow Z t \bar{t}$ | $[10]$ |
| $p p \rightarrow W^{+} W^{+} j j$ | $[56$, v3] |
| $p p \rightarrow b \bar{b} b \bar{b}$ | $[62,63]$ |
| $p p \rightarrow W^{+} W^{-} b \bar{b}$ | $[8,161]$ |
| $p p \rightarrow t \bar{t} b \bar{b}$ | $[8,161]$ |
| $u \bar{d} \rightarrow W^{+} g g g$ | $[161]$ |

Table 3: Some of the processes computed and checked with GoSAm
we employed MadDipole [162], while the real emission part is calculated using MadGraph/MadEvent [163]. The virtual matrix element is renormalized in the $\overline{M S}$ scheme, while massive particles are treated in the on-shell scheme. The renormalization terms specific to the massive MSSM particles have been added manually. In Fig $\sqrt[4]{ }$ we show the differential cross section for the $m_{\chi_{1}^{0} \chi_{1}^{0}}$ invariant mass, where we employed a jet veto to suppress large contributions from the channel $q g \rightarrow \chi_{1}^{0} \chi_{1}^{0} q$ which opens up at order $\alpha^{2} \alpha_{s}$, but for large $p_{T}^{j e t}$ belongs to the distinct process of neutralino pair plus one hard jet production at leading order.

Fig. 4: Comparison of the NLO and LO $m_{\chi_{1}^{0} \chi_{1}^{0}}$ distributions for the process $p p \rightarrow \chi_{1}^{0} \chi_{1}^{0}$ with a jet veto on jets with $p_{T}^{j e t}>20 \mathrm{GeV}$ and $\eta<4.5$. The band gives the dependence of the result on $\mu=\mu_{F}=\mu_{R}$ between $\mu_{0} / 2$ and $2 \mu_{0}$. We choose $\mu_{0}=m_{Z}$.

## Conclusions and Outlook

Several groups are currently working at the development of automated multi-purpose tools for one-loop calculations. For quite a long time, tree-level calculation have been fully automated and included in flexible multi-process tools [164, 165]. The level of automation achieved by one-loop calculations is suggesting the possibility of a similar success also at the next-lo-leading order. The target is to build efficient and flexible NLO programs which can be used to tackle the increasing need of precision required by the experimental collaborations.

GoSam is a flexible and broadly applicable tool for the fully automated evaluation of one-loop scattering amplitudes. In this approach, scattering amplitudes are generated in terms of Feynman diagrams and their reduction to master integrals can be performed in several ways, which can be selected at run-time. GoSAm can be used to calculate one-loop corrections both in QCD and electro-weak theory and offers the flexibility to link general model files for theories Beyond the Standard Model. The code performed well in reproducing a wide range of examples and we are looking forward to tackle more challenging calculations and interfacing with other existing tools in the near future.

## 3. AUTOMATION AND NUMERICAL LOOP INTEGRATION ${ }^{5}$

### 3.1 INTRODUCTION

Numerical methods are nowadays routinely used in fully differential fixed-order perturbative calculations for the integration over the phase-space of the final-state particles. The use of numerical methods for the phase-space integration allows the flexibility to compute any infrared-safe observable for a given process within a single numerical program. It is thus natural to investigate if numerical methods can also be applied for the loop integration in the virtual corrections [166, 167, $168,169,170,171,172,173$ [174, 175, 176]. A major breakthrough was achieved recently by showing that the numerical method is compatible in efficency with the commonly used approaches based on cut techniques and generalised unitarity or on Feynman graphs [70, [51, 53, 22, 20, 52, 117, 56, 54, 50, 48, 177, 111, 5, 178, 8, 12]. The implementation of the numerical method for the loop integration is process-independent and offers therefore the flexibility to compute several processes within one numerical program. We discuss the main principles of the numerical method for the loop integration at one-loop. In addition we give an outlook towards higher loops.

### 3.2 THE SUBTRACTION METHOD FOR THE LOOP INTEGRATION

The contributions to an infrared-safe $n$-jet observable observable $O$ at next-to-leading order are given by

$$
\begin{equation*}
\langle O\rangle^{N L O}=\int_{n+1} O_{n+1} d \sigma^{R}+\int_{n} O_{n} d \sigma^{V}+\int_{n} O_{n} d \sigma^{C} . \tag{16}
\end{equation*}
$$

[^195]Here a rather condensed notation is used. $d \sigma^{R}$ denotes the real emission contribution, whose matrix elements are given by the square of the Born amplitudes with $(n+3)$ partons $\left|A_{n+3}^{(0)}\right|^{2} . d \sigma^{V}$ denotes the virtual contribution, whose matrix elements are given by the interference term of the one-loop and Born amplitude $\operatorname{Re}\left(A_{n+2}^{(0)^{*}} A_{n+2}^{(1)}\right)$ and $d \sigma^{C}$ denotes a collinear subtraction term, which subtracts the initial state collinear singularities. Each term is separately divergent and only their sum is finite.

The subtraction method is widely used to render the real emission part of a NLO calculation suitable for a numerical Monte Carlo integration. One adds and subtracts a suitably chosen piece to be able to perform the phase-space integrations by Monte Carlo methods:

$$
\begin{equation*}
\langle O\rangle^{N L O}=\int_{n+1}\left(O_{n+1} d \sigma^{R}-O_{n} d \sigma^{A}\right)+\int_{n}\left(O_{n} d \sigma^{V}+O_{n} d \sigma^{C}+O_{n} \int_{1} d \sigma^{A}\right) . \tag{17}
\end{equation*}
$$

The first term $\left(O_{n+1} d \sigma^{R}-O_{n} d \sigma^{A}\right)$ is by construction integrable over the $(n+1)$-particle phase-space and can be evaluated numerically. The result of the integration of the subtraction term over the unresolved one-parton phase-space is written in a compact notation as

$$
\begin{equation*}
d \sigma^{C}+\int_{1} d \sigma^{A}=(\mathbf{I}+\mathbf{K}+\mathbf{P}) \otimes d \sigma^{B} \tag{18}
\end{equation*}
$$

The notation $\otimes$ indicates that colour correlations due to the colour charge operators $\mathbf{T}_{i}$ still remain. The terms with the insertion operators $\mathbf{K}$ and $\mathbf{P}$ pose no problem for a numerical evaluation. The term $\mathbf{I} \otimes d \sigma^{B}$ lives on the phase-space of the $n$-parton configuration and has the appropriate singularity structure to cancel the infrared divergences coming from the one-loop amplitude. Therefore $d \sigma^{V}+\mathbf{I} \otimes d \sigma^{B}$ is infrared finite.

We extend this subtraction method to the virtual part such that we can evaluate the one-loop integral of the one-loop amplitude numerically. The renormalised one-loop amplitude $\mathcal{A}^{(1)}$ is related to the bare amplitude $\mathcal{A}_{\text {bare }}^{(1)}$ by $\mathcal{A}^{(1)}=\mathcal{A}_{\mathrm{bare}}^{(1)}+\mathcal{A}_{\mathrm{CT}}^{(1)}$, where $\mathcal{A}_{\mathrm{CT}}^{(1)}$ denotes the ultraviolet counterterm from renormalisation. The bare amplitude involves the loop integration

$$
\begin{equation*}
\mathcal{A}_{\mathrm{bare}}^{(1)}=\int \frac{d^{D} k}{(2 \pi)^{D}} \mathcal{G}_{\mathrm{bare}}^{(1)} . \tag{19}
\end{equation*}
$$

where $\mathcal{G}_{\text {bare }}^{(1)}$ denotes the integrand of the bare one-loop amplitude. We introduce subtraction terms which match locally the singular behaviour of the bare integrand:

$$
\begin{equation*}
\mathcal{A}_{\text {bare }}^{(1)}+\mathcal{A}_{\mathrm{CT}}^{(1)}=\int \frac{d^{D} k}{(2 \pi)^{D}}\left(\mathcal{G}_{\text {bare }}^{(1)}-\mathcal{G}_{\mathrm{soft}}^{(1)}-\mathcal{G}_{\mathrm{coll}}^{(1)}-\mathcal{G}_{\mathrm{UV}}^{(1)}\right)+\left(\mathcal{A}_{\mathrm{CT}}^{(1)}+\mathcal{A}_{\mathrm{soft}}^{(1)}+\mathcal{A}_{\text {coll }}^{(1)}+\mathcal{A}_{\mathrm{UV}}^{(1)}\right) . \tag{20}
\end{equation*}
$$

Analogous to $\mathcal{G}_{\text {bare }}^{(1)}$, the integrands of the subtraction terms $\mathcal{A}_{x}^{(1)}$ are denoted by $\mathcal{G}_{x}^{(1)}$, where $x$ is equal to soft, coll or UV. The expression in the first bracket is finite and can therefore be integrated numerically in four dimensions. The integrated subtraction terms in the second bracket are easily calculated analytically in $D$ dimensions. The result can be written as

$$
\begin{equation*}
2 \operatorname{Re} \mathcal{A}^{(0)}\left(\mathcal{A}_{\mathrm{CT}}^{(1)}+\mathcal{A}_{\mathrm{soft}}^{(1)}+\mathcal{A}_{\mathrm{coll}}^{(1)}+\mathcal{A}_{\mathrm{UV}}^{(1)}\right)^{*} O_{n} d \phi_{n}=\mathbf{L} \otimes d \sigma^{B} . \tag{21}
\end{equation*}
$$

The insertion operator $\mathbf{L}$ contains the explicit poles in the dimensional regularisation parameter related to the infrared singularities of the one-loop amplitude. These poles cancel when combined with the insertion operator $\mathbf{I}$ :

$$
\begin{equation*}
(\mathbf{I}+\mathbf{L}) \otimes d \sigma^{B}=\text { finite } \tag{22}
\end{equation*}
$$

The operator $\mathbf{L}$ contains, as does the operator $\mathbf{I}$, colour correlations due to soft gluons. In analogy to the one-loop amplitude we can write $d \sigma^{V}=d \sigma_{\mathrm{CT}}+\int \frac{d^{D} k}{(2 \pi)^{D}} d \sigma_{\text {bare }}^{V}$ and then the NLO contributions reads

$$
\begin{align*}
& \langle O\rangle^{N L O}=  \tag{23}\\
& \quad \int_{n+1}\left(O_{n+1} d \sigma^{R}-O_{n} d \sigma^{A}\right)+\int_{n+\text { loop }} O_{n}\left(d \sigma_{\text {bare }}^{V}-d \sigma^{A^{\prime}}\right)+\int_{n} O_{n}(\mathbf{I}+\mathbf{L}+\mathbf{K}+\mathbf{P}) \otimes d \sigma^{B} .
\end{align*}
$$

In a condensed notation this reads

$$
\begin{equation*}
\langle O\rangle^{N L O}=\langle O\rangle_{\text {real }}^{N L O}+\langle O\rangle_{\text {virtual }}^{N L O}+\langle O\rangle_{\text {insertion }}^{N L O} . \tag{24}
\end{equation*}
$$

Every single term is finite and can be evaluated numerically.

### 3.3 THE SUBTRACTION TERMS

Amplitudes in QCD may be decomposed into group-theoretical factors (carrying the colour structures) multiplied by kinematic factors called partial amplitudes. At the loop level partial amplitudes may further be decomposed into primitive amplitudes. It is simpler to work with primitive one-loop amplitudes instead of a full one-loop amplitude. Our method exploits the fact that primitive one-loop amplitudes have a fixed cyclic ordering of the external legs and that they are gauge-invariant. The first point ensures that there are at maximum $n$ different loop propagators in the problem, where $n$ is the number of external legs, while the second property of gauge invariance is crucial for the proof of the method. We therefore consider in the following just a single primitive one-loop amplitude, which we denote by $A^{(1)}$, while keeping in mind that the full one-loop amplitude is just the sum of several primitive amplitudes multiplied by colour structures. We label the external momenta clockwise by $p_{1}, p_{2}, \ldots, p_{n}$ and define $q_{i}=p_{1}+$ $p_{2}+\ldots+p_{i}, k_{i}=k-q_{i}$. We can write the bare primitive one-loop amplitude in Feynman gauge as

$$
\begin{equation*}
A_{\text {bare }}^{(1)}=\int \frac{d^{D} k}{(2 \pi)^{D}} G_{\text {bare }}^{(1)}, \quad G_{\text {bare }}^{(1)}=P(k) \prod_{i=1}^{n} \frac{1}{k_{i}^{2}-m_{i}^{2}+i \delta} . \tag{25}
\end{equation*}
$$

$G_{b a r e}^{(1)}$ is the integrand of the bare one-loop amplitude. $P(k)$ is a polynomial in the loop momentum $k$. The $+i \delta$-prescription instructs us to deform - if possible - the integration contour into the complex plane to avoid the poles at $k_{i}^{2}=m_{i}^{2}$. If a deformation close to a pole is not possible, we say that the contour is pinched. If we restrict ourselves to non-exceptional external momenta, then the divergences of the one-loop amplitude related to a pinched contour are either due to soft or collinear partons in the loop. These divergences are regulated within dimensional regularisation by setting the number of space-time dimensions equal to $D=4-2 \varepsilon$. A primitive amplitude which has soft or collinear divergences must have at least one loop propagator which corresponds to a gluon. An amplitude which just consists of a closed fermion loop does not have any infrared divergences. We denote by $I_{g}$ the set of indices $i$, for which the propagator $i$ in the loop corresponds to a gluon. The soft and collinear subtraction terms for massless QCD read [169]

$$
\begin{align*}
G_{\mathrm{soft}}^{(1)} & =16 \pi \alpha_{s} i \sum_{j \in I_{g}} \frac{p_{j} \cdot p_{j+1}}{k_{j-1}^{2} k_{j}^{2} k_{j+1}^{2}} A_{j}^{(0)}, \\
G_{\mathrm{coll}}^{(1)} & =-8 \pi \alpha_{s} i \sum_{j \in I_{g}}\left[\frac{S_{j} g_{\mathrm{UV}}\left(k_{j-1}^{2}, k_{j}^{2}\right)}{k_{j-1}^{2} k_{j}^{2}}+\frac{S_{j+1} g_{\mathrm{UV}}\left(k_{j}^{2}, k_{j+1}^{2}\right)}{k_{j}^{2} k_{j+1}^{2}}\right] A_{j}^{(0)}, \tag{26}
\end{align*}
$$

where $S_{j}=1$ if the external line $j$ corresponds to a quark and $S_{j}=1 / 2$ if it corresponds to a gluon. The function $g_{\mathrm{UV}}$ ensures that the integration over the loop momentum is ultraviolet finite. Integrating
the soft and the collinear part we obtain

$$
\begin{align*}
& S_{\varepsilon}^{-1} \mu_{s}^{2 \varepsilon} \int \frac{d^{D} k}{(2 \pi)^{D}} G_{\mathrm{soft}}^{(1)}=-\frac{\alpha_{s}}{4 \pi} \frac{e^{\varepsilon \gamma_{E}}}{\Gamma(1-\varepsilon)} \sum_{j \in I_{g}} \frac{2}{\varepsilon^{2}}\left(\frac{-2 p_{j} p_{j+1}}{\mu_{s}^{2}}\right)^{-\varepsilon} A_{j}^{(0)}+\mathcal{O}(\varepsilon) \\
& S_{\varepsilon}^{-1} \mu_{s}^{2 \varepsilon} \int \frac{d^{D} k}{(2 \pi)^{D}} G_{\mathrm{coll}}^{(1)}=-\frac{\alpha_{s}}{4 \pi} \frac{e^{\varepsilon \gamma_{E}}}{\Gamma(1-\varepsilon)} \sum_{j \in I_{g}}\left(S_{j}+S_{j+1}\right) \frac{2}{\varepsilon}\left(\frac{\mu_{u v}^{2}}{\mu_{s}^{2}}\right)^{-\varepsilon} A_{j}^{(0)}+\mathcal{O}(\varepsilon) \tag{27}
\end{align*}
$$

$S_{\varepsilon}=(4 \pi)^{\varepsilon} e^{-\varepsilon \gamma_{E}}$ is the typical volume factor of dimensional regularisation, $\gamma_{E}$ is Euler's constant and $\mu$ is the renormalisation scale.

The ultraviolet subtraction terms correspond to propagator and vertex corrections. The subtraction terms are obtained by expanding the relevant loop propagators around a new ultraviolet propagator $\left(\bar{k}^{2}-\right.$ $\left.\mu_{\mathrm{UV}}^{2}\right)^{-1}$, where $\bar{k}=k-Q$ : For a single propagator we have

$$
\frac{1}{(k-p)^{2}}=\frac{1}{\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}}+\frac{2 \bar{k} \cdot(p-Q)}{\left(\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}\right)^{2}}-\frac{(p-Q)^{2}+\mu_{\mathrm{UV}}^{2}}{\left(\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}\right)^{2}}+\frac{[2 \bar{k} \cdot(p-Q)]^{2}}{\left(\bar{k}^{2}-\mu_{\mathrm{UV}}^{2}\right)^{3}}+\mathcal{O}\left(\frac{1}{|\bar{k}|^{5}}\right)
$$

We can always add finite terms to the subtraction terms. For the ultraviolet subtraction terms we choose the finite terms such that the finite parts of the integrated ultraviolet subtraction terms are independent of $Q$ and proportional to the pole part, with the same constant of proportionality for all ultraviolet subtraction terms. This ensures that the sum of all integrated UV subtraction terms is again proportional to a tree-level amplitude [167].

### 3.4 CONTOUR DEFORMATION

Having a complete list of ultraviolet and infrared subtraction terms at hand, we can ensure that the integration over the loop momentum gives a finite result and can therefore be performed in four dimensions. However, this does not yet imply that we can safely integrate each of the four components of the loop momentum $k^{\mu}$ from minus infinity to plus infinity along the real axis. There is still the possibility that some of the loop propagators go on-shell for real values of the loop momentum. If the contour is not pinched this is harmless, as we may escape into the complex plane in a direction indicated by Feynman's $+i \delta$-prescription. However, it implies that the integration should be done over a region of real dimension 4 in the complex space $\mathbb{C}^{4}$. Let us consider an integral corresponding to a primitive one-loop amplitude with $n$ propagators minus the appropriate IR- and UV-subtraction terms:

$$
\begin{equation*}
\int \frac{d^{4} \tilde{k}}{(2 \pi)^{4}}\left(\mathcal{G}_{\mathrm{bare}}^{(1)}-\mathcal{G}_{\mathrm{soft}}^{(1)}-\mathcal{G}_{\mathrm{coll}}^{(1)}-\mathcal{G}_{\mathrm{UV}}^{(1)}\right)=\int \frac{d^{4} \tilde{k}}{(2 \pi)^{4}} P(\tilde{k}) \prod_{j=1}^{n} \frac{1}{\tilde{k}_{j}^{2}-m_{j}^{2}+i \delta} \tag{28}
\end{equation*}
$$

where $P(\tilde{k})$ is a polynomial of the loop momentum $\tilde{k}^{\mu}$ and the integration is over a complex contour in order to avoid whenever possible the poles of the propagators. We set $\tilde{k}^{\mu}=k^{\mu}+i \kappa^{\mu}(k)$, where $k^{\mu}$ is real [170]. After this deformation our integral equals

$$
\begin{equation*}
\int \frac{d^{4} k}{(2 \pi)^{4}}\left|\frac{\partial \tilde{k}^{\mu}}{\partial k^{\nu}}\right| P(\tilde{k}(k)) \prod_{j=1}^{n} \frac{1}{k_{j}^{2}-m_{j}^{2}-\kappa^{2}+2 i k_{j} \cdot \kappa} \tag{29}
\end{equation*}
$$

To match Feynman's $+i \delta$-prescription we have to construct the deformation vector $\kappa$ such that

$$
\begin{equation*}
k_{j}^{2}-m_{j}^{2}=0 \quad \rightarrow \quad k_{j} \cdot \kappa \geq 0 \tag{30}
\end{equation*}
$$

We remark that the numerical stability of the Monte Carlo integration depends strongly on the definition of the deformation vector $\kappa$.

### 3.5 NLO results for $\mathbf{n}$-jets in electron-positron annihilation

We have calculated results for jet observables in electron-positron annihilation, where the jets are defined by the Durham jet algorithm [166]. The cross section for $n$ jets normalised to the LO cross section for $e^{+} e^{-} \rightarrow$ hadrons reads

$$
\begin{equation*}
\frac{\sigma_{n-j e t}(\mu)}{\sigma_{0}(\mu)}=\left(\frac{\alpha_{s}(\mu)}{2 \pi}\right)^{n-2} A_{n}(\mu)+\left(\frac{\alpha_{s}(\mu)}{2 \pi}\right)^{n-1} B_{n}(\mu)+\mathcal{O}\left(\alpha_{s}^{n}\right) . \tag{31}
\end{equation*}
$$

One can expand the perturbative coefficient $A_{n}$ and $B_{n}$ in $1 / N_{c}$ :

$$
A_{n}=N_{c}\left(\frac{N_{c}}{2}\right)^{n-2}\left[A_{n, \mathrm{lc}}+\mathcal{O}\left(\frac{1}{N_{c}}\right)\right], \quad B_{n}=N_{c}\left(\frac{N_{c}}{2}\right)^{n-1}\left[B_{n, \mathrm{lc}}+\mathcal{O}\left(\frac{1}{N_{c}}\right)\right] .
$$

We calculate the leading order coefficient $A_{n, \text { lc }}$ and the next-to-leading order coefficient $B_{n, \text { lc }}$ for $n \leq 7$ at the renormalisation scale $\mu$ equal to the centre-of-mass energy. The centre-of-mass energy is taken to be equal to the mass of the $Z$-boson. The scale variation can be restored from the renormalisation group equation. The calculation is done with five massless quark flavours. Fig. 5 ]shows the comparison of our

Fig. 5: Comparison of the NLO corrections to the two-, three- and four-jet rate between the numerical calculation and an analytic calculation. The error bars from the Monte Carlo integration are shown and are almost invisible.
numerical approach with the well-known results for two, three and four jets [179, 180, 181]. We observe an excellent agreement. The results for five, six and seven jets for the jet parameter $y_{c u t}=0.0006$ are

$$
\begin{array}{ll}
\frac{N_{c}^{4}}{8} A_{5, \mathrm{lc}}=(2.4764 \pm 0.0002) \cdot 10^{4}, & \frac{N_{c}^{5}}{16} B_{5, \mathrm{lc}}=(1.84 \pm 0.15) \cdot 10^{6}, \\
\frac{N_{c}^{5}}{16} A_{6, \mathrm{lc}}=(2.874 \pm 0.002) \cdot 10^{5}, & \frac{N_{c}^{6}}{32} B_{6, \mathrm{lc}}=(3.88 \pm 0.18) \cdot 10^{7}, \\
\frac{N_{c}^{6}}{32} A_{7, \mathrm{lc}}=(2.49 \pm 0.08) \cdot 10^{6}, & \frac{N_{c}^{7}}{64} B_{7, \mathrm{lc}}=(5.4 \pm 0.3) \cdot 10^{8} . \tag{32}
\end{array}
$$

### 3.6 FIRST STEPS TOWARDS NNLO

An NNLO calculation requires among other things also the calculation of the one-loop amplitude squared. The expansion in the dimensional regularisation parameter $\varepsilon$ of the one-loop amplitude starts at order $(-2)$ one would naively expect that up to order $\varepsilon^{0}$ the $\mathcal{O}(\uparrow)$ - and $\mathcal{O}\left(\varepsilon^{2}\right)$-terms of the one-loop amplitude are needed for an NNLO calculation. However, it is by no means obvious how the approaches for one-loop amplitudes based on unitarity or the numerical method can be extended to include the higherorder terms in the $\varepsilon$-expansion. It turns out that the computation of these higher-order terms can be avoided, provided a method is known to compute the finite two-loop remainder function. The one- and two-loop amplitudes can be written as [182]

$$
\begin{align*}
\mathcal{A}^{(1)} & =\mathbf{Z}^{(1)} \mathcal{A}^{(0)}+\mathcal{F}_{\text {minimal }}^{(1)}, \\
\mathcal{A}^{(2)} & =\left(\mathbf{Z}^{(2)}-\mathbf{Z}^{(1)} \mathbf{Z}^{(1)}\right) \mathcal{A}^{(0)}+\mathbf{Z}^{(1)} \mathcal{A}^{(1)}+\mathcal{F}_{\text {minimal }}^{(2)}, \tag{33}
\end{align*}
$$

where the operators $\mathbf{Z}^{(1)}$ and $\mathbf{Z}^{(2)}$ contain all the infrared poles and $\mathcal{F}_{\text {minimal }}^{(1)}$ and $\mathcal{F}_{\text {minimal }}^{(2)}$ are finite remainders. Here we used the convention that the operators $\mathbf{Z}^{(1)}$ and $\mathbf{Z}^{(2)}$ contain only pole terms, but no terms of order $\varepsilon^{k}$ with $k \geq 0$. This corresponds to a minimal scheme. The operators $\mathbf{Z}^{(1)}$ and $\mathbf{Z}^{(2)}$ are well-known. At NNLO it is sufficient to know the $\varepsilon^{0}$-terms of $\mathcal{F}_{\text {minimal }}^{(1)}$ and $\mathcal{F}_{\text {minimal }}^{(2)}$, the $\varepsilon^{1}$ - or $\varepsilon^{2}$-terms of $\mathcal{A}^{(1)}$ or $\mathcal{F}_{\text {minimal }}^{(1)}$ are not required [183].

## ACKNOWLEDGEMENTS

I would like to thank Simon Plätzer for fruitful discussions during the workshop.

## 4. TOWARDS THE AUTOMATION OF ONE-LOOP AMPLITUDES ${ }^{6}$

#### Abstract

A program is presented that computes one-loop amplitudes automatically for processes with up to 6 external particles based on the Feynman-diagram approach. Additionally, universal one-loop building blocks, which can be used to compute several processes at NLO QCD are calculated.

### 4.1 INTRODUCTION

The calculation of processes with multi-particle final states beyond the leading order approximation has been an active field of research during the last years as a consequence of the demand of high accuracy for signal and background processes at the LHC. A next-to-leading (NLO) calculation consists of virtual and real radiation processes which are infrared divergent (IR) separately and can be computed numerically only after extracting the divergences of the real radiation contributions. The one-loop virtual calculation for multiple particles poseses a challenge of complexity not only due to the large number of contributing diagrams, but also concerning the stability of the numerical code to evaluate them. In the last years, an enormous progress has been achieved applying new techniques and using traditional Feynman-diagram approach, leading to new NLO predictions.

Due to the large number of processes of potential interest at the LHC, the scientific community has worked in the automation of the NLO calculations. The automation of the real contributions including their infrared subtraction terms has been successfully implemented in several packages and the automation of the virtual corrections, which is a harder problem, is currently being achieved in several programs (see [184] and references therein).

In Ref. [185], the early stage of a program, in the framework of Mathematica [186] and FeynCalc [187], to compute automatically one-loop amplitudes based on traditional Feynman-diagram techniques and involving up to $2 \rightarrow 4$ processes was presented. This program will become publicly available in the future. The method used is described in Section 4.2. In Section 4.3, we present a set of universal one-loop building blocks that has been used to compute recently several processes included in the VBFNLO package [42, 41].

### 4.2 TOWARDS AN AUTOMATIC ONE-LOOP AMPLITUDE GENERATOR

The program above mentioned automatically simplifies a set of amplitudes up to Hexagons of rank 5. The result is given in terms of scalar and tensor integrals following the Passarino-Veltman convention [112, 185], spinor chains, polarization vectors and model parameters. The simplified expression is written automatically to FORTRAN routines. For massless propagators, the amplitudes can be evaluated also in Mathematica with unlimited precision, which is used for testing purposes. To achieve that, the scalar integrals, the tensor reduction formalism to extract the tensor coefficient integrals, and also the helicity method described in Ref. [188, 189] to compute the spinor products have been implemented at

[^196]the FORTRAN and Mathematica level. For the determination of the tensor integrals up to the box level, the Passarino-Veltman tensor reduction formalism [112] is used applying the LU decomposition method to avoid the explicit calculation of inverse Gram matrices by solving a system of linear equations, which is a more stable procedure close to singular points. Finally, for singular Gram determinants, special tensor reduction routines following Ref. [115] have been implemented, however, the external momenta convention (Passarino-like) was used. The impact of these methods is discussed in detail in Ref. [185]. For pentagons, in addition to the Passarino-Veltman formalism, the method proposed by Denner and Dittmaier [115, 190], applied also to hexagons, has been implemented. For that, the recursion relations of Ref. [115] in terms of the Passarino-Veltman external momenta convention have been re-derived. This last method is used for the numerical implementation at the FORTRAN level.

The Mathematica function does several algebraic manipulations that are summarized as follows:

- Simultaneous extraction of rational terms based on Dirac algebra manipulations and cancelation of scalar products against propagators.
- Reduction to a minimal basis of tensor and scalar integrals.
- Reduction to a minimal basis of spinor chains.
- The use of Chisholm identities, which are only valid in 4 dimensions, for the contraction of Lorentz indices among different spinor chains is applied, if selected.
- Factorization of loop dependent and independent factors (Useful to perform gauge tests, Ward identities or the re-evaluation of the amplitudes for different helicity polarization of gluons and fermions at a lower CPU cost).
As an example of the notation used, the following Hexagon diagram is used. This is written as follows:

where $g_{0}$ is the strong unrenormalized coupling, $\mathcal{C}_{i j}^{V_{1} V_{2} V_{3} V_{4}}$ is a color diagram dependent factor, e.g, $\mathcal{C}_{i j}^{\gamma \gamma g \gamma}=\left(T_{a}\right)_{i j}\left(C_{F}-1 / 2 C_{A}\right) . g_{\tau}^{V_{i} f}$ are electroweak couplings and $\mathcal{M}_{\tau}^{i j}$ represents the amplitude considering generic off-shell vector bosons with color indices $i j$ for a given helicity $\tau$. The amplitude $\mathcal{M}_{\tau}^{i j}$, omitting color indices, is written in terms of

$$
\begin{equation*}
\mathcal{M}_{\tau}=\mathcal{M}_{\tau}^{D=4}+(D-4) \mathcal{M}_{\tau}^{D R} \tag{35}
\end{equation*}
$$

where $\mathcal{M}_{\tau}^{D=4}$ is the amplitude that one would obtain performing the Dirac algebra manipulation in four dimensions, $D=4$, and $\mathcal{M}_{\tau}^{D R}$ contains the rational terms and vanishes in Dimensional Reduction $(D R)$. These functions are decomposed in the form:

$$
\begin{equation*}
\mathcal{M}^{(D=4, D R)}=\sum_{i, j} \mathrm{SM}_{i, \tau} \mathrm{Fl}_{j}, \tag{36}
\end{equation*}
$$

where $\mathrm{SM}_{i, \tau}$ is a basis of Standard Matrix elements corresponding to spinor products describing the quark line of Eq. (34] which are computed following the helicity method [188, 189] with a defined helicity, $\tau . \mathrm{F1}_{j}$ are complex functions which are further decomposed into dependent and independent loop integral parts,

$$
\begin{equation*}
\mathrm{F}_{j}=\sum_{l, k} \mathrm{~F}_{l} T_{k}\left(\epsilon\left(p_{n}\right) \cdot p_{m} ; \epsilon\left(p_{i}\right) \cdot \epsilon\left(p_{r}\right)\right) \tag{37}
\end{equation*}
$$

$T_{k}$ is a monomial function at most for each polarization vector $\epsilon\left(p_{x}\right)$, i.e., $\epsilon\left(p_{x}\right)^{0}$ or $\epsilon\left(p_{x}\right)^{1}$. The first possibility, $\epsilon\left(p_{x}\right)^{0}$, implies that the polarization vector appears in the set of Standard Matrix elements
$\mathrm{SM}_{i, \tau} . F_{l}$ contains kinematic variables $\left(p_{i} \cdot p_{j}\right)$, the scalar integrals ( $B_{0}, C_{0}, D_{0}$ ), and the tensor integral coefficients $\left(B_{i j}, C_{i j}, D_{i j}, E_{i j}, F_{i j}\right)$. Then, the full result is obtained from $\mathcal{M}_{\tau}^{D=4}$ and $\mathcal{M}_{\tau}^{D R}$ using the finite and the coefficients of the $1 / \epsilon^{n}$ poles of the scalar and tensor coefficient integrals:

$$
\begin{equation*}
\mathcal{M}_{v}^{D=4}=\widetilde{\mathcal{M}}_{v}+\frac{\mathcal{M}_{v}^{1}}{\epsilon}+\frac{\mathcal{M}_{v}^{2}}{\epsilon^{2}}, \quad(D-4) \mathcal{M}_{v}^{D R}=\widetilde{\mathcal{N}}_{v}+\frac{\mathcal{N}_{v}^{1}}{\epsilon} \tag{38}
\end{equation*}
$$

where, e.g., $\widetilde{\mathcal{M}}_{v}$ is the finite contribution obtained using the finite pieces of the scalar and tensor coefficient integrals including the finite contributions from rational terms arising in ultraviolet tensor coefficient integrals.

### 4.3 UNIVERSAL BUILDING BLOCKS

Based on the observation that the same one-loop virtual amplitudes appear in many processes (Fig. 6), we are aiming to collect a basis of universal building blocks, which can be used to compute all of the $2 \rightarrow 4$ processes at LHC at the QCD one-loop level (Similar to the philosophy of older versions of MADGRAPH [191] calling the HELAS [192] routines). This methodology of collecting topologies in groups has been proved very successful in the program VBFNLO, where for example a boxline routine, first line of Fig. 6, is computed and applied to $p p \rightarrow V V, p p \rightarrow V V V, p p \rightarrow V V j$ and EW production of $p p \rightarrow V j j$ and $p p \rightarrow H V j j$.

Fig. 6: Boxline contributions appearing in different processes.

To do that, we use the effective current approach described and applied in Refs. [39, 47, 31, 193, 21]. As illustration, the first diagram of the second raw of Fig. 6is used. This can be written as,

$$
\begin{equation*}
A_{V_{1} V_{2} V_{3} V_{4}, \tau}=J_{V_{1}^{*}}^{\mu_{1}} J_{V_{2}^{*}}^{\mu_{2}} \mathcal{M}_{\mu_{1} \mu_{2}, \tau} \equiv \mathcal{M}_{V_{1}^{*} V_{2}^{*}, \tau} \tag{39}
\end{equation*}
$$

where the color indices have been omitted. Here, $J_{V_{1}^{*}}^{\mu_{1}}$ and $J_{V_{2}^{*}}^{\mu_{2}}$ represent effective polarization vectors in the unitarity gauge for the EW sector including finite width effects in the scheme of Refs. [194, 195] and propagator factors, e.g.,

$$
\begin{equation*}
J_{V_{1}^{*}}^{\mu_{1}}\left(q_{1}\right)=\frac{-i}{q_{1}^{2}-M_{V_{1}^{*}}^{2}-i M_{V_{1}^{*}} \Gamma_{V_{1}^{*}}}\left(g_{\mu}^{\mu_{1}}-\frac{q_{1}^{\mu_{1}} q_{1 \mu}}{q_{1}^{2}-M_{V_{1}^{*}}^{2}-i M_{V_{1}^{*}} \Gamma_{V_{1}^{*}}}\right) \Gamma_{V_{1}^{*} V_{1} V_{3}}^{\mu} \tag{40}
\end{equation*}
$$

with $\Gamma_{V_{1}^{*}}$, the width of the $V_{1}^{*}$ vector boson, and $\Gamma_{V_{1}^{*} V_{1} V_{3}}^{\mu}$, the triple vertex, which can also contain the leptonic decay of the EW vector bosons including all off-shell effects or BSM physics. In this manner, we can then concentrate in computing, instead of $A_{V_{1} V_{2} V_{3} V_{4}, \tau}$, the virtual correction to two massive vector bosons attached to the quark line, $\mathcal{M}_{V_{1}^{*} V_{2}^{*}, \tau}$, or equivalently $\mathcal{M}_{\mu_{1} \mu_{2}, \tau}$, where the polarization vectors or effective currents have been factored out. In our approach, this basic building block is the so-called Boxline, which is computed only once and re-used in different processes.

We plan to do a classification of all the topologies that appear at 1 loop level for up to $2 \rightarrow 4$ processes and install a library with all the basic one-loop building blocks already computed and simplified. This would be an advantage since, for example for $q q \rightarrow V V V V$ production, up to 24 hexagons for a single subprocess would appear, corresponding to the permutations of the vector bosons on the hexagon of Eq. 34. In this approach, the amplitude is obtained by calling the same one-loop amplitude 24 times with the corresponding ordering of momenta and polarization vectors. We aim towards an automation of this procedure, which will result into a faster and shorter final FORTRAN code generation. The specific building blocks are collected into groups with specific gauge and IR factorization properties, e.g, factorization of the IR divergences against the corresponding born, known behavior under Ward identity checks.

In Fig. 7. we present the topologies that have been computed and tested. In the first line, corrections to a quark line with the emission of $\mathrm{V}_{n}$ vector bosons in a fixed order are represented for 4 different topologies. (The first 2 were explained in detail in Ref. [185], including their stability behavior). We have only depicted the virtual amplitude with the higher complexity for a giving building block, e.g. the boxline of Fig.6is obtained from the first diagram with two vector bosons attached, i.e., $n=2$ in $V_{n}$. The first two topologies of the second line are collected by putting together all possible Feynman-diagrams with a fixed order of the vector bosons and attaching it to the quark lines in all possible ways. The crossing of the fermion lines are treated as independent building blocks and are not depicted. Finally, the fermion-loop corrections for a fixed order of vector bosons, $V_{n}$, are computed in the last diagram of the second line

The use of modular structure routines, as the above presented, has been proved to be an advantage in the program VBFNLO [42, 41] since once a structure is computed and checked it can be re-used for different processes. For example, using the building blocks of the first and second topology together with the fermion-loop diagrams, results at NLO QCD for all $V V V$ [39, 47, 46, 45, 43, 44], several $V V j$ [31, 32, 196, 197], $H \gamma j j$ [198] and $W \gamma \gamma j$ [21] production channels have been computed recently. The last one representing the first calculation at this accuracy falling in the category of $V V V+j$ production. Up to the pentagon level, these building blocks are publicly available as part of the VBFNLO [42, 41] package together with the tensor reduction routines, excluding the routines for small Gram determinants which will become available in the future, in addition to the other building blocks.

### 4.4 CONCLUSIONS

A program which automatically evaluates one-loop amplitudes for up to $2 \rightarrow 4$ processes has been presented based on the traditional Feynman-diagram approach. The program has been developed in the framework of Mathematica and FeynCalc and writes down automatically the simplified expression to FORTRAN. Up to the pentagon level and for massless propagators, the code can be evaluated numerically inside Mathematica with unlimited precision which can be used for testing purposes. For the reduction of tensor integrals, we have developed a library that includes expansion for small Gram determinants. Using the leptonic tensor formalism, we are building a library of universal one-loop building blocks, which can be used to compute several processes at NLO QCD. Recently, following this strategy, we have reported results for all $V V V$ [39, 47, 46, 45, 43, 44], several $V V j$ [31, 32, 196, 197], $H \gamma j j$ [198] and $W \gamma \gamma j$ [21] production channels inside the VBFNLO collaboration. The ultimate goal is to generalize the library to compute all of the $2 \rightarrow 4$ processes at LHC at the QCD one-loop level, similar to the philosophy of older versions of MADGRAPH [191] calling the HELAS [192] routines,

Fig. 7: Topologies of universal building one-loop blocks. Only the most complicated diagram of each topology is depicted, e.g, the boxline of Fig 6 is obtained from the first diagram with two vector bosons attached, i.e., $V_{n}, n=2$.
and deliver a Mathematica package compatible with FeynArts [132], which can be used to compute full one-loop amplitudes automatically using the universal building blocks, resulting into a faster and shorter code generation.

## ACKNOWLEDGEMENTS

F.C acknowledges fruitful discussions with the members of the VBFNLO collaboration and partial support of a postdoctoral fellowship of the Generalitat Valenciana, Spain (Beca Postdoctoral d'Excel•lència), by the European FEDER and Spanish MICINN under the grant FPA2008-02878 and by the Deutsche Forschungsgemeinschaft via the Sonderforschungsbereich/Transregio SFB/TR-9 "Computational Particle Physics". The Feynman diagrams in this paper were drawn using Axodraw [139].

## 5. THE TWO-LOOP QCD VIRTUAL AMPLITUDE FOR W PAIR PRODUCTION WITH FULL MASS DEPENDENCE 7

### 5.1 INTRODUCTION

One of the main aims in the Large Hadron Collider (LHC) physics program is undoubtedly the discovery (or the exclusion) of the Higgs boson which is responsible for the fermion and gauge boson masses and also part of the mechanism of dynamical breaking of the Electroweak (EW) symmetry. Another important goal for the LHC is the precise measurement of the hadronic production of gauge boson pairs, $W W, W Z, Z Z, W \gamma, Z \gamma$, this in connection to the investigation of the non-Abelian gauge structure of the SM . W pair production,

$$
\begin{equation*}
q \bar{q} \rightarrow W^{+} W^{-}, \tag{41}
\end{equation*}
$$

[^197]plays an essential role as it serves as a signal process in the search for New Physics and also is the dominant irreducible background to the Higgs discovery channel $p p \rightarrow H \rightarrow W^{*} W^{*} \rightarrow l \bar{\nu} \bar{l}^{\prime} \nu^{\prime}$, in the intermediate Higgs mass range [199]. Both ATLAS and CMS collaborations have released first values for the $W W$ cross section [200, 201].

The process (41) is currently known at next-to-leading order (NLO) accuracy [202, 203, 204, 205, 206, 157, ?]. The NLO corrections were proven to be large enhancing the tree-level result by almost $70 \%$ which falls to a (still) large $30 \%$ after imposing a jet veto. Therefore, if a theoretical estimate for the W pair production is to be compared against experimental measurements at the LHC, one is bound to go one order higher in the perturbative expansion, namely, to the next-to-next-to-leading order (NNLO). This would allow, in principle, an accuracy of around $10 \%$.

High accuracy for the W pair production is also needed when the process is studied as background to Higgs production in order to match accuracies between signal and background. The signal process for the Higgs discovery via gluon fusion, $g g \rightarrow H$, as well as the process $H \rightarrow W W \rightarrow l \bar{\nu} \bar{l}^{\prime} \nu^{\prime}$ are known at NNLO [207, 208, 209, 210, 211, 212, 213, 214, 215, 216], whereas the EW corrections are known beyond NLO [217]. Another process that needs to be included in the background is the W pair production in the loop induced gluon fusion channel,

$$
\begin{equation*}
g g \rightarrow W^{+} W^{-} \tag{42}
\end{equation*}
$$

The latter contributes at $\mathcal{O}\left(\alpha_{s}^{2}\right)$ relative to the quark-anti-quark-annihilation channel but is nevertheless enhanced due to the large gluon flux at the LHC [218, 219].

The first main difficulty in studying the NNLO QCD corrections for W pair production is the calculation of the two-loop virtual amplitude since it is a $2 \rightarrow 2$ process with massive external particles. We have already computed the virtual corrections at the high energy limit [220, 97, 221]. However, this is not enough as it cannot cover the kinematical region close to threshold. Therefore, in order to cover all kinematical regions we proceed as follows. We perform a deep expansion in the W mass around the high energy limit which in combination with the method of numerical integration of differential equations [222, 223, 224] allows us the numerical computation of the two-loop amplitude with full mass dependence over the whole phase space.

### 5.2 THE HIGH ENERGY LIMIT

The methodology for obtaining the massive amplitude in the high energy limit, namely the limit where all the invariants are much larger than the W mass, is similar to the one followed in Refs. [225, 226]. The amplitude is reduced to an expression that only contains a small number of integrals (master integrals) with the help of the Laporta algorithm [227]. In the calculation for the two-loop amplitude there are 71 master integrals. Next step is the construction, in a fully automatised way, of the Mellin-Barnes (MB) representations [228, 229] of all the master integrals by using the MBrepresentation package [230]. The representations are then analytically continued in the number of space-time dimensions by means of the MB package [231], thus revealing the full singularity structure. An asymptotic expansion in the mass parameter ( W mass) is performed by closing contours and the integrals are finally resummed, either with the help of XSummer [232] or the PSLQ algorithm [233]. The result is expressed in terms of harmonic polylogarithms.

### 5.3 POWER CORRECTIONS AND NUMERICAL EVALUATION

The high energy limit by itself is not enough, as was mentioned before. The next step, following the methods applied in Ref. [234], is to compute power corrections in the W mass. Power corrections are good enough to cover most of the phase space, apart from the region near threshold as well as the regions corresponding to small angle scattering.

We recapitulate here some of the notation of Ref. [221] for completeness. The charged vectorboson production in the leading partonic scattering process corresponds to

$$
\begin{equation*}
q\left(p_{1}\right)+\bar{q}\left(p_{2}\right) \rightarrow W^{-}\left(p_{3}, m\right)+W^{+}\left(p_{4}, m\right) \tag{43}
\end{equation*}
$$

where $p_{i}$ denote the quark and W momenta and $m$ is the mass of the W boson.
We have chosen to express the amplitude in terms of the kinematic variables $x$ and $m_{s}$ which are defined to be

$$
\begin{equation*}
x=-\frac{t}{s}, \quad m_{s}=\frac{m^{2}}{s} \tag{44}
\end{equation*}
$$

where

$$
\begin{equation*}
s=\left(p_{1}+p_{2}\right)^{2} \text { and } t=\left(p_{1}-p_{3}\right)^{2}-m^{2} \tag{45}
\end{equation*}
$$

The variation then of $x$ within the range $[1 / 2(1-\beta), 1 / 2(1+\beta)]$, where $\beta=\sqrt{1-4 m^{2} / s}$ is the velocity, corresponds to angular variation between the forward and backward scattering.

It should be evident that any master integral $M_{i}$ can be written then as

$$
\begin{equation*}
M_{i}=M_{i}\left(m_{s}, x, \epsilon\right)=\sum_{j=k}^{l} \epsilon^{j} I_{i j}\left(m_{s}, x\right) \tag{46}
\end{equation*}
$$

where $\epsilon$ is the usual regulator in dimensional regularization $(d=4-2 \epsilon)$ and the lowest power of $\epsilon$ in the sum can be -4 .

The crucial point now is that the derivative of any Feynman integral with respect to any kinematical variable is again a Feynman integral with possibly higher powers of denominators or numerators which can also be reduced anew in terms of the initial set of master integrals. This means that one can construct a partially triangular system of differential equations in the mass, which can subsequently be solved in the form of a power series expansion, with the expansion parameter in our case being $m_{s}$ following the conventions above.

Let us differentiate with respect to $m_{s}$ and $x$, we will then have respectively

$$
\begin{equation*}
m_{s} \frac{d}{d m_{s}} M_{i}\left(m_{s}, x, \epsilon\right)=\sum_{j} C_{i j}\left(m_{s}, x, \epsilon\right) M_{j}\left(m_{s}, x, \epsilon\right) \tag{47}
\end{equation*}
$$

and

$$
\begin{equation*}
x \frac{d}{d x} M_{i}\left(m_{s}, x, \epsilon\right)=\sum_{j} C_{i j}^{\prime}\left(m_{s}, x, \epsilon\right) M_{j}\left(m_{s}, x, \epsilon\right) \tag{48}
\end{equation*}
$$

We use Eq. 47) to obtain the mass corrections for the master integrals calculating the power series expansion up to order $m_{s}^{11}$ (see also Ref. [234] for more details). This deep expansion in $m_{s}$ should be sufficient for most of the phase space but still not enough to cover the whole allowed kinematical region. The way to proceed from this point is to numerically integrate the system of differential equations.

In particular, we choose to work with the master integrals in the form of Eq. 46, where the $\epsilon$ dependence is explicit. We can then work with the coefficients of the $\epsilon$ terms and accordingly have

$$
\begin{equation*}
m_{s} \frac{d}{d m_{s}} I_{i}\left(m_{s}, x\right)=\sum_{j} J_{i j}^{M}\left(m_{s}, x\right) I_{j}\left(m_{s}, x\right) \tag{49}
\end{equation*}
$$

and

$$
\begin{equation*}
x \frac{d}{d x} I_{i}\left(m_{s}, x\right)=\sum_{j} J_{i j}^{X}\left(m_{s}, x\right) I_{j}\left(m_{s}, x\right) \tag{50}
\end{equation*}
$$

where the Jacobian matrices $J^{M}$ and $J^{X}$ have rational function elements.

By using this last system of differential equations, one can obtain a full numerical solution to the problem. What we are essentially dealing now with is an initial value problem and the main requirement is to have the initial conditions to proper accuracy. The initial conditions, namely the values of the master integrals at a proper kinematical point which we call initial point, are provided by the power series expansion. The initial point has to be chosen somewhere in the high energy limit region, where $m_{s}$ is small and therefore, the values obtained by the power series are very accurate. Starting from there, one can evolve to any other point of the phase space by numerically integrating the system of differential equations Eq. (49) and Eq. (50).

We parametrise with a suitable grid of points the region close to threshold and then we calculate the master integrals for all points of the grid by evolving as described previously. Given that the master integrals have to be very smooth (we remain above all thresholds) one can use, after having the values for the grid points, interpolation to get the values at any point of the region. We use 1600 points for the grid and take as initial conditions the values of the master integrals at the point $m_{s}=5 \times 10^{-3}, x=1 / 4$. The relative errors at that point were estimated not to exceed $10^{-18}$.

The numerical integration is performed by using one of the most advanced software packages implementing the variable coefficient multistep method (ODEPACK) [235]. We use quadruple precision to maximise accuracy. The values at any single grid point can be obtained in about 15 minutes in average (with a typical 2 GHz Intel Core 2 Duo system) after compilation with the Intel Fortran compiler. The accuracy is around 10 digits for most of the points of the grid. It is also worth noting that in order to perform the numerical integration one needs to deform the contour in the complex plane away from the real axis. This is due to the fact that along the real axis there are spurious singularities. We use an elliptic contour and we achieve a better estimate of the final global error by calculating more than once for each point of the grid, using each time different eccentricities. Grids of solutions can actually be constructed, which will be subsequently interpolated when implemented as part of a Monte Carlo program.

One very stringent test we use to cross-check the correctness and also the accuracy of our calculation is to compare the infrared pole structure of our two-loop result against the one predicted by Catani [182] (see also Refs. [236, 237, 238]). According to Catani, the infrared poles of the interference of the tree and the two-loop amplitudes follow a generic formula which in our case, since we work with the rescaled variables $m_{s}$ and $x$, can be cast into the following form:

$$
\begin{equation*}
\mathcal{C}_{\text {atani }}^{(0 \times 2)}\left(m_{s}, x, \frac{s}{\mu}\right)=2 \operatorname{Re}\left\{\mathrm{I}^{(1)}(\mathrm{ffl})\left\langle\mathrm{M}^{(0)} \mid \mathrm{M}^{(1)}\right\rangle+\mathrm{I}^{(2)}(\mathrm{ff})\left\langle\mathrm{M}^{(0)} \mid \mathrm{M}^{(0)}\right\rangle\right\} \tag{51}
\end{equation*}
$$

where $\mathrm{M}^{(0)}$ and $\mathrm{M}^{(1)}$ are the tree level and one-loop amplitudes respectively and $\mu$ is the renormalization scale. The operators $\mathrm{I}^{(1)}(\mathrm{ffl})$ and $\mathrm{I}^{(2)}(\mathrm{ffl})$ encode the information for the infrared pole structure and their exact expressions can be found in Ref. [97].

The way to perform the test is straightforward. For each point of the grid with coordinates $\left(m_{s(i)}, x_{(i)}\right)$, we compute the numerical value of the two-loop amplitude $\left(\mathrm{M}^{(2)}\right)$ interfered with the tree level amplitude

$$
\begin{equation*}
\mathcal{A}^{(0 \times 2)}\left(m_{s(i)}, x_{i}, \frac{s}{\mu}\right)=\left\langle\mathrm{M}^{(0)} \mid \mathrm{M}^{(2)}\right\rangle+\left\langle\mathrm{M}^{(2)} \mid \mathrm{M}^{(0)}\right\rangle \tag{52}
\end{equation*}
$$

by numerically integrating the differential equations as described previously and we also calculate the numerical value of the quantity $\mathcal{C}_{\text {atani }}^{(0 \times 2)}\left(m_{s(i)}, x_{(i)}, \frac{s}{\mu}\right)$ by using Eq. 51). Then, all we need to make sure is that the infrared singularities of the quantity $\left\{\mathcal{A}^{(0 \times 2)}\left(m_{s(i)}, x_{i}, \frac{s}{\mu}\right)-\mathcal{C}_{\text {atani }}^{(0 \times 2)}\left(m_{s(i)}, x_{i}, \frac{s}{\mu}\right)\right\}$ cancel numerically for every point $\left(m_{s(i)}, x_{(i)}\right)$ of the grid (ultraviolet divergencies have been removed by renormalization). We will not present here any numbers since the aim was to describe the general methods. The details and the results of the study will be presented in a future publication [239].

### 5.4 CONCLUSIONS

W pair production via quark-anti-quark-annihilation is an important signal process in the search for New Physics as well as the dominant irreducible background for one of the main Higgs discovery channels: $H \rightarrow W W \rightarrow 4$ leptons. Therefore, the accurate knowledge of this process is essential for the LHC. After having calculated the two-loop and the one-loop-squared virtual QCD corrections to the W boson pair production in the high energy limit we proceed to the next step. Namely, we use a combination of a deep expansion in the W mass around the high energy limit and of numerical integration of differential equations to compute the two-loop amplitude with full mass dependence over the whole phase space. A strigent cross-check of our calculation is to verify that the infrared structure of our result agrees with the prediction of the Catani formalism for the infrared structure of QCD amplitudes.

## 6. COMPUTATION OF INTEGRATED SUBTRACTION TERMS NUMERICALLY ${ }^{8}$

#### Abstract

We report on a numerical representation of the integrated subtraction terms of the NNLO subtraction scheme defined in Refs. [240, 241, 242, 243]. The integrated approximate cross sections themselves can be written as products of insertion operators (in colour space) times the Born, or the one-loop cross section. The insertion operator is constructed from the numerical representation of the integrated subtraction terms. We give selected results for the integrated doubly-collinear subtraction term.

### 6.1 INTRODUCTION

We consider the NNLO correction to a generic $m$-jet observable,

$$
\begin{equation*}
\sigma^{\mathrm{NNLO}}=\int_{m+2} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}} J_{m+2}+\int_{m+1} \mathrm{~d} \sigma_{m+1}^{\mathrm{RV}} J_{m+1}+\int_{m} \mathrm{~d} \sigma_{m}^{\mathrm{VV}} J_{m} . \tag{53}
\end{equation*}
$$

The three contributions on the right hand side are separately divergent in $d=4$ dimensions, but their sum is finite for IR safe observables. To obtain the finite NNLO correction, we first continue analytically all integrals to $d=4-2 \epsilon$ dimensions and then rewrite Eqn. (53) as

$$
\begin{equation*}
\sigma^{\mathrm{NNLO}}=\int_{m+2} \mathrm{~d} \sigma_{m+2}^{\mathrm{NNLO}}+\int_{m+1} \mathrm{~d} \sigma_{m+1}^{\mathrm{NNLO}}+\int_{m} \mathrm{~d} \sigma_{m}^{\mathrm{NNLO}} \tag{54}
\end{equation*}
$$

that is a sum of three integrals where the integrands,

$$
\begin{gather*}
\mathrm{d} \sigma_{m+2}^{\mathrm{NNLO}}=\left\{\mathrm{d} \sigma_{m+2}^{\mathrm{RR}} J_{m+2}-\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{2}} J_{m}-\left[\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}} J_{m+1}-\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{12}} J_{m}\right]\right\}_{\epsilon=0},  \tag{55}\\
\mathrm{~d} \sigma_{m+1}^{\mathrm{NNLO}}=\left\{\left[\mathrm{d} \sigma_{m+1}^{\mathrm{RV}}+\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}}\right] J_{m+1}-\left[\mathrm{d} \sigma_{m+1}^{\mathrm{RV}, \mathrm{~A}_{1}}+\left(\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}}\right)^{\mathrm{A}_{1}}\right] J_{m}\right\}_{\epsilon=0}, \tag{56}
\end{gather*}
$$

and

$$
\begin{equation*}
\mathrm{d} \sigma_{m}^{\mathrm{NNLO}}=\left\{\mathrm{d} \sigma_{m}^{\mathrm{VV}}+\int_{2}\left[\mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{2}}-\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{12}}\right]+\int_{1}\left[\mathrm{~d} \sigma_{m+1}^{\mathrm{RV}, \mathrm{~A}_{1}}+\left(\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{~A}_{1}}\right)^{\mathrm{A}_{1}}\right]\right\}_{\epsilon=0} J_{m}, \tag{57}
\end{equation*}
$$

[^198]are integrable in four dimensions by construction. The approximate cross sections $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{2}}$ and $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}$ regularise the doubly- and singly-unresolved limits of the real-emission contribution, $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}}$ respectively. The double subtraction due to the overlap of these two terms is compensated by $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{12}}$. These terms are given explicitly in Ref. [242]. Finally, $\mathrm{d} \sigma_{m+1}^{\mathrm{RV}, \mathrm{A}_{1}}$ and $\left(\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}\right)^{\mathrm{A}_{1}}$ regularise the singly-unresolved limits of $\mathrm{d} \sigma_{m+1}^{\mathrm{RV}}$ and $\int_{1} \mathrm{~d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}$ respectively. They are given explicitly in Ref. [243].

The construction of each approximate cross section in Eqns. (55-57) is based on the known and universal IR limits of tree level and one-loop squared matrix elements, and proceeds in two steps. First, the IR factorisation formulae are written in such a way that their complicated overlap structure can be disentangled ("matching of limits") [240, 244]. Second, we define "extensions" of the formulae, so that they are unambiguously defined away from the strict IR limits [241, 242, 243]. These extensions are defined by the use of various momentum mappings that map a set of $m+1$ or $m+2$ momenta into a set of $m$ momenta,

$$
\begin{equation*}
\{p\}_{m+1} \longrightarrow\{\tilde{p}\}_{m} \quad \text { and } \quad\{p\}_{m+2} \longrightarrow\{\tilde{p}\}_{m} \tag{58}
\end{equation*}
$$

such that (i) the delicate structure of cancellations among the matched limit formulae in various limits is respected (ii) exact momentum conservation is implemented, and (iii) the original $m+1$ or $m+2$ particle phase space factorises exactly into the product of an $m$ particle phase space and a one- or two-particle phase space measure,

$$
\begin{equation*}
\mathrm{d} \phi_{m+r}\left(\{p\}_{m+r} ; Q\right)=\mathrm{d} \phi_{m}\left(\{\tilde{p}\}_{m} ; Q\right)\left[\mathrm{d} p_{r, m}\right], \quad r=1,2 . \tag{59}
\end{equation*}
$$

To finish the definition of the scheme, one must compute once and for all the one- and two-particle integrals, denoted formally as $\int_{1}$ and $\int_{2}$, appearing in Eqns. 5657 .

In general the integrated subtraction terms are integrals of extensions over the whole phase space of combinations of the QCD splitting functions and squared soft currents. In this proceedings we discuss two examples: (i) the singly-collinear subtractions $\mathcal{C}_{i r}^{(\ell, 0)}$ and (ii) the doubly-collinear subtractions $\mathcal{C}_{i r, j s}^{(0,0)}$, which are part of $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{1}}$ and $\mathrm{d} \sigma_{m+2}^{\mathrm{RR}, \mathrm{A}_{2}}$ in Eqn. 55 , respectively. The precise definitions of these terms can be found in Ref. [242]. The meaning of the superscript is irrelevant for our present purpose (also explained in Ref. [242]).

Denoting a generic subtraction term by $\mathcal{X}^{(\ell, k)}$ (such as $\mathcal{C}_{i r}^{(\ell, 0)}$ ) the integrated counterterms can be written in the following general form:

$$
\begin{equation*}
\int_{r} \mathcal{X}^{(\ell, k)}=\left[\frac{\alpha_{\mathrm{s}}}{2 \pi} S_{\epsilon}\left(\frac{\mu^{2}}{Q^{2}}\right)^{\epsilon}\right]^{r+\ell} N_{X}(\epsilon) X^{(\ell)}(x, \ldots) \operatorname{Re}\left\langle\mathcal{M}_{m}^{(0)}(\{\tilde{p}\})\right| \boldsymbol{T}_{i} \cdot \boldsymbol{T}_{j} \ldots\left|\mathcal{M}_{m}^{(k)}(\{\tilde{p}\})\right\rangle, \tag{60}
\end{equation*}
$$

where $S_{\epsilon}=(4 \pi)^{\epsilon} / \Gamma(1-\epsilon)$, and $X^{(\ell)}(x, \ldots)$ represents a function that depends on kinematical invariants of the factorized $m$-parton phase space. It results in the integration of the subtraction term $\mathcal{X}^{(\ell, k)}$ over the factorized phase spaces [ $\mathrm{d} p_{r, m}$ ] in Eqn. 59). In a NNLO computation the possible cases are $r+\ell+k=1$ with $\ell+k=0$ or 1 , and $r=2$ with $\ell+k=0$. We use the colour- and spin-state notation of Ref. [236], when the amplitude for a scattering process involving $m$ final-state momenta, $\left|\mathcal{M}_{m}^{(k)}\right\rangle$, is an abstract vector in colour and spin space; $k$ denotes the number of loops. Colour interactions at QCD vertices are represented by associating colour charges $\boldsymbol{T}_{i}$ with the emission of a gluon from each parton $i$. There are $2 r$ such colour charges. Then the functions $X^{(\ell)}$ are dimensionless in colour-space. For certain subtraction terms, universal, possibly $\epsilon$-dependent numerical factors, $N_{X}(\epsilon)$ appear naturally, which can be factored out. Our purpose is to compute all functions $X^{(\ell)}$, which we discuss next.

### 6.2 INTEGRATING THE COUNTERTERMS

The actual computation of the integrated counterterms leads to a large number of multi-dimensional integrals. The ultimate goal is to find the analytical form of the coefficients of a Laurent expansion (in
$\epsilon$ ) of these integrals, which turns out to be a rather tedious job. In order to compute these coefficients as efficiently as possible, we have explored several methods.

First, it is possible to extend the method of integration-by-parts identities and solving of differential equations, developed for computing multi-loop Feynman integrals [245, 246], to the relevant phase space integrations [247]. This method yields $\epsilon$-expansions with fully analytical coefficients, with the final results being expressed in terms of two-dimensional harmonic polylogarithms (after a suitable basis extension, see Ref. [247] for details). This approach was used successfully to compute a class of singlyunresolved integrals [247].

Second, the phase space integrals that arise can be computed via the method of Mellin-Barnes (MB) representations [228, 229, 248]. Here we obtain the $\epsilon$-expansion coefficients in terms of complex contour integrals over $\Gamma$-functions. Performing these integrals by the use of the residue theorem, a representation in terms of harmonic sums is obtained. In many cases, the sums can be evaluated in a closed form, yielding an analytical result. In some instances however, we find multi-dimensional MB integrals that are very difficult to compute fully analytically. Nevertheless, in these situations a direct numerical evaluation of the appropriate MB representations provides a fast and reliable way to obtain final results with small numerical uncertainties. We stress that for phenomenological applications, this is all that is required, since the numerical uncertainty of the complete computation is dominated by the phase space integrations. We have used the MB method to compute all singly-unresolved integrals [249], and all two-particle integrals appearing in $\int_{2} \mathrm{~d} \sigma_{m+2}^{R R, A_{12}}$ as well [91].

Finally, the method of iterated sector decomposition [250] can also be used to calculate the integrals we encounter [251]. Sector decomposition produces a representation of the $\epsilon$-expansion where the coefficients are given in terms of (mostly quite cumbersome) finite integrals over the unit hypercube. The analytical evaluation of these integrals is not feasible except for the simplest cases. Nevertheless, this method is simple to implement and can be automated to a large extent. In fact there are several computer programs that use various implementations of sector decomposition to provide numerical values of coefficients of the powers of $\epsilon$ in the Laurent expansion of dimensionally regulated integrals [252, 253, 254]. We found the program $\operatorname{SecDec}$ powerful and flexible to generate sufficiently precise values of our integrated subtraction terms.

Choosing the Cuhre integrator implemented in SecDec, we can easily reach $10^{-7}$ relative precision for the integration. Such precision is sufficient for our purposes: (i) to demonstrate the cancellation of the $\epsilon$ poles numerically, and (ii) to compute the finite integrals in Eqns. (56) and (57). As the numerical uncertainty of the second item is limited more by the Monte Carlo integration over the $m+1$ and $m$ particle phase spaces, for item (ii) much lower (not better than $10^{-3}$ ) precision is sufficient. This looser requirement on the precision for the $\mathrm{O}(1)$ terms and the fact that the integrated subtraction terms are smooth functions of their parameters, with logarithmic behaviour for asymptotically small values of the parameters, makes possible that we find sufficient approximations to the integrated subtraction terms.

### 6.3 APPROXIMATE INTEGRATED SUBTRACTION TERMS

The computation of the integrated subtraction terms at any given values of the kinematical parameters, as required in the Monte Carlo integration over the phase space, is not feasible. In order to demonstrate the cancellation of the $\epsilon$ poles numerically we can choose several randomly selected phase space points and evaluate the necessary integrals with high precision. The cancellation cannot depend on the particular phase space point. In the case of the finite remainders, in order to compute the phase space integrals in Eqns. 56 ) and (57), we are able to find sufficiently precise approximations to the integrated subtraction terms using a procedure that can be automated to high degree. The latter point is also important as there are several hundred integrals to compute. In the following, we outline our procedure for two cases: (i) an example with integrals depending on one kinematical parameter, $\left(\int_{1} \mathcal{X}^{(\ell, k)}=\int_{1} \mathcal{C}_{i r}^{(\ell, 0)}\right)$ and (ii) another example with integrals depending on two kinematical parameters, $\left(\int_{2} \mathcal{X}^{(\ell, k)}=\int_{2} \mathcal{C}_{i r, j s}^{(0,0)}\right)$.

In order to compute $\int_{1} \mathcal{C}_{i r}^{(\ell, 0)}$, we have to integrate the azimuthally averaged Altarelli-Parisi splitting functions $P_{f_{i} f_{r}}^{(\ell)}\left(z_{i, r}, z_{r, i} ; \epsilon\right)$ in $4-2 \epsilon$ dimensions for the splitting process $f_{i r} \rightarrow f_{i}+f_{r}$, with $z_{i}$ being the momentum fraction of parton $f_{i}$. It was discussed in Ref. [249] that the corresponding functions $C_{i r}^{(\ell)}$ can be expressed as combinations of the integrals (we changed the notation from $\mathcal{I}$ to $\mathcal{I}_{C}$ )

$$
\begin{equation*}
\mathcal{I}_{C}\left(x ; \epsilon, \alpha_{0}, d_{0}, \kappa, k, \delta, g_{I}^{( \pm)}\right)=\frac{16 \pi^{2}}{S_{\epsilon}} Q^{2 \epsilon} \int_{1}\left[\mathrm{~d} p_{1, m+1}^{(i r)}\right] \frac{z_{r}^{k+\delta \epsilon}}{s_{i r}^{1+\kappa \epsilon}} g_{I}^{( \pm)}\left(z_{r}\right) f\left(\alpha_{0}, \alpha_{i r}, d(m, \epsilon)\right) . \tag{61}
\end{equation*}
$$

In terms of explicit integration variables these collinear integrals have the general form [249]

$$
\begin{align*}
& \mathcal{I}_{C}\left(x ; \epsilon, \alpha_{0}, d_{0} ; \kappa, k, \delta, g_{I}^{( \pm)}\right)=x \int_{0}^{\alpha_{0}} \mathrm{~d} \alpha \alpha^{-1-(1+\kappa) \epsilon}(1-\alpha)^{2 d_{0}-1}[\alpha+(1-\alpha) x]^{-1-(1+\kappa) \epsilon} \\
& \quad \times \int_{0}^{1} \mathrm{~d} v[v(1-v)]^{-\epsilon}\left(\frac{\alpha+(1-\alpha) x v}{2 \alpha+(1-\alpha) x}\right)^{k+\delta \epsilon} g_{I}^{( \pm)}\left(\frac{\alpha+(1-\alpha) x v}{2 \alpha+(1-\alpha) x}\right) . \tag{62}
\end{align*}
$$

The necessary functions $g_{I}^{( \pm)}$are listed in Ref. [249], where analytic results of these integrals for $\alpha_{0}=1$ and $d_{0}=3$ are also presented.

Our present goal is to provide sufficiently precise numerical approximations to the functions $\mathcal{I}_{C}(x)$ in a simple way. The motivation is that often it is difficult to perform the analytic computation with arbitrary values of the parameters. For instance, the derivation with $\alpha_{0}=1$ is rather different from a derivation with $\alpha_{0}<1$. Also, the choice for $d_{0}$ is to some extent arbitrary, and a new choice requires a completely new analytic computation. Thus, for the sake of flexibility we propose a fully numerical approach here.

First we used the program SecDec, modified such that it can compute the value of the integral at multiple values of the parameter $x$ in a single run. For simplicity, we call the $\mathrm{O}(1)$ terms of the integral 'measurements'. Then, inspired by the analytic results in Ref. [249], we fitted these measurements by combinations of logarithms and polynomials in $x$ of the form

$$
\begin{equation*}
\mathcal{F}_{C}\left(x ; \kappa=0, k, \delta=0, g_{I}^{( \pm)}=1\right)=\sum_{n=0}^{n_{\max }} P_{n}^{(m)}(x, k) \log ^{n}(x), \quad P_{n}^{(m)}(x, k)=\sum_{n=0}^{m} a_{n}^{(k)} x^{n} \tag{63}
\end{equation*}
$$

where the upper limit $n_{\max }$ is determined by the power $-n_{\text {max }}$ of the leading pole in the Laurentexpansion (in $\epsilon$ ) of the integral. As for the degree of the polynomials we tried several simple choices ( $m=1,2,3$ ). We found that splitting the region of the parameter space into an asymptotic ( $0<x \leq$ $10^{-4}$ ) and a non-asymptotic ( $10^{-4}<x \leq 1$ ) region, we could provide a fit with $m=2$ that approximates the analytic result within relative difference few times $10^{-4}$. The loss of relative precision is associated with phase space points where the function changes sign, and its numerical value is close to zero (around $x=0.2$ ).

In Fig. 8 we show the approximate function $\mathcal{F}_{C}\left(x ; \alpha_{0}, d_{0}, 0,-1,0,1\right)$ together with the 'measurements', which coincide with the known exact analytic result to at least six digit accuracy. We find very good agreement, which is characterized by the ratio of the two values in the lower panels. In Fig. 8 b we show the approximate function for $\alpha_{0}=0.1$ and $d_{0}=3-3 \epsilon$ together with the corresponding 'measurements'. In this case the analytic results are not available.

Building on the experience gained in studying the one-parameter case, we worked out a similar strategy for the integrated subtraction term $\int_{2} \mathcal{C}_{i r, j s}^{(0,0)}$. The corresponding functions $C_{i r, j s}^{(0,0)}$ can be ex-

Fig. 8: The fitted function $\mathcal{F}_{C}(x ; 0,-1,0,1)$ compared to the integral $\mathcal{I}(x ; 0,-1,0,1)$ at a) $\alpha_{0}=1$ and $d_{0}=3$, b) $\alpha_{0}=0.1$ and $d_{0}=3-3 \epsilon$.
pressed as combination of the integrals

$$
\begin{align*}
& \mathcal{I}_{2 C}\left(x_{i}, x_{j} ; \epsilon, \alpha_{0}, d_{0} ; k, l\right)=x_{i} x_{j} \int_{0}^{1} \mathrm{~d} \alpha \int_{0}^{1} \mathrm{~d} \beta \Theta\left(\alpha_{0}-\alpha-\beta\right) \\
& \quad \times(1-\alpha-\beta)^{2 d_{0}-2(1-\epsilon)} \alpha^{-1-\epsilon} \beta^{-1-\epsilon}\left(\alpha+(1-\alpha-\beta) x_{i}\right)^{-1-\epsilon}\left(\beta+(1-\alpha-\beta) x_{j}\right)^{-1-\epsilon} \\
& \quad \times \int_{0}^{1} \mathrm{~d} v v^{-\epsilon}(1-v)^{-\epsilon} \int_{0}^{1} \mathrm{~d} u u^{-\epsilon}(1-u)^{-\epsilon}\left(\frac{\alpha+(1-\alpha-\beta) x_{i} v}{2 \alpha+(1-\alpha-\beta) x_{i}}\right)^{k}\left(\frac{\beta+(1-\alpha-\beta) x_{j} u}{2 \beta+(1-\alpha-\beta) x_{j}}\right)^{l} . \tag{64}
\end{align*}
$$

We again run SecDec with $\alpha_{0}=0.1$ and $d_{0}=3-3 \epsilon$ at several hundred different values of the kinematic parameters to obtain the 'measurements'. To reach $10^{-7}$ relative precision for all such 'measurements' takes several hours on a single CPU. Then we fitted these 'measurements' with the function

$$
\begin{equation*}
\mathcal{F}_{2 C}\left(x_{i}, x_{j} ; k, l\right)=\sum_{n_{i}=0}^{n_{\max }} \sum_{n_{j}=0}^{n_{\max }-n_{i}} P_{n_{i}}^{(m)}\left(x_{i}, k, l\right) P_{n_{j}}^{(m)}\left(x_{j}, k, l\right) \log ^{n_{i}}\left(x_{i}\right) \log ^{n_{j}}\left(x_{j}\right) . \tag{65}
\end{equation*}
$$

We divide the parameter space $0<x_{i}, x_{j} \leq 1$ into four regions: (i) $0<x_{i}, x_{j} \leq 10^{-4}$, (ii) $0<x_{i} \leq$ $10^{-2}$ and $10^{-4}<x_{j} \leq 1$, (iii) $0<x_{j} \leq 10^{-2}$ and $10^{-4}<x_{i} \leq 1$, (iv) $10^{-2}<x_{i}, x_{j} \leq 1$. Using $m=2$, we are able to fit the original function $\mathcal{I}_{2 C}$ to per mille precision almost everywhere. The ratio of the fitted function $\mathcal{F}_{2 C}$ to the numerical evaluation of $\mathcal{I}_{2 C}$ is shown in Fig. 9 together whith the fitted function $\mathcal{F}_{2 C}$ itself.

## CONCLUSIONS

We have worked out a numerical procedure for providing simple approximations of the integrated subtraction terms of the NNLO subtraction scheme defined in Refs. [240, 241, 242, 243]. We use the publicly available program SecDec to compute the coefficients of the Laurent expansion of the necessary integrals to high numerical precision. We found that the integrals that depend on one or two kinematical invariants can be approximated with simple combinations of polynomials and logarithms. The precision of these approximations is usually at per mille or better.

## Part III

## PARTON DISTRIBUTION FUNCTIONS

## 7. WHICH EXPERIMENTS CONSTRAIN THE GLUON PDF IN A GLOBAL QCD FIT? 9

#### Abstract

Based on computation of PDF-induced correlations, we identify the experiments in CTEQ and MSTW global QCD analyses that are sensitive to the gluon parton density in the proton. The Tevatron inclusive jet production at large momentum fractions $x$ and DIS charm quark production at moderately small $x$ show the strongest correlation with the gluon PDF. The strength of the PDF-induced correlation between the gluon PDF and inclusive (di)jet production data is different in the CTEQ and MSTW analyses.

### 7.1 Introduction

The parton distribution function (PDF) of gluons in a proton, $g(x, \mu)$, plays an important role in hadron collider phenomenology. It arises in cross sections for production of hadronic final states, massive scalar

[^199]

Fig. 10: CT10 and CTEQ 6.6 PDF uncertainty bands at $\mu=2 \mathrm{GeV}$ (left) and 100 GeV (right), taken from Ref. [255]. The CTEQ 6.6 best-fit PDFs and uncertainties are indicated by solid curves and hatched bands, while those of CT10 are indicated by dashed curves and dotted bands.
bosons, and hypothetical elementary particles, often in a combination with an overall normalization prefactor proportional to $\alpha_{s}$. The gluon distributions from CT10 [255] and CTEQ 6.6 [256] PDF sets are shown in Fig 10. The figure shows that the gluon PDF is constrained well by fitted experiments at the intermediate momentum fractions $x$, but the uncertainty grows in the region $x>0.1$. We may ask which experiments in the global fit impose the most significant constraints on the the gluon PDF. It is often said that the precise neutral-current DIS data provides the tightest constraints on the gluon PDF at $x$ of order $10^{-3}$, while inclusive jet production at the Tevatron plays the key role in constraining the gluon at $x>0.1$. However, the net PDF uncertainty reflects subtle interplay of numerous constraints imposed by QCD theory and multiple experiments, as well as various correlated uncertainties in experimental measurements. In this contribution, we identify the experiments with the strongest sensitivity to the gluon PDF by using a method of PDF-induced correlations that was developed in Refs. [256, 257, 258]. The analysis of correlations provides a systematic way to identify such experiments and also to establish specific ranges of $x$ and $Q$ where the correlations of the experimental data sets with the gluon PDF are the most pronounced.

### 7.2 Log-likelihood $\chi^{2}$ and PDF-induced correlations

The quality of theory description of an experimental data set can be quantified by the log-likelihood function $\chi^{2}$. Many high-energy physics experiments publish three kinds of measurement errors for each data point $i$ : the statistical error $\sigma_{i}$, uncorrelated systematic error $u_{i}$, and correlated systematic errors $\left\{\beta_{1 i}, \beta_{2 i}, \beta_{3 i} \ldots . \beta_{K i}\right\}$ of $K$ different types. To compare a theory prediction $T_{i}$ to the data value $D_{i}$ for a data point $i$, while accounting for all types of errors, the $\chi^{2}$ function can be constructed as [259, 260]

$$
\begin{equation*}
\chi^{2}=\sum_{\text {expt. }}\left[\sum_{i=1}^{N_{e}}\left(\frac{D_{i}-T_{i}(a)-\sum_{k=1}^{K} r_{k} \beta_{k i}}{\alpha_{i}^{2}}\right)^{2}+\sum_{k=1}^{K} r_{k}^{2}\right] \tag{66}
\end{equation*}
$$

where $\alpha_{i}^{2}=\sigma_{i}^{2}+u_{i}^{2}$ is the combined uncorrelated error; $r_{k}$ are random parameters describing each of $K$ correlated errors (each distributed according to the standard normal distribution); $N_{e}$ is the number of
the data points; and $K$ is the number of the sources of the correlated systematic errors.
Analytic minimization of the function (66) with respect to the correlated systematic parameters $r_{k}$ renders the following result [257, 259]:

$$
\begin{equation*}
\left.r_{k}\right|_{\text {best fit }}=\sum_{k^{\prime}=1}^{K} A_{k k^{\prime}}^{-1} B_{k^{\prime}}, \tag{67}
\end{equation*}
$$

where $A_{k k^{\prime}}$ and $B_{k}$ are given by

$$
\begin{equation*}
A_{k k^{\prime}}=\delta_{k k^{\prime}}+\sum_{i=1}^{N_{e}} \frac{\beta_{k i} \beta_{k^{\prime} i}}{\alpha_{i}^{2}}, \quad \text { and } \quad B_{k}=\sum_{i=1}^{N_{e}} \frac{\beta_{k i}\left(D_{i}-T_{i}\right)}{\alpha_{i}^{2}} . \tag{68}
\end{equation*}
$$

Substituting Eq. 67] into Eq. (66], we obtain a reduced $\chi^{2}$ function [257, 259],

$$
\begin{equation*}
\chi^{2}=\sum_{\text {expt. }}\left[\sum_{i=1}^{N_{e}} \frac{\left(D_{i}-T_{i}\right)^{2}}{\alpha_{i}^{2}}-\sum_{k, k^{\prime}=1}^{K} B_{k} A_{k k^{\prime}}^{-1} B_{k^{\prime}}\right] . \tag{69}
\end{equation*}
$$

In this function, the information about the systematic shifts in $r_{k}$ is included implicitly. Often, the influence of the correlated shifts on the PDFs is substantial.

Next, we wish to discuss correlations between PDF uncertainties of two variables, $X(\vec{a})$ and $Y(\vec{a})$, where $\vec{a}=\left\{a_{1}, a_{2}, \ldots, a_{N}\right\}$ is the vector of $N$ PDF parameters. The correlations can be computed either in the Hessian [256, 257, 258] or Monte-Carlo [261] approaches. In this note we will adopt the Hessian approach.

A symmetric PDF uncertainty $\Delta X$ corresponds to the maximal variation of $X$ for all combinations of PDF parameters that lie within the tolerance hypersphere $\Delta \chi^{2} \leq T^{2}$. This uncertainty is given by

$$
\begin{equation*}
\Delta X=\frac{1}{2} \sqrt{\sum_{i=1}^{N}\left[X_{i}^{+}-X_{i}^{-}\right]^{2}} \tag{70}
\end{equation*}
$$

in terms of the value $X_{0}$ of $X$ obtained with the central PDF set, and values $X_{i}^{+}$and $X_{i}^{-}$of $X$ obtained for maximal positive and negative displacements of each orthonormal PDF parameter $a_{i}$ within the tolerance hypersphere. The same "master equation" defines $\Delta Y$, the PDF uncertainty of the variable $Y$.

In the linear approximation, the pairs of values of $X$ and $Y$ that are allowed within the PDF uncertainty correspond to the points inside an ellipse in the $X-Y$ plane. The boundary of the ellipse is parametrically described by

$$
\begin{align*}
& X=X_{0}+\Delta X \cos \theta  \tag{71}\\
& Y=Y_{0}+\Delta Y \cos (\theta+\varphi) \tag{72}
\end{align*}
$$

where the parameter $\theta$ varies between 0 and $2 \pi$, and the relative phase angle $\varphi$ is a function of $X_{i}^{ \pm}$and $Y_{i}^{ \pm}$. The PDF uncertainties $\Delta X$ and $\Delta Y$ are calculated according to Eq. 70). The angle $\varphi$ is included between the gradients $\vec{\nabla} X$ and $\vec{\nabla} Y$ of $X$ and $Y$ in the PDF parameter space. Its cosine,

$$
\begin{equation*}
\cos \varphi=\frac{\vec{\nabla} X \cdot \vec{\nabla} Y}{\Delta X \Delta Y}=\frac{1}{4 \Delta X \Delta Y} \sum_{i=1}^{N}\left(X_{i}^{(+)}-X_{i}^{(-)}\right)\left(Y_{i}^{(+)}-Y_{i}^{(-)}\right) \tag{73}
\end{equation*}
$$

quantifies the degree of similarity in the PDF dependence of $X$ and $Y$. If $X$ and $Y$ are strongly correlated (corresponding to $\cos \varphi \rightarrow 1$ ) or anti-correlated $(\cos \varphi \rightarrow-1)$, the PDF uncertainties of $X$ and $Y$ are driven by essentially the same combinations of PDF parameters. Conversely, the PDF dependence of $X$ is independent from the PDF dependence of $Y$ if $\cos \varphi \approx 0$.

### 7.3 Which experiments are sensitive to the gluon PDF?

If an experimental cross section $\sigma$ strongly constrains a PDF $f_{a}(x, Q)$ for some combination of $x$ and $Q$, we expect that Eq. $\sqrt{73} \mid$ returns $|\cos \varphi|$ close to unity when using $X=f_{a / A}(x, Q)$ and $Y=\sigma$. If the experimental data set includes several data points, we can use $Y=\chi^{2}$. The strength of the constraint on the PDF from this experiment is determined by $|\cos \varphi|$ and the magnitude of $\chi^{2}$. In the majority of the fitted experiments, $\chi^{2} / N_{e}$ is close to 1 , so that $|\cos \varphi|$ tends to be more important for distinguishing between the sensitivities of the experiments than the magnitude of $\chi^{2}$.

Following this approach, we compute $\cos \varphi$ between the NLO gluon PDF $g(x, Q)$ in various $x$ ranges (for $Q^{2}=10 \mathrm{GeV}^{2}$ ), and $\chi^{2}$ for typical experimental data sets that are used in the PDF analysis. In this study, we compute $\cos \varphi$ for the experiments from the CT10 analysis that are listed in Table 4 . In the figures, we refer to each experiment by its numerical ID that is shown in the left column of Table 4 .

The $\cos \varphi$ values between the gluon PDF at a given $x$ value and $\chi^{2}$ for each experiment are plotted as two-dimensional contour plots for CT10 NLO PDFs [255] in the left panel of Fig. [11, and for MSTW' 08 NLO PDFs [262] in the right panel. The horizontal axis indicates the range of $x$ in $g(x, Q)$. The vertical axis indicates the ID of the experiment. At the bottom of the figure, we show the color legend adopted to draw the contour plots. The color legend is chosen so as to emphasize only cells with large correlation ( $\cos \varphi>0.5$, dark yellow-red colors) or large anticorrelation ( $\cos \varphi<-0.5$, blue colors). The regions with $|\cos \varphi|<0.5$ are filled with a light-yellow color. The $\chi^{2}$ values for each data set are computed according to Eqs. (66) and (69) using the CTEQ fitting code for both CT10 and MSTW PDF sets.

Visual inspection of two panels of Fig. 11 reveals both similarities and differences in the pattern of correlations of the gluon PDF in the CT10 and MSTW PDF sets. In the case of the CT10 PDF (left panel), the gluon PDF has a pronounced anti-correlation (blue spots) with HERA charm and bottom SIDIS production data sets (experiments $140,143,145,156,157$ ) at $x<0.1$, as well as with Tevatron inclusive jet production data sets (experiments $504,505,514$, and 515) at $x>0.05$. Some correlations (brown and red spots) are also observed, but they are not as pronounced as the anti-correlations. Weaker (anti-)correlations can be noticed with the NMC $F_{2}^{p}$, CDHSW $F_{2}^{p}$, and E605 pp Drell-Yan process data, corresponding to experiments 103, 108, and 201.

While the gluon PDF of the MSTW'08 set (right panel of Fig. 11) also shows an (anti-)correlation with the heavy-quark DIS and jet production data, the overall pattern of the correlations is somewhat different from the CT10 case. Here, the gluon PDF is mostly correlated with high- $x$ jet production (experiments 504, 505,514, and 515), while it is either correlated or anti-correlated with heavy-quark DIS experiments (experiments 140, 143, 145, 156, 157). In addition, we observe significant (anti-)correlations with the combined HERA DIS data set ( $\mathrm{ID}=159$ ) and fixed-target DIS experiments ( $\mathrm{ID}=101-124$ ) that are not seen in the CT10 panel.

We now turn to the correlations of the gluon and $u$-quark PDFs with $\chi^{2}$ values in individual bins of Tevatron inclusive jet and dijet production data. For this purpose, we represent $\chi^{2}$ for one experimental data set in Eq. 69 as a sum of contributions $\chi_{i}^{2}$ from individual data points $i$ :

$$
\begin{equation*}
\chi^{2}=\sum_{i=1}^{N_{e}} \chi_{i}^{2}, \tag{74}
\end{equation*}
$$

where

$$
\begin{equation*}
\chi_{i}^{2}=\frac{D_{i}-T_{i}}{\alpha_{i}} \sum_{j=1}^{N_{e}}\left\{\delta_{i j}-\frac{D_{j}-T_{j}}{\alpha_{j}} \sum_{k, k^{\prime}=1}^{K} \frac{\beta_{k i}}{\alpha_{i}} A_{k k^{\prime}}^{-1} \frac{\beta_{k^{\prime} j}}{\alpha_{j}}\right\} . \tag{75}
\end{equation*}
$$

Each contribution $\chi_{i}^{2}$ accounts for the effect of correlated systematic shifts through the term that includes $A_{k k^{\prime}}^{-1}$ on the right-hand side of Eq. 75 . Again, the constraining power of each point is determined both

Fig. 11: Correlation between the gluon distribution from CT10 NLO (left) and MSTW2008 NLO (right) PDF sets and $\chi^{2}$ for the experiments used in the CT10 global QCD analysis. The color of each cell indicates the value of $\cos \varphi$ according to the included legend. The ID's of individual experiments are listed in Table 4

| ID | Experimental data set |
| :---: | :---: |

Table 4: Experimental data sets examined in this analysis.

Fig. 12: Correlation cosine between $\chi_{i}^{2}$ in each $p_{T}$ bin from D $\emptyset$ Run- 2 inclusive jet production and gluon and $u$ quark distributions from CT10 and MSTW 2008 NLO sets. The horizontal axis refers to the $x$ value in the PDF. The vertical axis indicates the numerical ID of the experimental bin for which $\chi^{2}$ is computed. The ID for each bin is indicated as $100 i_{y}+i_{p_{T}}$, where $i_{y}=1, \ldots 6$ and $i_{p_{T}}$ are the ID's of the corresponding rapidity interval and the $p_{T}$ interval, respectively.

Fig. 13: Correlation cosine between $\chi_{i}^{2}$ in each $m_{j j}$ bin from D $\emptyset$ Run-2 dijet production and gluon and $u$ quark distributions from CT10 and MSTW 2008 NLO sets. The horizontal axis refers to the $x$ value in the PDF. The vertical axis indicates the numerical ID of the experimental bin for which $\chi^{2}$ is computed. The ID for each bin is indicated as $100 i_{y_{\max }}+i_{m_{j j}}$, where $i_{y_{\max }}=1, . ., 6$ and $i_{m_{j j}}$ are the ID's of the corresponding intervals in $y_{\max }$ and $m_{j j}$, respectively.
by the value of $|\cos \varphi|$ and the magnitude of $\chi_{i}^{2}$, with the latter being comparable to unity for the majority of the data points.

For D $\emptyset$ Run-2 single-inclusive jet cross sections [287], we plot the $\cos \varphi$ values for the gluon and $u$-quark PDFs, with $\chi_{i}^{2}$ computed for each bin of the jet's transverse momentum $p_{T}$ and rapidity $y$. The resulting contour plots are shown in Fig. 12. Similarly, for DØ Run-2 dijet cross sections [289], Fig. 13 shows the contour plots of $\cos \varphi$ for $\chi_{i}^{2}$ in the bins of of dijet invariant mass $m_{j j}$ and maximal absolute rapidity $|y|=\max \left(\left|y_{1}\right|,\left|y_{2}\right|\right)$ of the dijets. In both figures, theory cross sections are computed at NLO (without threshold resummation corrections) with the FASTNLO code [290, 291], using the settings described in Section 13. The same color legend as in Fig. 11 is used. Similar patterns of correlations were found with the CDF Run-2 inclusive jet data (not shown).

The upper panels in both figures show $\cos \varphi$ for CT 10 NLO and MSTW' 08 NLO gluon PDFs. The correlated experimental errors modify the correlations by smearing the $\cos \varphi$ distribution. The pattern of $\cos \varphi$ indicates clearly that the (di)jet data are very sensitive to the gluon at $x$ above 0.01 . However, the correlation is weaker for the CT10 gluon PDF (left panel) then for MSTW'08 PDF (right panel), suggesting that the importance of the constraints on the gluon PDF from the jet data is not the same in two fits. In addition, the MSTW'08 $u$-quark PDF shows mild (anti-)correlation with both single-inclusive jet data and dijet data, as can be observed in the right lower panels in Figs. 12 and 13 . No pronounced (anti-)correlations with the $u$-quark PDF or other quark PDFs of physical flavors are observed for the CT10 set, shown in the lower left panels.

The contour plots confirm the expectation that the inclusive jet data play an important role in constraining the gluon PDF. While the constraints are strongest at $x>0.1$, they extend down to $x$ as low as 0.05 for both CT10 and MSTW sets, as can be observed in Figs. 12 and 13 . The gluon PDF is sensitive to constraints from heavy-quark semi-inclusive DIS production at even lower $x$ values, cf. Fig. 11. As the HERA data on heavy-quark DIS production continue to improve, it will play an increasingly important role in constraining the low- $x$ gluon density.

While the patterns of PDF-induced correlations are visually similar for the CT10 and MSTW'08 sets, they are not completely identical. Constraints on the gluon PDF from Tevatron jet production may not be as strong in the CT10 fit as in the MSTW'08 fit, according to Figs. 12 and 13 It remains to be investigated what causes the observed differences between CT10 and MSTW sets in the correlations involving the gluon PDF. Several features are different in these fits, including different heavy-quark DIS schemes, choice of experimental data sets, PDF parametrizations, and radiative contributions in theoretical cross sections. A combination of these effects may indirectly affect the strength of the constraints imposed on the gluon density by the collider jet data.

## 8. PDF CONSTRAINTS FROM ELECTROWEAK VECTOR BOSON PRODUCTION AT THE LHC ${ }^{10}$

#### Abstract

We present a study of the impact of the recent $W$ and $Z$ measurements from ATLAS, CMS and LHCb on parton distribution functions. We show that the NNPDF2.1 NNLO predictions are consistent with all the new data, but that these provide significant further constraints on the light quarks and antiquarks

[^200]at medium and small- $x$. We conclude that these data already have the potential to play a useful role in future global PDF analyses.

### 8.1 LHC measurements sensitive to PDFs

The LHC has already provided an impressive set of measurements which are sensitive to parton distributions: inclusive jet and dijet data [292, 293, 294], electroweak vector boson production [295, 296, 297, 298, 299, 300] (both inclusive and in association with heavy quarks [301]) and direct photon production [302, 303]. The purpose of this contribution is to quantify the impact on PDFs of a subset of these data, the $W$ and $Z$ inclusive production measurements. In this first section we will review the status of LHC data relevant for PDF determination and then in the next section we will study how the $W, Z$ data impact on the NNPDF analysis.

Let's begin this short review of LHC data with electroweak vector boson production. ATLAS has measured the $W$ lepton and $Z$ rapidity distributions using the 2010 data ( $36 \mathrm{pb}^{-1}$ ) and determined the full covariance matrix of correlated experimental uncertainties [295]. This measurement supersedes the original muon asymmetry measurement from $W$ decays [296], for which the covariance matrix was not available. The CMS collaboration has presented a preliminary measurement of the muon asymmetry with 2011 data ( $234 \mathrm{pb}^{-1}$ ) [297] which supersedes the 2010 data [298]. In addition it has presented a measurement of the normalized $Z$ rapidity distribution using 2010 data [299]. In neither of these two measurements has the full covariance matrix been made available. Finally, the LHCb Collaboration has presented preliminary results for the $Z$ rapidity distribution, $W$ lepton asymmetry and W lepton charge ratio using 2010 data [300].

| Data Set | Ref. | $N_{\text {dat }}$ | $\left[\eta_{\text {min }}, \eta_{\text {max }}\right]$ | $\left\langle\sigma_{\text {stat }}\right\rangle(\%)$ | $\left\langle\sigma_{\text {sys }}\right\rangle$ (\%) | $\left\langle\sigma_{\text {norm }}\right\rangle$ (\%) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| ATLAS W,Z $36 \mathrm{pb}^{-1}$ | [295] | 30 | [0, 3.2] | 1.9 | 1.7 | 3.4 |
| ATLAS $W^{+} 36 \mathrm{pb}^{-1}$ | [295] | 11 | [0, 2.4] | 1.4 | 1.3 | 3.4 |
| ATLAS $W^{-} 36 \mathrm{pb}^{-1}$ | [295] | 11 | [0, 2.4] | 1.6 | 1.4 | 3.4 |
| ATLAS $Z 36 \mathrm{pb}^{-1}$ | [295] | 8 | [0, 3.2] | 2.8 | 2.4 | 3.4 |
| CMS $Z$ rapidity $36 \mathrm{pb}^{-1}$ | [299] | 35 | [0, 3.6] | 12.3 | - | 0 |
| CMS muon asymmetry $234 \mathrm{pb}^{-1}$ | [297] | 11 | [0, 2.4] | 1.7 | 3.1 | 0 |
| LHCb $Z$ rapidity $36 \mathrm{pb}^{-1}$ | [300] | 5 | [2, 4.5] | 20 | 5 | 3.4 |
| LHCb $W$ lepton asymmetry $36 \mathrm{pb}^{-1}$ | [300] | 5 | [2, 4.5] | 16 | 21 | 0 |

Table 5: The number of data points, kinematical coverage and average statistical, systematic and normalization percentage uncertainties for each of the experimental LHC $W$ and $Z$ datasets considered in the present analysis. For the CMS $Z$ rapidity data, the systematic uncertainty is included in the statistical uncertainty: there is no normalization uncertainty because these data are normalised to the total cross-section.

The kinematical coverage of each of the various LHC $W$ and $Z$ dataset with the corresponding average experimental uncertainties for each dataset are summarized in Table5. As we can see the LHC electroweak data span a large range in rapidity up to $\eta=4.5$. Each of the three processes considered, $W^{+}, W^{-}$and $Z$ is sensitive to different partonic subprocesses.

There are other LHC datasets potentially sensitive to PDFs. Jet production from the Tevatron has been a very important measurement not only to constrain the gluon at high $x$, but in determining the strong coupling from a global PDF analysis [304, 305]. Similar constraints are expected from the LHC jet data, extended into a wider kinematical range. From the $2010\left(36 \mathrm{pb}^{-1}\right)$ dataset inclusive jet and dijet production has been measured by both CMS [292, 293] and ATLAS [294], however only for ATLAS is the full experimental covariance matrix available. The LHC inclusive jet data can be treated within a global analysis framework using tools like FastNLO or APPLgrid [306]. Since the full NNLO corrections to the inclusive jet production are unknown, jet data in a NNLO analysis can be included only within some approximation: for example with NNLO PDF evolution and coupling running but with NLO matrix elements, or else with NLO matrix elements supplemented with Sudakov estimates of the

NNLO corrections. Another LHC measurement that has the potential to constrain the gluon PDFs is prompt photon production from ATLAS [302] and CMS [303]: its consistency with NLO QCD and their impact on the NNPDF2.1 PDFs will be discussed in detail in Ref. [307].

### 8.2 PDF constraints from LHC $W$ and $Z$

Until recently all available NNPDF sets [308, 309, 261, 310, 311, 312, 313] were based on non-LHC data. NNPDF2.2 [314] was the first set to include LHC data, the $W$ lepton asymmetry from ATLAS and CMS [298, 296]. However now these two datasets are outdated, the first because now the full correlation matrix of the $W$ and $Z$ lepton distributions is available, and the second because data from higher luminosities is also available. So we have chosen to continue to use as our baseline the NNPDF2.1 NNLO set.

We now study the impact of the latest LHC $W$ and $Z$ data on the NNPDF parton distributions. All our theoretical NNLO predictions will be computed with DYNNLO [315] with the same cuts and settings as in the respective measurements. The impact of the new data will be quantified using the reweighting method of Refs. [316, 314] applied to the $N_{\text {rep }}=1000$ replicas of the NNPDF2.1 NNLO set.

To begin with, we have computed the $\chi^{2}$ for each of the datasets in Table 5 for the most recent NNLO PDF sets currently available on LHAPDF: NNPDF2.1, MSTW08 [262], ABKM09 [317], HERAPDF1.5 [318] and JR09 [319]. When available, we use the full experimental covariance matrix. Normalization uncertainties are included using the $t_{0}$ method [320]. This is important specially for the treatment of the ATLAS differential distributions where normalization uncertainties are comparable to the statistical and systematic uncertainties (See Table 5).

The results are summarized in Table 6. For the ATLAS $W$ and $Z$ lepton distributions we show the results both for the total dataset and the individual subsets, where in the latter case cross-correlations between subsets have been neglected. In all cases the theoretical NNLO predictions have been obtained with DYNNLO as discussed above. We can see that none of these PDF sets describes the ATLAS and CMS data perfectly, although NNPDF2.1 and HERAPDF1.5 give probably the best description, while ABKM09 and JR09 are significantly worse. All five sets give a reasonable description of the LHCb data within their large uncertainties.

| Dataset | $\chi^{2}$ NNPDF2.1 | $\chi^{2}$ MSTW08 | $\chi^{2}$ ABKM09 | $\chi^{2}$ JR09 | $\chi^{2}$ HERAPDF1.5 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| ATLAS | 2.7 | 3.6 | 3.6 | 5.0 | 2.0 |
| ATLAS $W^{+} 36 \mathrm{pb}^{-1}$ | 5.7 | 6.5 | 11.4 | 5.4 | 5.3 |
| ATLAS $W^{-} 36 \mathrm{pb}^{-1}$ | 2.5 | 4.1 | 5.4 | 8.0 | 6.4 |
| ATLAS $Z 36 \mathrm{pb}^{-1}$ | 1.8 | 3.7 | 4.2 | 6.5 | 2.9 |
| CMS | 2.0 | 3.0 | 2.8 | 3.6 | 2.8 |
| CMS $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.9 | 2.9 | 2.7 | 2.0 | 3.0 |
| CMS muon asymmetry $234 \mathrm{pb}^{-1}$ | 2.0 | 3.4 | 3.0 | 8.7 | 2.1 |
| LHCb | 0.8 | 0.7 | 1.2 | 0.4 | 0.6 |
| LHCb $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.1 | 0.7 | 0.8 | 0.6 | 0.8 |
| LHCb $W$ lepton asymmetry $36 \mathrm{pb}^{-1}$ | 0.5 | 0.6 | 1.6 | 0.2 | 0.5 |

Table 6: Comparison between LHC $W$ and $Z$ data and the most recent NNLO PDFs. For each PDF set we provide the $\chi^{2} / d o f$ between data and theory predictions, computed using the $t_{0}$-method.

For the ATLAS data, we would like to emphasize the importance of properly taking into account the correlations between datasets, specially the normalization: the description of the individual $W^{+}$, $W^{-}$and $Z$ datasets is always worse than the overall description because of these cross-correlations. For the CMS $Z$ rapidity distribution we find that the fixed order NNLO description seems rather worse than the NLO+LL prediction implemented in POWHEG [299]: the origin of this difference should be investigated in future studies.

We now discuss the impact of these LHC EW data into the NNPDF2.1 NNLO PDFs [313]. In Table 7 we summarize the initial $\chi^{2}$ for each dataset, the $\chi^{2}$ after reweighting, $\chi_{\mathrm{rw}}^{2}$. We find excellent agreement with all the LHC electroweak measurements after reweighting. Some comparisons between data and theory for a selected observables are shown in Fig. 14. From top to bottom we show the comparison with ATLAS, CMS and LHCb data. In each case we have included all the most updated electroweak datasets from each collaboration.

In Table 7 we also show the effective number of replicas left after the reweighting, defined as in Ref. [316] using the Shannon entropy,

$$
\begin{equation*}
N_{\text {eff }} \equiv \exp \left\{\frac{1}{N_{\text {rep }}} \sum_{k=1}^{N_{\text {rep }}} w_{k} \ln \left(N_{\text {rep }} / w_{k}\right)\right\} \tag{76}
\end{equation*}
$$

In each case we have performed the reweighting separately for each of the experimental datasets individually, for the combined datasets from each experiment, and finally with all three combined together.

| Dataset | $\chi^{2}$ | $\chi_{\mathrm{rw}}^{2}$ | $N_{\text {eff }}$ |
| :---: | :---: | :---: | :---: |
| ATLAS | 2.7 | 1.2 | 16 |
| ATLAS $W^{+} 36 \mathrm{pb}^{-1}$ | 5.7 | 1.5 | 17 |
| ATLAS $W^{-} 36 \mathrm{pb}^{-1}$ | 2.5 | 1.0 | 205 |
| ATLAS $Z 36 \mathrm{pb}^{-1}$ | 1.8 | 1.1 | 581 |
| CMS | 2.0 | 1.2 | 56 |
| CMS $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.9 | 1.4 | 223 |
| CMS muon asymmetry $234 \mathrm{pb}^{-1}$ | 2.0 | 0.4 | 200 |
| LHCb | 0.8 | 0.8 | 972 |
| LHCb $Z$ rapidity $36 \mathrm{pb}^{-1}$ | 1.1 | 1.0 | 962 |
| LHCb $W$ lepton asymmetry $36 \mathrm{pb}^{-1}$ | 0.8 | 0.5 | 961 |
| All data combined | 2.1 | 1.2 | 4 |

Table 7: The impact of LHC electroweak measurements on the NNPDF2.1 NNLO PDFs. For each dataset we show the initial $\chi^{2}$, the $\chi^{2}$ after reweighting these particular dataset and the effective number of replicas $N_{\text {eff }}$ in this case. We show both the results for individual datasets as well as for the combined impact of all datasets within the same experiment. All the results have been computed starting with $N_{\text {rep }}=1000$ replicas.

When all the datasets are taken together, the initial $\chi^{2}=2.1$, already quite reasonable is reduced down to $\chi_{\mathrm{rw}}^{2}=1.2$, thus obtaining a very good overall description of all the most recent LHC electroweak data. The effective number of replicas for all combined datasets is only $N_{\text {eff }}=4$ however: from this we conclude that to determine the combined impact of these data on PDFs would require many more replicas (around 25,000 in fact, to obtain reasonable statistical accuracy), or, more practically, a new fit. Note that the fact that the total effective number of replicas for the whole dataset is rather smaller than that of any individual subset confirms their mutual compatibility and the lack of any appreciable tension. Comparing the effective number of replicas for the individual datasets, the most constraining data are the ATLAS $W$ and $Z$ distributions, specially the very precise $W^{+}$data. On the other hand the LHCb data have a rather small impact.

Let us now examine how various PDFs change when new experiments are added. In particular we show in Fig. 15 the NNPDF2.1 NNLO $d\left(x, Q^{2}\right)$ and $\bar{u}\left(x, Q^{2}\right)$ PDFs at $Q^{2}=M_{W}^{2}$ as ratios to the central value before including the new data. As described above, we put together all the data from a given experiment. As can be seen, the ATLAS data give a moderate reduction in PDF uncertainties, and a somewhat softer small- $x$ sea quarks, although the old and new PDFs agree at the 1 -sigma level. For CMS the central values for the old and new PDFs are unchanged with a moderate error reduction at medium- $x$. Finally, for LHCb the PDF uncertainties are almost unaffected, due to the low constraining power of these datasets.

Fig. 14: Comparison between data and theory before and after reweighting for NNPDF2.1 NNLO compared to the various LHC EW datasets considered. From top to bottom we show comparisons with ATLAS ( $W^{+}$lepton $Z$ rapidity distributions), CMS ( $W$ lepton asymmetry and $Z$ rapidity distribution) and LHCb data (same as CMS). For the ATLAS data the error bars include statistical and systematic uncertaintes, but not the normalization uncertainties.

### 8.3 Conclusions

In this contribution we have quantified the impact of the most updated LHC electroweak data on the NNPDF2.1 NNLO parton distributions. NNPDF2.1 provides a reasonable description of all these datasets even before their impact on the PDFs is included. We find that all the datasets are mutually consistent, with no obvious tensions. The PDF uncertainties for the light quarks and antiquarks at medium and small- $x$ are moderately reduced. The ATLAS $W, Z$ data seem to prefer a softer small- $x$ sea. It is clear from our results that the LHC $W$ and $Z$ data should play an important part in any future PDF global fit.

## 9. HEAVY QUARK PRODUCTION IN THE ACOT SCHEME AT NNLO AND $\mathbf{N}^{3} \mathbf{L O}^{11}$

#### Abstract

We extend the ACOT scheme for heavy quark production to NNLO and $\mathrm{N}^{3} \mathrm{LO}$ for the structure functions $F_{2}$ and $F_{L}$ in deep-inelastic scattering (DIS). We use the fully massive ACOT scheme up to NLO, and estimate the dominant heavy quark mass effects at the higher orders using the massless Wilson coefficients together with a generalized slow-rescaling prescription. We present results for $F_{2}$ and $F_{L}$ showing the effect of the higher orders and the contributions from the heavy flavors.

### 9.1 INTRODUCTION

The production of heavy quarks in high energy processes has become an increasingly important subject of study both theoretically and experimentally. The theory of heavy quark production in perturbative Quantum Chromodynamics ( pQCD ) is more challenging than that of light parton (jet) production because of the additional heavy quark mass scale. The correct theory must properly take into account the changing role of the heavy quark over the full kinematic range of the relevant process from the threshold region (where the quark behaves like a typical "heavy particle") to the asymptotic region (where the same quark behaves effectively like a parton, similar to the well known light quarks $\{u, d, s\}$ ).

With the ever-increasing precision of experimental data and the progression of theoretical calculations and parton distribution function (PDF) evolution to next-to-next-to-leading order (NNLO) of QCD, there is a clear need to implement the heavy quark schemes at this order and beyond. The most important case is arguably the heavy quark treatment in inclusive deep-inelastic scattering (DIS) since the very precise HERA data for DIS structure functions and cross sections form the backbone of any modern global analysis of PDFs. Here, the heavy quark structure functions contribute up to $30 \%$ or $40 \%$ to the inclusive structure functions at small momentum fractions $x$. Extending the heavy quark schemes to higher orders is relevant for extracting precision PDFs, and hence for accurate predictions of observables at the LHC.

An example where higher order corrections are particularly important is the longitudinal structure function $F_{L}$ in DIS. The leading order $\mathcal{O}\left(\alpha_{s}^{0}\right)$ contributions to this structure function vanishes for massless quarks due to helicity conservation (Callan-Gross relation). Since the first unsuppressed contribution to $F_{L}$ is at next-to-leading order, the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ corrections are more important than for $F_{2}$. In Fig. 16 we show the preliminary results for the $F_{L}$ measurement from the H1 and ZEUS experiments [321]. In Fig. 17 displays sample Feynman diagrams at the various orders. Producing an accurate

[^201]

Fig. 17: Example Feynman diagrams contributing to DIS heavy quark production (from left): LO $\mathcal{O}\left(\alpha_{S}^{0}\right)$ quark-boson scattering $Q V \rightarrow Q$, NLO $\mathcal{O}\left(\alpha_{S}^{1}\right)$ boson-gluon scattering $g V \rightarrow Q \bar{Q}$, NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ boson-gluon scattering $g V \rightarrow g Q \bar{Q}$ and $\mathrm{N}^{3} \mathrm{LO} \mathcal{O}\left(\alpha_{S}^{3}\right)$ boson-gluon scattering $g V \rightarrow g g Q \bar{Q}$.
prediction for $F_{L}$ is a challenge, particularly in the region of low $Q^{2}$ and small $x$.
In this paper, we will briefly outline the method we used to incorporate the higher order terms, the key elements of the ACOT scheme, and the treatment of the heavy quark masses. We then present results for the $F_{2}$ and $F_{L}$ neutral current DIS structure functions.

### 9.2 THE ACOT SCHEME AND ITS EXTENSION BEYOND NLO

Fig. 18: Comparison of schemes for $F_{2}^{c}$ at $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical.

The ACOT scheme [322, 323] is based upon the factorization theorem for heavy quarks[324]; hence, it is valid at any order of perturbation theory. The factorization proof ensures that the ACOT scheme can be applied throughout the full kinematic regime, and that there is a smooth transition from a massless result $(m=0)$ to the heavy-mass decoupling limit $(m \rightarrow \infty)$.

In the limit where the quark $Q$ of mass $m$ is relatively heavy compared to the characteristic energy scale ( $\mu \lesssim m$ ), the ACOT result naturally reduces to the Fixed-Flavor-Number-Scheme (FFNS). In the FFNS, the heavy quark is treated as being extrinsic to the hadron, and there is no corresponding heavy quark PDF, $f_{Q}(x, \mu)=0$. Conversely, in the limit where the quark mass is relatively light $(\mu \gtrsim m)$, the ACOT result reduces to the $\overline{M S}$ Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS) exactlywithout any finite renormalizations. In this limit, the quark mass $m$ no longer plays any dynamical role; it serves purely as a regulator. This feature is presented in Fig. 18 where we can see that the ACOT scheme precisely matches the results of the FFNS and ZM-VFNS schemes in their respective limits.

Additionally Fig. 18 shows the results obtained within the Simplified-ACOT scheme (SACOT) [325]. The S-ACOT scheme drops the heavy quark mass dependence for the hard-scattering

Fig. 19: $F_{L}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$, (left to right). The three lines show the mass effects via the scaling variable: $n=\{0,1,2\}$, (Red, Green, Blue). We observe the effect of the $n$-scaling is negligible except for small $x$ and $Q$ values.
processes with incoming heavy quarks or with internal on-shell cuts on a heavy quark line. The S-ACOT scheme is not an approximation; it is an exact renormalization scheme, extensible to all orders. Note, the ACOT and S-ACOT results agree throughout the kinematic region.

### 9.21 Beyond NLO

While there is no conceptual difficulty with extending the ACOT scheme beyond NLO, the fully massive Wilson coefficients have yet to be computed ${ }^{[12}$ However massless calculations of NNLO and even $\mathrm{N}^{3} \mathrm{LO}$ for $F_{2}$ and $F_{L}$ structure functions are available $\sqrt{13}$

The question is: can we use these results, together with the knowledge that ACOT reduces to the massless $\overline{M S}$ (ZM-VFNS) for $m \rightarrow 0$, to estimate mass effects at NNLO and $\mathrm{N}^{3} \mathrm{LO}$ ? Obviously we cannot restore the fully massive ACOT result from the massless limit, but we can try to extract the dominant higher order contributions. There are two ways in which mass effects enter the calculation. The first is "dynamically" through the mass dependent Wilson coefficients. The second is "kinematically" via the restricted phase space. Comparisons using the fully massive results at NLO suggest that the kinematic mass effects are dominant, and that much of this dependence can be obtained with a rescaling of the Bjorken $x$ variable. We introduce a generalized rescaling $x \rightarrow x\left[1+(n m / Q)^{2}\right]$ where $n=0$ is the massless result, $n=1$ is the original Barnett[329] rescaling, and $n=2$ is the $\chi$-rescaling [330].

Thus, our strategy is as follows. We use the fully massive ACOT result to NLO [331], and add to this the massless NNLO and $\mathrm{N}^{3} \mathrm{LO}$ contributions using the generalized rescaling prescription. By varying $n$, we can investigate the influence of the kinematic mass in our results. We argue that the massless Wilson coefficients at NNLO and $\mathrm{N}^{3} \mathrm{LO}$, together with the generalized rescaling prescription provide a good approximation of the exact result. At worst, the error is of order $\alpha \alpha_{S}^{2} \times\left[m^{2} / Q^{2}\right]$, and comparative studies at NLO suggest the error is less. ${ }^{[14}$ For example, in Fig. 19 we display the results of $F_{L}$ for $n=\{0,1,2\}$. The effects of the detailed mass dependence is most noticeable for low $Q^{2}$ and small $x$. While the massless scaling result $(n=0)$ does deviate from the other curves, comparing the $n=1$ and $n=2$ curves we observe the details of the mass rescaling are relatively small. While this is not a proof ${ }_{[15}^{15}$ this result does give us confidence that the mass effects are under control.

Fig. 20: Fractional contribution for each quark structure function $F_{2, L}^{i}$ for each flavor $i=\{u, d, s, c, b\}$ for (a) $F_{2}^{i}$ and (b) $F_{L}^{i}$ vs. $Q$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$ (left to right) for the ACOT- $\chi$ scheme.

### 9.3 RESULTS

In Fig. 20 we display the fractional contributions to the structure functions $F_{2}$ and $F_{L}$. At larger values of $x$ and low $Q$, we observe that the heavy flavor contributions are minimal. For example, for $x=10^{-1}$, we see that the $u$-quark structure function $F^{u}$ comprises $\sim 80 \%$ of the total structure function. In contrast, at $x=10^{-5}$ and large $Q$ we see that the contributions of the $u$ and $c$ quarks are comparable (as they couple with a factor 4/9), and the $d$ and $s$ quarks contributions are comparable (as they couple with a factor $1 / 9$ ).

Figure 20 also shows how the $\chi$-rescaling introduces a damping of the heavy quark contributions as we move from large $Q^{2}$ values to smaller values. The $\chi$-rescaling ensures the heavy quarks $(c, b)$ are appropriately suppressed for low $Q^{2}$ scales.

In Fig. 21a we display the results for $F_{2}$ vs. $Q$ computed at various orders; the ratio to the $\mathrm{N}^{3} \mathrm{LO}$ result is displayed in Fig. 21b For large $x$ (c.f. $x=0.1$ ) we find the perturbative calculations are particularly stable. We see that the LO result is within $20 \%$ of the others at small $Q$, and within $5 \%$ at large $Q$. The NLO is within $2 \%$ at small $Q$, and indistinguishable from the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ for $Q$ values above $\sim 10 \mathrm{GeV}$. The NNLO and $\mathrm{N}^{3} \mathrm{LO}$ results are essentially identical throughout the kinematic range. For smaller $x$ values $\left(10^{-3}, 10^{-5}\right)$, the contributions of the higher order terms are slightly larger. Here, the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ coincide for $Q$ values above $\sim 5 \mathrm{GeV}$, but the NLO result can differ by $\sim 5 \%$ for low $Q^{2}$ scales.

In Fig. 22 we display the results for $F_{L}$ vs. $Q$ computed at various orders. In contrast to $F_{2}$, we find that NLO corrections are large; this is expected because the LO corrections to $F_{L}$ (which violate

[^202]
(a) $F_{2}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$ (red, green, blue, cyan) for fixed $x=\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$, (left to right) for ACOT- $\chi$ scheme.

(b) Ratio of $F_{2}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$ (red, green, blue, cyan) compared to $F_{2}$ at $\mathrm{N}^{3} \mathrm{LO}$ for fixed $x=$ $\left\{10^{-1}, 10^{-3}, 10^{-5}\right\}$, (left to right) for ACOT- $\chi$ scheme.

Fig. 21: $F_{2}$ vs. $Q$ at $\left\{\mathrm{LO}, \mathrm{NLO}, \mathrm{NNLO}, \mathrm{N}^{3} \mathrm{LO}\right\}$.
the Callan-Gross relation) are suppressed by $\left(m^{2} / Q^{2}\right)$ compared to the dominant gluon contributions which enter at NLO. Consequently, we observe that the LO result for $F_{L}$ receives large contributions from the higher order terms. Essentially, NLO is the first non-trivial order for $F_{L}$, and the subsequent contributions then converge. For example, at large $x$ (c.f. $x=0.1$ ) for $Q \sim 10 \mathrm{GeV}$ we find the NLO results yields $\sim 70 \%$ of the total, the NNLO is a $\sim 20 \%$ correction, and the $\mathrm{N}^{3} \mathrm{LO}$ is a $\sim 10 \%$ correction. For lower $x$ values $\left(10^{-3}, 10^{-5}\right.$ ) the convergence of the perturbative series improves, and the NLO results is within $\sim 10 \%$ of the $\mathrm{N}^{3} \mathrm{LO}$ result. Curiously, for $x=10^{-5}$ the NNLO and $\mathrm{N}^{3} \mathrm{LO}$ roughly compensate each other so that the NLO and the $\mathrm{N}^{3} \mathrm{LO}$ match quite closely for $Q \gtrsim 2 \mathrm{GeV}$.

### 9.4 CONCLUSIONS

We have computed the $F_{2}$ and $F_{L}$ structure functions in the ACOT scheme at NNLO and $\mathrm{N}^{3} \mathrm{LO}$. The full mass dependence is computed to NLO, and the dominant mass effects for the higher orders are approximated using a generalized rescaling; the details of this rescaling are demonstrated to be small. This allows us to make detailed predictions throughout the kinematic range investigated by HERA, and we obtain a reasonable estimate of the uncertainty due to the higher order mass effects. Together with the precise HERA data, these calculations facilitate accurate determination of the PDFs which are the foundation of the LHC calculations.

## PHENOMENOLOGICAL STUDIES OF OBSERVABLES AND UNCERTAINTIES

## 10. FINITE-WIDTH EFFECTS IN TOP-QUARK PAIR PRODUCTION AND DECAY AT THE LHC ${ }^{16}$

#### Abstract

We investigate finite-top-width effects in top-quark pair production by comparing NLO QCD predictions for $\mathrm{pp} \rightarrow$ WWb $\overline{\mathrm{b}}$ to corresponding $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow$ WWb $\bar{b}$ results in the narrow-top-width limit. Finite-top-width effects, which result from non-resonant and off-shell contributions, are discussed in detail for the case of the inclusive cross section (with experimental cuts) and for selected differential observables in the di-lepton channel.

### 10.1 INTRODUCTION

Top-quark pair production at hadron colliders allows for key tests of the Standard Model and represents an omnipresent background to Higgs-boson and new-physics searches. The very large t $\bar{t}$ samples from the Tevatron and the LHC, and the steadily increasing systematic precision call for a continu-

[^203]ous improvement of theory predictions ${ }^{17}$ In this context, a reliable theoretical description of experimental cuts and exclusive $t \bar{t}$ observables, which depend on details of the $\mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ final state, requires higher-order calculations for top-pair production and decay. The first NLO QCD predictions for $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}+X[335,336$, 337] have been obtained in the narrow-top-width limit, an approximation where the $2 \rightarrow 4$ particle process is factorised into on-shell $t \bar{t}$ production and (anti)top decays, taking into account spin correlations. In this framework, it was shown that NLO QCD effects in top-quark decays have a significant impact on the kinematic properties of final-state leptons and b-jets [335, 336, 337], and play an important role for top-mass measurements at the LHC [338]. More recently, NLO QCD predictions for the complete $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}+X$ process became available [25, 23], which include all effects related to the finite top-quark width, i.e. on- and off-shell intermediate top quarks, non-resonant contributions, and their interference with resonant t $\bar{t}$ production. Besides new evidence for the importance of NLO corrections to $t \bar{t}$ production and decay, these studies provided a first quantitative assessment of finite-width effects in the inclusive cross section. Applying a numerical $\Gamma_{\mathrm{t}} \rightarrow 0$ extrapolation to the $\mathrm{NLO} \mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ predictions, it was found that finite-topwidth contributions to the WWbb cross section at the Tevatron and the LHC ( 7 TeV ) range from 0.2 to 1 percent [25, 23], which is perfectly consistent with the expected order of magnitude ( $\Gamma_{\mathrm{t}} / m_{\mathrm{t}} \simeq 0.9 \%$ ) of finite-top-width effects in inclusive observables.

In this study, we pursue the investigation of finite-top-width effects by means of a tuned comparison of the $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ NLO calculation of Ref. [25] against the narrow-top-width approximation of Ref. [336]. This permits us, for the first time, to investigate $\Gamma_{\mathrm{t}}$-effects in different phenomenologically interesting regions of the $\mathrm{WWb} \overline{\mathrm{b}}$ phase space, where large off-shell and non-resonant contributions cannot be excluded a priori as in the case of inclusive observables.

### 10.2 NARROW-TOP-WIDTH APPROXIMATION AND FINITE-WIDTH EFFECTS

Let us start by recalling the main features of the NLO QCD calculations of $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ in narrow-top-width approximation [336] and $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ with finite-top-width effects [25]. For brevity, we denote them as $t \bar{t}$ and WWbb calculations, respectively. Both calculations implement leptonic W-boson decays in spin-correlated narrow-W-width approximation.

In the narrow-top-width limit of Ref. [336], top-quark resonances are approximated by

$$
\begin{equation*}
\lim _{\Gamma_{\mathrm{t}} / m_{\mathrm{t}} \rightarrow 0} \frac{1}{\left(p_{\mathrm{t}}^{2}-m_{\mathrm{t}}^{2}\right)^{2}+m_{\mathrm{t}}^{2} \Gamma_{\mathrm{t}}^{2}}=\frac{\pi}{m_{\mathrm{t}} \Gamma_{\mathrm{t}}} \delta\left(p_{\mathrm{t}}^{2}-m_{\mathrm{t}}^{2}\right), \tag{77}
\end{equation*}
$$

with delta functions that enforce the on-shell conditions, $p_{\mathrm{t}}^{2}=m_{\mathrm{t}}^{2}$, and are accompanied by $1 / \Gamma_{\mathrm{t}}$ factors. Contributions of $\mathcal{O}\left(\Gamma_{\mathrm{t}} / m_{\mathrm{t}}\right)$, i.e. terms that do not involve two resonant top propagators, are systematically neglected. The differential $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$ cross section is factorised into the $\mathrm{pp} \rightarrow \mathrm{t} \mathrm{\bar{t}}$ cross section times $\mathrm{t} \rightarrow \mathrm{Wb}$ partial decay widths, $\mathrm{d} \sigma=\left(\mathrm{d} \sigma_{\mathrm{t} \overline{\mathrm{t}}} \mathrm{d} \Gamma_{\mathrm{t}} \mathrm{d} \Gamma_{\overline{\mathrm{t}}}\right) / \Gamma_{\mathrm{t}}^{2}$, taking into account top-quark spin correlations. The LO and NLO predictions can be schematically expressed as

$$
\begin{align*}
\mathrm{d} \sigma_{\mathrm{LO}} & =\Gamma_{\mathrm{t}, \mathrm{LO}}^{-2}\left(\mathrm{~d} \sigma_{\mathrm{tt}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{0}\right), \\
\mathrm{d} \sigma_{\mathrm{NLO}} & =\Gamma_{\mathrm{t}, \mathrm{NLO}}^{-2}\left[\left(\mathrm{~d} \sigma_{\mathrm{tt}}^{0}+\mathrm{d} \sigma_{\mathrm{t} \mathfrak{t}}^{1}\right) \mathrm{d} \Gamma_{\mathrm{t}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{0}+\mathrm{d} \sigma_{\mathrm{tt}}^{0}\left(\mathrm{~d} \Gamma_{\mathrm{t}}^{1} \mathrm{~d} \Gamma_{\mathrm{t}}^{0}+\mathrm{d} \Gamma_{\mathrm{t}}^{0} \mathrm{~d} \Gamma_{\mathrm{t}}^{1}\right)\right], \tag{78}
\end{align*}
$$

where the superscripts 0 and 1 indicate tree-level quantities and NLO corrections, respectively. The NLO prediction involves three terms, where the corrections are applied either to $\mathrm{d} \sigma_{\mathrm{tt}}$ or to one of the decays. All ingredients of $\mathrm{d} \sigma_{\mathrm{LO}}$ and $\mathrm{d} \sigma_{\mathrm{NLO}}$ have to be evaluated with input parameters at the corresponding perturbative order. In particular, LO and NLO predictions must be computed using $\Gamma_{\mathrm{t}, \mathrm{LO}}$ and $\Gamma_{\mathrm{t}, \mathrm{NLO}}$ decay widths, as indicated in $\left.\boxed{78}\right|^{18}$ This guarantees that-up to higher-order corrections-the integration over

[^204]the phase space of each top decay in (78) is consistent with the branching fraction
\[

$$
\begin{equation*}
\frac{\int \mathrm{d} \Gamma_{\mathrm{t} \rightarrow \mathrm{~b} l \nu}}{\Gamma_{\mathrm{t}}}=\frac{\Gamma_{\mathrm{t} \rightarrow \mathrm{~b} l \nu}}{\Gamma_{\mathrm{t}}}=\mathrm{BR}(\mathrm{t} \rightarrow \mathrm{~b} l \nu) . \tag{79}
\end{equation*}
$$

\]

In this context, let us point out that a consistent inclusion of finite-W-width corrections-both in the scattering amplitudes and the $\Gamma_{\mathrm{t}}$ input parameters-is expected to lead to doubly-suppressed effects. This is due to the fact that, in the $\Gamma_{\mathrm{t}} \rightarrow 0$ limit, $\mathcal{O}\left(\Gamma_{\mathrm{W}}\right)$ corrections to the numerator and denominator of the branching fraction (79) cancel. Finite-W-width corrections are thus expected to produce very small effects of $\mathcal{O}\left(\frac{\Gamma_{\mathrm{W}} \Gamma_{\mathrm{t}}}{M_{\mathrm{w}} m_{\mathrm{t}}}\right)$ in inclusive observables. This justifies the use of the narrow-W-width approximation in combination with finite-top-width contributions, which is the approach adopted in Ref. [25], although in kinematic regions where finite- $\Gamma_{\mathrm{t}}$ effects become large also finite-W-width corrections [23] might become non-negligible.

The calculation of Ref. [25] provides a full description of $\mathrm{pp} \rightarrow \mathrm{W}^{+} \mathrm{W}^{-} \mathrm{b} \overline{\mathrm{b}}$ at order $\mathcal{O}\left(\alpha_{\mathrm{S}}^{3} \alpha^{2}\right)$. The top-quark width is incorporated into the complex top mass, $\mu_{\mathrm{t}}^{2}=m_{\mathrm{t}}^{2}-\mathrm{i} m_{\mathrm{t}} \Gamma_{\mathrm{t}}$, in the complex-mass scheme [339]. In this way, off-shell-top contributions are consistently described by Breit-Wigner distributions. Besides contributions with two intermediate top resonances, also singly- and non-resonant diagrams are taken into account, including interferences. A few representative tree diagrams are shown in Fig 23. The NLO WWbb̄ predictions involve factorisable corrections to doubly-resonant diagrams, which provide the off-shell extension of NLO corrections in $t \bar{t}$ approximation (78). In addition, there are non-factorisable corrections, where $t \bar{t}$ production and decay parts of the process are connected via exchange of QCD partons, and NLO corrections to singly- and non-resonant topologies. Further technical aspects are discussed in the original publications [336, 25].

Fig. 23: Representative LO diagrams of doubly-resonant (upper line), singly-resonant (first diagram in lower line), and non-resonant type (last two diagrams in lower line).

### 10.3 NUMERICAL RESULTS

### 10.31 Input parameters and setup

In the following we compare $\mathrm{t} \overline{\mathrm{t}}$ and $\mathrm{WWb} \overline{\mathrm{b}}$ predictions for $\mathrm{W}^{+}\left(\rightarrow \nu_{\mathrm{e}} \mathrm{e}^{+}\right) \mathrm{W}^{-}\left(\rightarrow \mu^{-} \bar{\nu}_{\mu}\right) \mathrm{b} \overline{\mathrm{b}}$ production at the Tevatron ( $\mathrm{p} \overline{\mathrm{p}}$ collisions at 1.96 TeV ) and the LHC ( pp collisions at 7 and 14 TeV ). These results are based on the same input parameters and cuts as in Ref. [25]. In NLO (LO) QCD we employ MSTW2008NLO (LO) parton distributions [262] and describe the running of the strong coupling constant $\alpha_{\mathrm{S}}$ with two-loop (one-loop) accuracy, including five active flavours. Contributions induced by the strongly suppressed bottom-quark density are neglected. For the gauge-boson and top-quark masses we use $m_{\mathrm{t}}=172 \mathrm{GeV}, M_{\mathrm{W}}=80.399 \mathrm{GeV}$, and $M_{\mathrm{Z}}=91.1876 \mathrm{GeV}$. The masses of all other quarks, including b-quarks, are neglected. In view of the negligibly small Higgs-mass dependence we adopt the $M_{\mathrm{H}} \rightarrow \infty$ limit, i.e. we omit diagrams involving Higgs bosons. The electroweak couplings are derived

Table 8: Integrated $\nu_{\mathrm{e}} \mathrm{e}^{+} \mu^{-} \bar{\nu}_{\mu} \mathrm{b} \overline{\mathrm{b}}$ cross section in narrow-with approximation $\left(\sigma_{\mathrm{t} \overline{\mathrm{t}}}\right)$ and including finite-top-width effects $\left(\sigma_{\mathrm{WWb}} \overline{\mathrm{b}}\right)$. The relative error of the narrow-width approximation (sixth column) is compared to the prediction of Ref. [25] (seventh column). Factor-two scale variations in $\sigma_{\mathrm{tt}}$ and $\sigma_{\mathrm{Wwb} \overline{\mathrm{b}}}$ are shown as sub- and super-scripts, while statistical errors are given in parenthesis.
from the Fermi constant $G_{\mu}=1.16637 \times 10^{-5} \mathrm{GeV}^{-2}$ in the $G_{\mu}$-scheme, where the sine of the mixing angle and the electromagnetic coupling read $s_{\mathrm{w}}^{2}=1-M_{\mathrm{W}}^{2} / M_{\mathrm{Z}}^{2}$ and $\alpha=\sqrt{2} G_{\mu} M_{\mathrm{W}}^{2} s_{\mathrm{w}}^{2} / \pi$. For consistency, we perform the LO and NLO calculations using the top-quark widths $\Gamma_{\mathrm{t}, \mathrm{LO}}=1.4655 \mathrm{GeV}$ and $\Gamma_{\mathrm{t}, \mathrm{NLO}}=1.3376 \mathrm{GeV}$ [340], respectively. Since the leptonic W-boson decay does not receive NLO QCD corrections we employ the NLO W-boson width $\Gamma_{\mathrm{W}}=2.0997 \mathrm{GeV}$ everywhere.

Final-state quarks and gluons with pseudo-rapidity $|\eta|<5$ are converted into infrared-safe jets using the anti- $k_{\mathrm{T}}$ algorithm [341]. For the Tevatron (LHC) we set the jet-algorithm parameter $R=0.4$ (0.5) and apply the transverse-momentum and pseudo-rapidity cuts $p_{\mathrm{T}, \mathrm{b}-\mathrm{jet}}>20(30) \mathrm{GeV},\left|\eta_{\mathrm{b}-\mathrm{jet}}\right|<2.5$. Moreover, we require a missing transverse momentum of $p_{\mathrm{T}, \mathrm{miss}}>25(20) \mathrm{GeV}$ and charged leptons with $p_{\mathrm{T}, l}>20 \mathrm{GeV}$ and $\left|\eta_{l}\right|<2.5$.

For the renormalisation and factorisation scales we adopt the central value $\mu=m_{\mathrm{t}}$ and study factor-two variations of $\mu=\mu_{\mathrm{ren}}=\mu_{\mathrm{fact}}$, i.e. we compare predictions at $\mu / m_{\mathrm{t}}=0.5,1,2$. The scale variations are applied also to $\Gamma_{\mathrm{t}, \mathrm{NLO}}$, but not to $\Gamma_{\mathrm{W}}$.

### 10.32 Integrated cross section

Results for the integrated $\nu_{\mathrm{e}} \mathrm{e}^{+} \mu^{-} \bar{\nu}_{\mu} \mathrm{b} \overline{\mathrm{b}}$ cross sections and scale uncertainties at the Tevatron and the LHC are reported in Table 8. While the $\sigma_{\text {Wwb币 }}$ results for Tevatron and LHC at 7 TeV correspond to those of Ref. [25] ${ }^{19}$, the ones for LHC at 14 TeV as well as all $\sigma_{\mathrm{t} \bar{\epsilon}}$ predictions are new. Comparing all $\mathrm{WWb} \overline{\mathrm{b}}$ and $t \bar{t}$ predictions we find that finite-top-width effects never exceed one percent, both in LO and NLO. The statistical precision of the calculations permits us to assess the error of the NWA, $\sigma_{\mathrm{t} \overline{\mathrm{t}}} / \sigma_{\mathrm{WWbb}}-1$, with an accuracy of $1-3$ permille. At the Tevatron, the NWA overestimates the WWb $\bar{b}$ cross section by an amount very close to $\Gamma_{\mathrm{t}} / m_{\mathrm{t}} \simeq 0.9 \%$, both in LO and NLO. The error of the NWA at the 7 (14) TeV LHC ranges between 4 and 8 permille. As shown in the last column of Table 8 these finite-width effects are in very good agreement with the results of the $\Gamma_{\mathrm{t}} \rightarrow 0$ extrapolation in Ref. [25]. Similar results can be found also in Ref. [23].

[^205]
### 10.33 Differential distributions

The small finite-width corrections to the integrated cross section demonstrate that-in presence of standard LHC and Tevatron cuts-the NWA provides a fairly accurate description of inclusive WWb̄ production. It is thus interesting to investigate to which extent this conclusion applies to the various phenomenologically important regions of the WWb $\overline{\mathrm{b}}$ phase space. To this end we have compared $\mathrm{t} \overline{\mathrm{t}}$ and WWbb predictions for a few differential observables that are relevant for top-pair production, either as signal or as background to Higgs production or new physics. Note that we refrain from selecting kinematic variables like the top-quark invariant mass or imposing cuts of type $M_{\mathrm{Wb}}>200 \mathrm{GeV}$, which would lead to obvious enhancements of non-resonant contributions.

In Figs. 2427 we present predictions for some invariant-mass and transverse-momentum distributions, restricting ourselves to the case of the 7 TeV LHC. For each observable we display $t \bar{t}$ (dashed curves) and $\mathrm{WWb} \overline{\mathrm{b}}$ (solid curves) results in LO (blue) and NLO (red) approximation. Absolute predictions (left plots) are complemented by the ratios $\left(\mathrm{d} \sigma_{\mathrm{LO}}-\mathrm{d} \sigma_{\mathrm{NLO}}\right) / \mathrm{d} \sigma_{\mathrm{NLO}}$ (upper right plots) and $\left(\mathrm{d} \sigma_{\mathrm{t} \bar{t}}-\mathrm{d} \sigma_{\mathrm{WWb} \overline{\mathrm{b}}}\right) / \mathrm{d} \sigma_{\mathrm{WWb}}$ (lower right plots), which indicate the relative error of LO and narrow-width approximations w.r.t. the best predictions, i.e. NLO and WWb $\overline{\mathrm{b}}$.

Fig. 24: Distribution in the transverse momentum of the harder b-jet at the 7 TeV LHC: LO (blue) and NLO (red) predictions in narrow-width approximation ( $\mathrm{t} \overline{\mathrm{t}}$, dashed) and including finite-top-width effects (WWb $\overline{\mathrm{b}}$, solid). Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrow-width (lower-right) approximations w.r.t. NLO and WWb̄ predictions, respectively.

The transverse-momentum distribution of the harder b-jet is shown in Fig. 24 In the range below 200 GeV , which contains the bulk of the cross section, the NLO and finite-width corrections behave similarly as for the integrated cross section: LO predictions deviate from NLO ones by about $-20 \%$, and the error of the NWA ranges between +1 and $-4 \%$. Finite-width effects tend to increase with $p_{\mathrm{T}}$ and reach the $10 \%$ level around 300 GeV . Within the entire $p_{\mathrm{T}}$ range the LO/NLO ratios resulting from the $t \bar{t}$ and WWbb̄ calculations are almost equal. Equivalently, we find the same $\mathrm{d} \sigma_{\mathrm{tt}} / \mathrm{d} \sigma_{\mathrm{WWbb}}$ ratios in LO and NLO.

Fig. 25: Distribution in the transverse momentum of the b̄ di-jet system at the 7 TeV LHC: LO (blue) and NLO (red) predictions in narrow-width approximation ( $\mathrm{t} \overline{\mathrm{t}}$, dashed) and including finite-top-width effects (WWb百, solid). Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrow-width (lower-right) approximations w.r.t. NLO and WWb̄ predictions, respectively.

In Fig. 25 we show the transverse-momentum distribution of the $b \bar{b}$ di-jet system. This kinematic variable plays an important role in boosted-Higgs searches with a large t $\bar{t}$ background. In particular, the strategy proposed in Ref. [342] to extract a pp $\rightarrow \mathrm{H}(\rightarrow \mathrm{b} \overline{\mathrm{b}}) \mathrm{W}$ signal at the LHC is based on the selection of boosted $\mathrm{H} \rightarrow \mathrm{b} \overline{\mathrm{b}}$ candidates with $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}}>200 \mathrm{GeV}$, which permits to reduce $\mathrm{t} \overline{\mathrm{t}}$ contamination (and other backgrounds) in a very efficient way. As can be seen from Fig. 25, the suppression of $t \bar{t}$ production is indeed particularly strong at $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}} \gtrsim 150 \mathrm{GeV}$. This is due to kinematic constraints that characterise the LO and narrow-width approximations: in order to acquire $p_{\mathrm{T}, \mathrm{b}}>\left(m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2}\right) /\left(2 m_{\mathrm{t}}\right) \simeq 65 \mathrm{GeV}$ b-quarks need to be boosted via the $p_{\mathrm{T}}$ of their parent (anti)top quarks, and the fact that top and antitop quarks have opposite transverse momenta (at LO) makes it difficult to generate a b $\bar{b}$ system with high $p_{\mathrm{T}}$. The NLO and finite-width corrections undergo less stringent kinematic restrictions, resulting into a significant enhancement of $W W b \overline{\mathrm{~b}}$ events at large $p_{\mathrm{T}, \mathrm{b}}$. This is clearly reflected in the differences between the various curves in the left plot of Fig. 25. The most pronounced effect comes from the NLO corrections, where the $t \bar{t}$ system can acquire large transverse momentum by recoiling against extra jet radiation. As indicated by the right-upper plot, the NLO correction represents $50-80 \%$ of the cross section at high $p_{\mathrm{T}}$, corresponding to a huge $K$-factor of $2-5$. Finite-width effects (lower-right plot) lead to a further significant, although less dramatic, enhancement; for example, non-resonant topologies can lead to direct b $\overline{\mathrm{b}}$ production via high- $p_{\mathrm{T}}$ gluons that recoil against $\mathrm{W}^{+} \mathrm{W}^{-}$pairs. For $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}}>200 \mathrm{GeV}$, we find that $20-40 \%$ of the LO WWbb cross section is due to finite-width contributions, while this fraction decreases to $7-15 \%$ at NLO. This reduction is related to the dominance of the jet-emission contribution, which we expect to be rather well described by the NWA. On the other hand, an optimal suppression of the $t \bar{t}$ background will require a very tight jet-veto [342], and in this case we expect finite-width corrections to the NLO t̄ predictions to be as large as in LO.

The distribution in the missing transverse momentum, i.e. the vector sum of the $\nu_{e}$ and $\bar{\nu}_{\mu}$ trans-

Fig. 26: Distribution in the missing transverse momentum at the 7 TeV LHC: LO (blue) and NLO (red) predictions in narrow-width approximation ( $\mathrm{t} \overline{\mathrm{t}}$, dashed) and including finite-top-width effects (WWb $\overline{\mathrm{b}}$, solid). Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrowwidth (lower-right) approximations w.r.t. NLO and WWb̄̄ predictions, respectively.
verse momenta, is displayed in Fig. 26. This distribution is relevant for new-physics searches based on missing transverse energy plus jets and leptons. Its tail features a qualitatively similar behaviour as in the case of $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}}$, due to analogous kinematic constraints. However, in the case of $p_{\mathrm{T}, \mathrm{miss}}$ the corrections are less pronounced: the NLO correction does not exceed $40-50 \%$ of the full prediction, and finite-width contributions stay below roughly $10 \%$.

Figure 27 displays the distribution in the invariant mass of the positron and a b-jet, i.e. the visible products of a top-quark decay. More precisely, assuming that the charge of the b-jet is not known, the $\mathrm{e}^{+} \mathrm{b}$ pair is built by selecting the b-jet that yields the smallest invariant mass ${ }^{20}$ In narrow-width and LO approximation this kinematic quantity is characterised by a sharp upper bound, $M_{\mathrm{e}^{+} \mathrm{b}}^{2}<m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2} \simeq$ $(152 \mathrm{GeV})^{2}$, which renders it very sensitive to the top-quark mass. The value of $m_{\mathrm{t}}$ can be extracted with high precision using, for instance, the invariant-mass distribution of a positron and a $J / \psi$ from a $B$ meson decay [343, 338], an observable that is closely related to $M_{\mathrm{e}^{+} \mathrm{b}}$. In the region below the kinematic bound, the NLO corrections to $M_{\mathrm{e}^{+} \mathrm{b}}$ vary between $5-30 \%$, and the impact of the NLO shape distortion on a precision $m_{\mathrm{t}}$-measurement is certainly significant. For $M_{\mathrm{e}^{+} \mathrm{b}}<150 \mathrm{GeV}$, the NWA agrees with the WWb $\bar{b}$ predictions at the $1 \%$ level or better. In contrast, in the vicinity of the kinematic bound the impact of finite-width (and NLO) corrections becomes clearly more important, giving rise to a tail that extends above $M_{\mathrm{e}^{+} \mathrm{b}}^{2}=m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2}$. The resulting contribution to the total cross section is fairly small, but the impact of such finite-width effects on the top-mass measurement might be non-negligible, given the high $m_{\mathrm{t}}$-sensitivity of the $M_{\mathrm{e}^{+} \mathrm{b}}^{2} \simeq m_{\mathrm{t}}^{2}-M_{\mathrm{W}}^{2}$ region.

[^206]

Fig. 27: Distribution in the invariant mass of the positron-b-jet system (as defined in the text) at the 7 TeV LHC: LO (blue) and NLO (red) predictions in narrow-width approximation ( $\mathrm{t} \overline{\mathrm{t}}$, dashed) and including finite-top-width effects (WWb $\bar{b}$, solid). Plotted are absolute predictions (left) and relative deviations of LO (upper-right) and narrow-width (lower-right) approximations w.r.t. NLO and WWb $\bar{b}$ predictions, respectively.

### 10.4 CONCLUSIONS

Based on recent NLO QCD calculations, we have presented a systematic comparison of top-pair production and decay in narrow-top-width approximation, $\mathrm{pp} \rightarrow \mathrm{t} \overline{\mathrm{t}} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$, against the complete $\mathrm{pp} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$ process, which involves finite-top-width effects of non-resonant and off-shell type.

At the Tevatron and the LHC ( 7 and 14 TeV ), finite-top-width contributions to the integrated cross section (in the di-lepton channel) turn out not to exceed one percent. This confirms previous estimates based on the $\Gamma_{\mathrm{t}} \rightarrow 0$ extrapolation of $\mathrm{pp} \rightarrow \mathrm{WWb} \overline{\mathrm{b}}$ predictions. At the 7 TeV LHC, we also investigated differential observables that are relevant either for top-pair production as a signal or as a background in Higgs or new-physics searches. In the case of the b-jet transverse momentum and $p_{\mathrm{T}, \mathrm{miss}}$ distributions, finite-width effects remain very small over a large kinematic range and reach the $10 \%$ level only around 300 GeV . In contrast, the $p_{\mathrm{T}}$-distribution of the b $\overline{\mathrm{b}}$ di-jet system receives $\Gamma_{\mathrm{t}}$-corrections beyond 20-30\% for $p_{\mathrm{T}, \mathrm{b} \overline{\mathrm{b}}} \gtrsim 200 \mathrm{GeV}$, a kinematic region that plays an important role in $\mathrm{pp} \rightarrow \mathrm{H}(\rightarrow \mathrm{b} \overline{\mathrm{b}}) \mathrm{W}$ searches based on boosted $\mathrm{H} \rightarrow \mathrm{b} \overline{\mathrm{b}}$ candidates. For the lepton-b-jet invariant-mass distribution-an observable that provides high sensitivity to the top-quark mass-finite-width corrections do not exceed one percent in the range that contains the bulk of the cross section, but become more sizable in the region of highest $m_{\mathrm{t}}$-sensitivity. This motivates more detailed studies of finite-width effects in the context of high-precision $m_{\mathrm{t}}$-measurements at the LHC. The results of this investigation of finite-width effects in t̄̄ production give also useful insights into possible limitations of treating associated top-pair production processes in the narrow-width approximation, since NLO calculations for $\mathrm{pp} \rightarrow \mathrm{WWb} \mathrm{\bar{b}}$ and similar reactions will not be available too soon.

M.S. is grateful for support from the Director's Fellowship of Argonne National Laboratory under DOE grant DE-AC02-06CD11357. The presented results of the calculation described in Ref. [336] were performed on the Homewood High Performance Cluster of Johns Hopkins University supported by grant NSF-OCI-108849.

## 11. Strong and Smooth Ordering in Antenna Showers ${ }^{21}$

#### Abstract

We comment on strong and smooth ordering in antenna showers, and extend the definition of smooth ordering to include the case of $g \rightarrow q \bar{q}$ splittings. We define three observables in hadronic $Z$ decays that can be used to probe the subleading properties of shower models.

### 11.1 INTRODUCTION

Traditional parton showers are based on collinear factorization, and the shower evolution proceeds via $1 \rightarrow 2$ branchings, on which additional constraints have to be imposed to ensure momentum conservation and QCD coherence (see [344]). Antenna showers are instead based on momentum-conserving and intrinsically coherent $2 \rightarrow 3$ branchings, as pioneered by Ariadne [345, 346]. This note concerns the antenna shower implementation in the Vincia code [347], a plug-in to Pythia 8 [348], though we emphasize that the notion of smooth ordering could be applied to other shower types as well.

In leading-logarithmic (LL) antenna showers, the fundamental step is a Lorentz-invariant $2 \rightarrow 3$ branching process by which two on-shell "parent" partons are replaced by three on-shell "daughter" partons. This $2 \rightarrow 3$ process makes use of three ingredients [349]:

1. An antenna function that captures the leading tree-level singularities of QCD matrix elements.
2. An antenna phase space - an exact, momentum-conserving and Lorentz-invariant factorization of the pre- and post-branching phase spaces.
3. A kinematics map, specifying how the global orientation of the post-branching momenta are related to the pre-branching ones.
Antenna showers come in two varieties: global and sector. The two kinds differ in how the collinear singularities of gluons are partitioned among neighboring antennae, see [350, 351]. Here, we shall only be concerned with the global type [345, 352, 347, 349], in which the gluon-collinear singularity is partitioned such that two neigbouring antennae each contain "half" of it; their sum reproduces the full singularity.

If each antenna in a global shower is allowed to emit in its full phase space, the resulting shower evolution amounts to an incoherent addition of independently radiating dipoles. This tends to overcount regions in which several dipole terms contribute at the same level, i.e., in regions where dipole-dipole interference effects (or, equivalently, multipole effects) are important [353, 351]. The situation is analogous to, though less severe than, the case of traditional parton showers with virtuality-ordering [354], which represent an incoherent addition of independent monopoles. In parton/monopole showers, multiparton interference effects for soft radiation can be taken into account by the requirement of angular ordering [355], while in dipole/antenna showers, typically a measure of transverse momentum is used, such as

$$
\begin{equation*}
p_{\perp A}^{2}=\frac{s_{i j} s_{j k}}{s_{I K}} \tag{80}
\end{equation*}
$$

for a branching $I K \rightarrow i j k$, with $s_{a b} \equiv 2 p_{a} \cdot p_{b}=\left(p_{a}+p_{b}\right)^{2}$ for massless partons. Some alternative possibilities are compared in [349].

[^207]
### 11.2 STRONG AND SMOOTH ORDERING

In a strongly-ordered shower, each consecutive branching is required to occur at a lower scale in the evolution variable than that of the previous one: $Q_{n+1}<Q_{n}$. This can be represented as a step function in the evolution variable, multiplying the branching kernels. In a smoothly-ordered shower [349], the step function is replaced by a smooth dampening factor designed to leave the soft and collinear limits unchanged while suppressing radiation at scales above $\sim Q_{n}$. Specifically, for evolution in $p_{\perp}$, we replace the strong-ordering condition as follows,

$$
\begin{equation*}
\Theta\left(\hat{p}_{\perp}-p_{\perp}\right) P_{L L} \rightarrow P_{i m p} P_{L L} \equiv \frac{\hat{p}_{\perp}^{2}}{\hat{p}_{\perp}^{2}+p_{\perp}^{2}} P_{L L} \tag{81}
\end{equation*}
$$

where $\hat{p}_{\perp}$ characterizes the scale of the previous branching ${ }^{22}, p_{\perp}$ is the scale of the emission under consideration, and $P_{L L}$ is an ordinary LL shower kernel, which in our case is represented by a gluonemission antenna function. (We return to the case of $g \rightarrow q \bar{q}$ below.)

Thus, for $p_{\perp} \ll \hat{p}_{\perp}$ (the strongly-ordered limit) the smooth-ordering factor $P_{\text {imp }}$ tends to unity, while for $p_{\perp} \sim \hat{p}_{\perp}$ (the ordering threshold) it tends to $1 / 2$, and finally for $p_{\perp} \gg \hat{p}_{\perp}$ (highly unordered), it tends to zero $\propto \hat{p}_{\perp}^{2} / p_{\perp}^{2}$. Note that, since $P_{L L}$ is likewise $\propto 1 / p_{\perp}^{2}$, the net effect of the suppression factor is to modify the behavior of the splitting kernel from $1 / p_{\perp}^{2}$ in the strongly-ordered limits to $1 / p_{\perp}^{4}$ for highly unordered branchings, similar to what has been studied for initial-state parton showers in [356]; above the strong-ordering threshold, the branching probability is explicitly suppressed beyond LL.

For a rigourous interpretation of the $P_{\text {imp }}$ factor one would have to analyze the $2 \rightarrow 4$ antennae [79] and check that the combination of two $2 \rightarrow 3$ antennae times this factor does indeed reproduce subleading aspects of the full $2 \rightarrow 4$ function. In the absence of such a study, one may still physically interpret its purpose in the following way: the LL antenna functions are derived assuming the outgoing partons/jets to be massless. This is a good approximation if the virtuality that they can acquire (through further showering) is restricted by the strong-ordering threshold. When allowing unordered branchings, however, the corresponding Feynman diagrams contain highly off-shell propagators, which the $P_{\text {imp }}$ factor attempts to mimic by introducing an "effective mass" in the denominator of eq. 81.

For gluon emissions, it was shown in [349] that the smooth-ordering condition does lead to a systematic improvement in the shower. Since it simultaneously guarantees a complete phase-space coverage (contrary to the case for strong ordering [357, 349]), it is the default option in Vincia.

Antenna showers including $g \rightarrow q \bar{q}$ splittings were studied in [358], in which evolution in $m_{q \bar{q}}^{2}$ was introduced for such branchings. This is based on the observation [359] that the scale controlling the divergences of $g \rightarrow q \bar{q}$ splittings is the invariant mass of the pair, not its $p_{\perp}$. By analogy with the physical interpretation given to the $P_{\text {imp }}$ factor for gluon emissions above, it therefore seems well-motivated to study a "generalized" $P_{\text {imp }}$ factor where each scale depends on whether we are dealing with a gluon or a quark:

$$
\begin{equation*}
P_{i m p}=\frac{\hat{Q}_{E}^{2}}{\hat{Q}_{E}^{2}+Q_{E}^{2}}, \tag{82}
\end{equation*}
$$

where $Q_{E}$ is the evolution variable: $p_{\perp}$ for gluons and invariant mass for quark-antiquark pairs.
We can assess the improvement that this produces in the shower by plotting the ratio of the shower approximation vs. the LO matrix element for $Z \rightarrow q \bar{q}^{\prime} q^{\prime} \bar{q}$ and $Z \rightarrow q \bar{q}^{\prime} q^{\prime} g \bar{q}$. This is shown in fig. 28, where the histograms represent the distribution of $\log _{10}(\mathrm{PS} / \mathrm{ME})$ in a flat phase-space scan, normalized to unity (i.e., the same type of distributions that were shown in [349, 358, 351]). Points to the left of zero are undercounted by the shower approximation, while points to the right are overcounted. Although the agreement is by no means perfect, we do observe a slight improvement in the shower approximation

[^208]

Fig. 28: Comparison between generalized $\tilde{P}_{i m p}$ and "old" $P_{i m p}$ factor in the global shower approximations to LO matrix elements, for processes involving a $g \rightarrow q \bar{q}$ splitting. Left: $Z \rightarrow q \bar{q}^{\prime} q^{\prime} \bar{q}$. Right: $Z \rightarrow q \bar{q}^{\prime} q^{\prime} q \bar{q}$. In both cases, GKS matching to the LO matrix element for the preceding multiplicity ( $Z \rightarrow 3$ and $Z \rightarrow 4$, respectively) has been included, and the Ariadne factor was applied to $g \rightarrow q \bar{q}$ splittings.
when the $P_{i m p}$ factor is defined in terms of $Q_{E}$ (solid black histogram), as compared to the definition used previously (dashed histogram). Note that we used the so-called Ariadne factor in the shower approximation for all cases, see [358], and that the distributions were made including GKS matching to the preceding multiplicities [349].

### 11.3 SENSITIVE OBSERVABLES IN HADRONIC Z DECAYS

The properties of shower and matrix-element matching algorithms are coming under increasing scrutiny, not least due to the desire of achieving reliable descriptions of jet production and jet properties, such as jet substructure, for signal and background estimates at the LHC.

For final-state radiation, i.e., jet broadening and jet splitting, hadronic $Z$ decays are the main reference, with a large set of events shapes and jet resolutions/rates being used to constrain and tune shower algorithms (see, e.g., [360, 344]). However, in the logarithmically dominated regions, these observables are typically dominated by leading logs, and are well described by all coherent and reasonably well-tuned shower algorithms on the market. In order to probe the subleading properties in a more dedicated way, we have found the following three simple observables useful, each designed to isolate a specific aspect.

We consider hadronic $Z$ events (photon ISR is switched off, and matching beyond 3 jets is switched off for the strongly-ordered showers) and use the $k_{T}$ clustering algorithm [361] to cluster all events back to two jets. The $3 \rightarrow 2$ clustering scale is denoted $y_{23}=k_{T 3}^{2} / m_{Z}^{2}$, and so on for higher jet numbers. We require all $y_{i j}$ entering in the observables below to be greater than 0.005 , to remove contamination from $B$ decays and lower scales. Since the original topology contains two jets, we also keep track of which "side" each clustering happens on. Strong ordering corresponds to $y_{23} \gg y_{34} \gg \ldots$, while events with, e.g., $y_{34} \sim y_{23}$ should be more sensitive to the ordering condition and to the effective $1 \rightarrow 3$ spliting kernels.

The first observable is thus simply the ratio $y_{34} / y_{23}$, in events where the $4 \rightarrow 3$ and $3 \rightarrow 2$ clusterings happen in the same jet. This distribution is illustrated in the left-hand pane of fig. 29, with logarithmic axes. Vertical error bars indicate the expected $1 \sigma$ statistical error with 400 k hadronic $Z$ decays. Since the $k_{T}$ algorithm allows for unordered clustering scales, the distribution extends beyond $\xi_{24}=\ln \left(y_{34} / y_{24}\right)=0$. Default Pythia (thick solid line) is compared to three different Vincia settings: smooth (thin solid) and strong (dashed) ordering in $p_{\perp}$ and strong ordering in dipole virtuality, $m_{D}$ (dotted). Note here that ordering in the variables $p_{\perp}$ or $m_{D}$ does not directly imply ordering in $k_{T}$.

Fig. 29: Left: $\xi_{24}=\ln \left(y_{34} / y_{23}\right)$ in "same-side" 4-jet events. Right: Ratio of jet masses, $m_{L}^{2} / m_{H}^{2}$, in "compressed" 4-jet events. Error bars indicate expected $1 \sigma$ statistical errors with 400 k hadronic $Z$ decays.

The fact that the $P_{\text {imp }}$ factor also suppresses branchings slightly below the strong-ordering threshold is manifest in the thin solid line lying below the other ones in the region just below zero, which should be statistically significant with a sample size of $\sim 0.5 \mathrm{M}$ events. Note as well that these distributions become indistinguishable if one does not make the requirement of sameside clustering (not shown), presumably since opposite-side collinear splittings then dominate.

A related observable is shown in the right-hand pane of fig. 29. To force a "compressed" scale hierarchy, we impose the cut $y_{34}>0.5 y_{23}$, and plot the ratio $M_{L}^{2} / M_{H}^{2}$ of the masses of the jets at the end of the clustering. With four partons at LO, the light jet mass is zero if both the $4 \rightarrow 3$ and $3 \rightarrow 2$ clusterings happen in the same jet, while it is non-zero otherwise. Thus, the region close to zero isolates events with a $1 \rightarrow 3$ splitting occurring in one of the jets, while the region above $\sim 0.25$ is dominated by opposite-side $1 \rightarrow 2$ splittings. In Pythia and in mass-ordered Vincia, the peak at zero is stronger than in the $p_{\perp}$-ordered Vincia cases, while there is no difference between strong and smooth ordering in this variable. It thus serves as a useful complement to $\xi_{24}$.

Finally, in fig. 30, we consider 4-jet events in which the second and third jets (ordered in energy) are nearly collinear and back-to-back to the hardest jet. Specifically, we impose the cuts $\theta_{12}>120^{\circ}$, $\theta_{13}>120^{\circ}$, and $\theta_{23}<30^{\circ}$. We then plot the angle of the fourth (softest) jet with respect to the hardest one. Again the strong and smooth ordering options are indistinguishable, but interesting differences with respect to both Pythia and mass-ordered Vincia are visible. Mass-ordering tends to produce a broader distribution, with more radiation at right angles to the hardest jet (consistent with mass-ordering prioritizing wide-angle emissions over collinear ones), and the $p_{\perp}$-ordered Vincia showers exhibit a stronger collinear peak than the Pythia one. A similar observable was proposed in [362].

We conclude that, if all three observables could be measured with an accuracy of $\sim 5-10 \%$ or better, a useful and multi-dimensional constraint on the subleading shower aspects would be obtained, including sensitivity both to the type and shape of the ordering condition, and to the form of the effective $1 \rightarrow 3$ probabilities produced by the shower. We emphasize that we have here restricted our attention to shower models that are virtually indistinguishable on all other observables we have considered.

## ACKNOWLEDGEMENTS

We thank D. Kosower, S. Plätzer, and G. Salam for discussions on definitions of sensitive observables. This work was supported by the European Commission (HPRN-CT- 200-00148), FPA2009-09017 (DGI

## 12. PERTURBATIVE UNCERTAINTIES AND RESUMMATION FOR EXCLUSIVE JET CROSS SECTIONS ${ }^{23}$

### 12.1 Introduction

In this writeup we discuss predictions for exclusive jet cross sections, which have a particular number of jets in the final state. There are several motivations for analyzing events by dividing the data into exclusive jet bins, in particular when the relevant backgrounds strongly depend on the number of jets, or when the sensitivity can be increased by optimizing the analysis for the individual jet bins. As our primary example we will consider the Higgs analysis in the $H \rightarrow W W$ channel, which is performed separately in exclusive 0 -jet, 1 -jet, and 2 -jet bins [363, 364, 365]. Other examples are vector-boson fusion analyses, which are typically performed in the exclusive 2-jet channel, boosted $H \rightarrow b \bar{b}$ analyses that include a veto on additional jets, as well as $H \rightarrow \tau \tau$ and $H \rightarrow \gamma \gamma$ which benefit from improved sensitivity when the Higgs recoils against a jet. The importance of the Higgs +1 jet channel in $H \rightarrow \tau \tau$ and $H \rightarrow W W^{*}$ was demonstrated explicitly in Refs. [366, 367]. Another motivation for studying exclusive jet bins are the $W+$ jets channels, which are important backgrounds for new physics searches. We will use the notation $\sigma_{N}$ for an exclusive $N$-jet cross section (with exactly $N$ jets), and the notation $\sigma_{\geq N}$ for an inclusive $N$-jet cross section (with $N$ or more jets).

To explore the implications of the jet bin restrictions, consider a simple example where we divide the total cross section, $\sigma_{\text {total }}$, into an exclusive 0 -jet bin, $\sigma_{0}\left(p^{\mathrm{cut}}\right)$, and the remaining inclusive $(\geq 1)$-jet bin, $\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right)$,

$$
\begin{equation*}
\sigma_{\mathrm{total}}=\int_{0}^{p^{\mathrm{cut}}} d p \frac{d \sigma}{d p}+\int_{p^{\mathrm{cut}}} d p \frac{d \sigma}{d p} \equiv \sigma_{0}\left(p^{\mathrm{cut}}\right)+\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right) . \tag{83}
\end{equation*}
$$

Here $p$ denotes the kinematic variable which is used to divide up the cross section into jet bins. A typical choice is $p \equiv p_{T}^{\text {jet }}$, defined by the largest $p_{T}$ of any jet in the event, such that $\sigma_{0}\left(p_{T}^{\text {cut }}\right)$ only contains events with jets having $p_{T} \leq p_{T}^{\mathrm{cut}}$, and $\sigma_{\geq 1}\left(p_{T}^{\mathrm{cut}}\right)$ contains events with at least one jet with $p_{T} \geq p_{T}^{\text {cut }}$. By defining $\sigma_{0}\left(p_{T}^{\text {cut }}\right)$ and $\sigma_{\geq 1}\left(p_{T}^{\text {cut }}\right)$ one has divided up initial-state radiation from the

[^209]colliding hard partons and soft radiation in the event. This restriction on additional emissions changes the coefficients appearing in the $\alpha_{s}$ expansion and leads to the appearance of double and single logarithms of the form $\alpha_{s} \ln ^{2}\left(p^{\text {cut }} / Q\right)$ and $\alpha_{s} \ln \left(p^{\text {cut }} / Q\right)$ (with higher powers $\alpha_{s}^{n} \ln ^{m \leq 2 n}\left(p^{\text {cut }} / Q\right)$ appearing at higher orders in perturbation theory). Here $Q$ is the hard scale of the process, such as $Q=m_{H}$ for Higgs production, and most often we have $p^{\text {cut }} \ll Q$. These changes to the perturbation series can modify the convergence of fixed-order results and make it prudent to consider resummed cross section predictions that include an all-orders resummation of the large logarithms. For $N$ jets the analog of Eq. 833) is $\sigma_{\geq N}=\sigma_{N}\left(p_{N+1}^{\mathrm{cut}}\right)+\sigma_{\geq N+1}\left(p_{N+1}^{\mathrm{cut}}\right)$ and the same discussion applies regarding the large logarithms of $p_{N}^{\text {cut }}$ that are not present in $\sigma_{\geq N}$, but are present in each of $\sigma_{N}$ and $\sigma_{\geq N+1}$.

The definition of $\sigma_{0}\left(p^{\mathrm{cut}}\right)$ may include dependence on rapidity and on the grouping of particles. For a jet-based variable like $p_{T}^{\text {jet }}$ the former is induced by only considering jets within the rapidity range $\left|\eta^{\text {jet }}\right| \leq \eta^{\text {cut }}$, and the latter enters through the choice of jet algorithm. These dependencies make theoretical predictions more difficult. In Higgs production via gluon fusion the cross section is known to next-to-next-to-leading order (NNLO) [208, 368, 207, 209, 210, 211, 369, 370], and NNLO results including full kinematic information are available through FeHiP [214, 371] and HNNLO [90, 216] (as well as by combining the total NNLO cross section with MCFM [157, 372] for some distributions). When the measurements are performed in exclusive jet bins, the perturbative uncertainties in the theoretical predictions must also be evaluated separately for each individual jet bin [373]. When combining channels with different jet multiplicities, the correlations between the theoretical uncertainties can be significant and must be taken into account [26]. The perturbative predictions can be made more precise by including a resummation of large $p^{\text {cut }}$ dependent logarithms on top of the fixed-order predictions. At the leading logarithmic level this can be achieved with standard parton shower Monte Carlo programs, regardless of the precise definition of $p^{\mathrm{cut}}$. So far a next-to-next-to-leading logarithmic (NNLL) resummed result for a jet-veto variable only exists for beam thrust [374], $\mathcal{T}_{\mathrm{cm}}$, which is a rapidity weighted $E_{T}$-like inclusive variable. The definitions of the jet-veto variables we will use are

$$
\begin{equation*}
p_{T}^{\text {jet }}=\left|\sum_{k \in \mathrm{jet}} \vec{p}_{T k}\right|, \quad \quad \mathcal{T}_{\mathrm{cm}}=\sum_{k}\left|\vec{p}_{T k}\right| e^{-\left|\eta_{k}\right|}=\sum_{k}\left(E_{k}-\left|p_{k}^{z}\right|\right) . \tag{84}
\end{equation*}
$$

For $p_{T}^{\text {jet }}$ our jets are defined using anti- $k_{T}$ [341] with $R=0.5$, and we consider jets that satisfy a rapidity cut $|\eta| \leq \eta^{\text {cut }}$. For $\mathcal{T}_{\text {cm }}$ the sum is over all objects in the final state except the Higgs decay products, and can in principle be considered over particles, topo-clusters, or jets with a small $R$ parameter. In all our results we consistently use MSTW2008 NNLO PDFs [262].

In this writeup we will explore fixed NNLO and resummed NNLL+NNLO predictions for $H+$ 0 -jet cross sections and compare various methods for evaluating the uncertainty as a function of cuts on $p_{T}^{\text {jet }}$ and $\mathcal{T}_{\mathrm{cm}}$. The three methods we will discuss for evaluating the uncertainties in exclusive jet cross sections are
A) "Direct Exclusive Scale Variation". Here the uncertainties are evaluated by directly varying the renormalization and factorization scales in the fixed-order predictions for each exclusive jet cross section $\sigma_{N}$. This implies that the uncertainties are $100 \%$ correlated for different $N$ s.
B) "Combined Inclusive Scale Variation", as proposed in Ref. [26] and utilized in Refs. [363, 364 365]. Here, the perturbative uncertainties in the inclusive $N$-jet cross sections, $\sigma_{\geq N}$, are treated as the primary uncertainties that can be evaluated by scale variations in fixed-order perturbation theory. These uncertainties are treated as uncorrelated for different $N$. The exclusive $N$-jet cross sections are obtained using $\sigma_{N}=\sigma_{\geq N}-\sigma_{\geq N+1}$. The uncertainties and correlations follow from standard error propagation, including the appropriate anticorrelations between $\sigma_{N}$ and $\sigma_{N \pm 1}$ related to the division into jet bins.
C) "Uncertainties from Resummation." Resummed calculations for exclusive jet cross sections can provide uncertainty estimates that allow one to simultaneously include both types of correlated
and anticorrelated uncertainties as in methods A and B. The magnitude of the uncertainties may also be reduced from the resummation of large logarithms.
In all three methods, adding the exclusive jet cross sections yields the expected scale variation in the total cross section. Method B avoids a potential underestimate of the uncertainties in individual jet bins due to strong cancellations that can potentially take place in method A. Method B produces realistic perturbative uncertainties for exclusive jet cross sections when using fixed-order predictions for various processes, since it accounts for the presence of large logarithms at higher orders caused by the jet binning. In Method C one utilizes higher-order resummed predictions for the exclusive jet cross sections, which allow one to obtain improved central values and further refined uncertainty estimates.

The basic structure of the large logarithms in the perturbative series is discussed in Sec. 12.2. In Sec. 12.3 we discuss and compare the above three methods to determine the perturbative uncertainties. The work discussed here regarding methods A, B, and C builds on work done in Refs. [375, 26], was initiated at Les Houches, and has also been incorporated in the second Higgs Yellow Book report [376] (Secs. 5.2 and 5.5.) We also review recent work by others that can be found in [376](Sec. 5.3).

Note that here we are only discussing the theoretical uncertainties due to unknown higher-order perturbative corrections, which are commonly estimated using scale variation. Parametric uncertainties, such as PDF choices and $\alpha_{s}\left(m_{Z}\right)$ uncertainties, must be treated appropriately as common sources for all investigated channels.

### 12.2 Theoretical Motivation

### 12.21 Structure of the Perturbative Series

We begin by discussing the structure of the large logarithms in exclusive jet cross sections. For Higgs production from gluon fusion with $p_{T}^{\text {jet }} \leq p_{T}^{\text {cut }}$ the leading double logarithms appearing at $\mathcal{O}\left(\alpha_{s}\right)$ are

$$
\begin{equation*}
\sigma_{0}\left(p_{T}^{\mathrm{cut}}\right)=\sigma_{B}\left(1-\frac{3 \alpha_{s}}{\pi} 2 \ln ^{2} \frac{p_{T}^{\mathrm{cut}}}{m_{H}}+\cdots\right), \tag{85}
\end{equation*}
$$

where $\sigma_{B}$ is the Born (tree-level) cross section.
The total cross section only depends on the hard scale $Q=m_{H}$, which means by choosing the factorization and renormalization scales $\mu_{f} \simeq \mu_{r} \simeq m_{H}$, the fixed-order expansion does not contain large logarithms and has the structure

$$
\begin{equation*}
\sigma_{\text {total }} \simeq \sigma_{B}\left[1+\alpha_{s}+\alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] . \tag{86}
\end{equation*}
$$

Our expressions for perturbative series such as this one are schematic, showing the scaling of the terms without the coefficient functions. The convolution with the parton distribution functions (PDFs) are also not displayed. For $g g \rightarrow H$, the coefficients of this series can be large, corresponding to the well-known large K factors. As usual, varying the scale in $\alpha_{s}(\mu)$ (and the PDFs) one obtains an estimate of the size of the missing higher-order terms in this series, which we denote by $\Delta_{\text {total }}$.

The inclusive 1 -jet cross section has the perturbative structure

$$
\begin{equation*}
\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right) \simeq \sigma_{B}\left[\alpha_{s}\left(L^{2}+L+1\right)+\alpha_{s}^{2}\left(L^{4}+L^{3}+L^{2}+L+1\right)+\mathcal{O}\left(\alpha_{s}^{3} L^{6}\right)\right], \tag{87}
\end{equation*}
$$

where the logarithms $L=\ln \left(p^{\text {cut }} / m_{H}\right)$. For $p^{\text {cut }} \ll m_{H}$ these logarithms can get large enough to overcome the $\alpha_{s}$ suppression. In the limit $\alpha_{s} L^{2} \simeq 1$, the fixed-order perturbative expansion breaks down and the logarithmic terms must be resummed to all orders in $\alpha_{s}$ to obtain a meaningful result. For typical experimental values of $p^{\text {cut }}$ fixed-order perturbation theory can still be considered, but the logarithms cause large corrections at each order and dominate the series.

The exclusive 0 -jet cross section is equal to the difference between Eqs. (86) and (87), and so has the schematic structure
$\sigma_{0}\left(p^{\mathrm{cut}}\right)=\sigma_{\text {total }}-\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right)$

$$
\begin{equation*}
\simeq \sigma_{B}\left\{\left[1+\alpha_{s}+\alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right]-\left[\alpha_{s}\left(L^{2}+L+1\right)+\alpha_{s}^{2}\left(L^{4}+L^{3}+L^{2}+L+1\right)+\mathcal{O}\left(\alpha_{s}^{3} L^{6}\right)\right]\right\} \tag{88}
\end{equation*}
$$

In this difference, the large positive corrections in $\sigma_{\text {total }}$ partly cancel against the large negative logarithmic corrections in $\sigma_{\geq 1}$. For example, at $\mathcal{O}\left(\alpha_{s}\right)$ there is a value of $L$ for which the $\alpha_{s}$ terms in Eq. (88) cancel exactly. At this $p^{\text {cut }}$ the NLO 0 -jet cross section has vanishing scale dependence and is equal to the LO cross section, $\sigma_{0}\left(p^{\mathrm{cut}}\right)=\sigma_{B}$. Due to this cancellation, a standard use of scale variation in $\sigma_{0}\left(p^{\mathrm{cut}}\right)$ does not actually probe the size of the large logarithms, and does not provide an estimate of $\Delta_{\text {cut }}$. This issue impacts the uncertainties in the experimentally relevant region for $p^{\text {cut }}$.

For example, for $g g \rightarrow H$ (with $\sqrt{s}=7 \mathrm{TeV}, m_{H}=165 \mathrm{GeV}, \mu_{f}=\mu_{r}=m_{H} / 2$ ), one finds [214, 371, 90, 216]

$$
\begin{align*}
\sigma_{\text {total }} & =(3.32 \mathrm{pb})\left[1+9.5 \alpha_{s}+35 \alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] \\
\sigma_{\geq 1}\left(p_{T}^{\mathrm{jet}} \geq 30 \mathrm{GeV},\left|\eta^{\mathrm{jet}}\right| \leq 3.0\right) & =(3.32 \mathrm{pb})\left[4.7 \alpha_{s}+26 \alpha_{s}^{2}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] \tag{89}
\end{align*}
$$

In $\sigma_{\text {total }}$ one can see the impact of the well-known large $K$ factors. (Using instead $\mu_{f}=\mu_{r}=m_{H}$ the $9.5 \alpha_{s}$ and $35 \alpha_{s}^{2}$ coefficients in $\sigma_{\text {total }}$ increase to $11 \alpha_{s}$ and $65 \alpha_{s}^{2}$.) In $\sigma \geq 1$, one can see the impact of the large logarithms on the perturbative series. Taking their difference to get $\sigma_{0}$, one observes a sizeable numerical cancellation between the two series at each order in $\alpha_{s}$.

### 12.22 Perturbative Series for the Event Fraction

Experimentally the desired quantity which incorporates the jet-veto cut is the exclusive 0-jet event fraction

$$
\begin{equation*}
f_{0}\left(p^{\mathrm{cut}}\right)=\frac{\sigma_{0}\left(p^{\mathrm{cut}}\right)}{\sigma_{\mathrm{total}}}=1-\frac{\sigma_{\geq 1}\left(p^{\mathrm{cut}}\right)}{\sigma_{\mathrm{total}}} . \tag{90}
\end{equation*}
$$

One option for treating $f_{0}\left(p^{\mathrm{cut}}\right)$ is to consider it as a derived quantity, given the basic observables $\left\{\sigma_{0}, \sigma_{\text {total }}\right\}$ or $\left\{\sigma_{\geq 1}, \sigma_{\text {total }}\right\}$. In this approach, which was utilized in Ref. [26] and Ref. [376](Secs. 5.2 and 5.5), one propagates the uncertainties from the $\sigma_{i} \mathrm{~s}$ to derive those for $f_{0}\left(p^{\mathrm{cut}}\right)$. This approach is natural from the perspective of utilizing log-resummed computations for $\sigma_{0}\left(p^{\mathrm{cut}}\right)$. In particular, it maintains the constraint that for large $p^{\text {cut }}$ we have monotonic convergence of $\sigma_{0} \rightarrow \sigma_{\text {total }}$ and $f_{0} \rightarrow 1$, a property that relies on a phase space cut reducing the cross section, but does not depend on perturbation theory.

When using fixed-order predictions for the various cross sections, an alternative to Eq. (90) considered in Ref. [376](Sec. 5.3) is to analyze the perturbation theory for $f_{0}\left(p^{\mathrm{cut}}\right)$ directly. In this case different schemes of organizing the perturbation series, by keeping or dropping various $\mathcal{O}\left(\alpha_{s}^{3}\right)$ terms, give a method to estimate the size of the higher-order perturbative corrections. Three such schemes were considered in Ref. [376](Sec. 5.3) (which we label here by schemes 1,2,3). It is convenient to define the perturbative corrections to the cross section by dividing each of them by the Born cross section $\sigma_{B}$, such that we can write

$$
\begin{align*}
\sigma_{\text {total }} & =\sigma_{B}\left[1+\hat{\sigma}_{\text {total }}^{(1)}+\hat{\sigma}_{\text {total }}^{(2)}+\mathcal{O}\left(\alpha_{s}^{3}\right)\right], \\
\sigma_{\geq 1}\left(p^{\text {cut }}\right) & =\sigma_{B}\left[\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\text {cut }}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\text {cut }}\right)+\mathcal{O}\left(\alpha_{s}^{3}\right)\right] . \tag{91}
\end{align*}
$$

With this notation the result of treating $f_{0}$ as a derived quantity is

$$
\begin{equation*}
\left[f_{0}\left(p^{\mathrm{cut}}\right)\right]^{(\text {scheme } 1)}=1-\frac{\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\mathrm{cut}}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\mathrm{cut}}\right)}{1+\hat{\sigma}_{\text {total }}^{(1)}+\hat{\sigma}_{\text {total }}^{(2)}}+\mathcal{O}\left(\alpha_{s}^{3}\right), \tag{92}
\end{equation*}
$$

while at the same order in perturbation theory we can also consider the following expressions for $f_{0}$ :

$$
\begin{align*}
& {\left[f_{0}\left(p^{\mathrm{cut}}\right)\right]^{\text {(scheme } 2)}=1-\frac{\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\mathrm{cut}}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\mathrm{cut}}\right)}{1+\hat{\sigma}_{\text {total }}^{(1)}}+\mathcal{O}\left(\alpha_{s}^{3}\right),} \\
& {\left[f_{0}\left(p^{\mathrm{cut}}\right)\right]^{(\text {scheme } 3)}=1-\left[\hat{\sigma}_{\geq 1}^{(1)}\left(p^{\mathrm{cut}}\right)+\hat{\sigma}_{\geq 1}^{(2)}\left(p^{\mathrm{cut}}\right)\right]+\hat{\sigma}_{\geq 1}^{(1)} \hat{\sigma}_{\text {total }}^{(1)}+\mathcal{O}\left(\alpha_{s}^{3}\right) .} \tag{93}
\end{align*}
$$

We will contrast using the expressions in Eq. (92) and Eq. (93) with various methods for analyzing the uncertainty in our discussion below.

### 12.3 Uncertainty Analysis for Exclusive Jet Bins

As described in Sec. 12.21, the phase space restriction defining $\sigma_{0}$ changes its perturbative structure compared to that of $\sigma_{\text {total }}$. In general this gives rise to an additional perturbative uncertainty due to missing higher-order terms depending on $p^{\text {cut }}$. We will call the associated jet-binning uncertainty $\Delta_{\text {cut }}$. This can be thought of as an uncertainty related to the presence of large logarithms of $p^{\text {cut }}$ at higher orders in perturbation theory. In Eq. (83) both $\sigma_{0}$ and $\sigma_{\geq 1}$ depend on the phase space cut, $p^{\text {cut }}$, and by construction this dependence cancels in $\sigma_{0}+\sigma_{\geq 1}$. Hence, the additional uncertainty $\Delta_{\text {cut }}$ induced by $p^{\text {cut }}$ must be $100 \%$ anticorrelated between $\sigma_{0}\left(p^{\text {cut }}\right)$ and $\sigma_{\geq 1}\left(p^{\text {cut }}\right)$, such that it cancels in their sum. For example, using a covariance matrix to model the uncertainties and correlations, the contribution of $\Delta_{\text {cut }}$ to the covariance matrix for $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ must be of the form

$$
C_{\mathrm{cut}}=\left(\begin{array}{cc}
\Delta_{\mathrm{cut}}^{2} & -\Delta_{\mathrm{cut}}^{2}  \tag{94}\\
-\Delta_{\mathrm{cut}}^{2} & \Delta_{\mathrm{cut}}^{2}
\end{array}\right) .
$$

The questions then are: (1) How can we estimate $\Delta_{\text {cut }}$ in a simple way, and (2) how is the perturbative uncertainty $\Delta_{\text {total }}$ of $\sigma_{\text {total }}$ related to the uncertainties of $\sigma_{0}$ and $\sigma_{\geq 1}$ ?

### 12.31 Perturbative Uncertainties for Method A

When using method A to estimate the perturbative uncertainties one simply uses a common scale variation to estimate the uncertainty $\Delta_{0}$ in $\sigma_{0}$ and the uncertainty $\Delta_{\geq 1}$ in $\sigma_{\geq 1}$. By doing so the uncertainties are $100 \%$ correlated, corresponding to a covariance matrix in method A for $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ given by

$$
C_{A}=\left(\begin{array}{cc}
\Delta_{0}^{2} & \Delta_{0} \Delta_{\geq 1}  \tag{95}\\
\Delta_{0} \Delta_{\geq 1} & \Delta_{\geq 1}^{2}
\end{array}\right)
$$

Here $\Delta_{\text {total }}=\Delta_{0}+\Delta_{\geq 1}$ is the scale uncertainty in $\sigma_{\text {total }}$. When instead of $\sigma_{0}$ we directly calculate the 0 -jet event fraction $f_{0}$ using Eq. (92) or one of the expressions in Eq. (93), we can again determine the method A uncertainty estimate by scale variation in $f_{0}$ (we will refer to these results as methods $A_{1}, A_{2}$, and $A_{3}$ respectively).

In this method $\Delta_{\text {cut }}$ is not included because, as explained below Eq. (88), varying the perturbative scale in $\Delta_{0}$ does not probe the presence of the higher order large logarithms depending on $p^{\text {cut }}$. This method can lead to an underestimate of the perturbative uncertainty in $\sigma_{0}$ (and hence $f_{0}$ ), since there is a region of $p^{\text {cut }}$ values where scale variation is no longer a reasonable estimate of higher order corrections because of the vanishing of the $\mu$ dependence.

### 12.32 Perturbative Uncertainties for Method B

Since the perturbative series for $\sigma_{\geq 1}$ in Eq. (87) is dominated by the large logarithms of $p^{\text {cut }}$, we can use its scale variation $\Delta_{\geq 1}$ to get an estimate for their size by taking $\Delta_{\text {cut }}=\Delta_{\geq 1}$ [26]. Since $\Delta_{\text {cut }}$ and $\Delta_{\text {total }}$ are by definition uncorrelated, by setting $\Delta_{\text {cut }}=\Delta_{\geq 1}$ we are effectively treating the perturbative
series for $\sigma_{\text {total }}$ and $\sigma_{\geq 1}$ as independent with uncorrelated perturbative uncertainties. That is, considering $\left\{\sigma_{\text {total }}, \sigma_{\geq 1}\right\}$, the covariance matrix is diagonal,

$$
\left(\begin{array}{cc}
\Delta_{\text {total }}^{2} & 0  \tag{96}\\
0 & \Delta_{\geq 1}^{2}
\end{array}\right)
$$

where $\Delta_{\text {total }}$ and $\Delta_{\geq 1}$ are evaluated by separate scale variations in the fixed-order predictions for $\sigma_{\text {total }}$ and $\sigma_{\geq 1}$. This is consistent, since for small $p^{\text {cut }}$ the two series have very different structures. In particular, there is no reason to believe that the same cancellations in $\sigma_{0}$ will persist at every order in perturbation theory at a given $p^{\text {cut }}$. It follows that the perturbative uncertainty in $\sigma_{0}=\sigma_{\text {total }}-\sigma_{\geq 1}$ is given by $\Delta_{\text {total }}^{2}+\Delta_{\geq 1}^{2}$, and the resulting covariance matrix for $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ in method B is

$$
C_{B}=\left(\begin{array}{cc}
\Delta_{\geq 1}^{2}+\Delta_{\text {total }}^{2} & -\Delta_{\geq 1}^{2}  \tag{97}\\
-\Delta_{\geq 1}^{2} & \Delta_{\geq 1}^{2}
\end{array}\right) .
$$

Note that all of $\Delta_{\text {total }}$ occurs in the uncertainty for $\sigma_{0}$. This is reasonable from the point of view that $\sigma_{0}$ starts at the same order in $\alpha_{s}$ as $\sigma_{\text {total }}$ and contains the same leading virtual corrections. The method B uncertainty for the event fraction $f_{0}$ follows most naturally by error propagation from the cross sections, treating it as a derived quantity.

The limit $\Delta_{\text {cut }}=\Delta_{\geq 1}$ that Eq. (97) is based on is of course an approximation. However, the preceding arguments show that it is a more reasonable starting point than method A , since the latter does not account for the additional $p^{\text {cut }}$ induced uncertainties.

The generalization of the above discussion to more jets and several jet bins is straightforward. For the $N$-jet bin we replace $\sigma_{\text {total }} \rightarrow \sigma_{\geq N}, \sigma_{0} \rightarrow \sigma_{N}$, and $\sigma_{\geq 1} \rightarrow \sigma_{\geq N+1}$. If the perturbative series for $\sigma_{\geq N}$ exhibits large $\alpha_{s}$ corrections due to its logarithmic series or otherwise, then the presence of a different series of large logarithms in $\sigma_{\geq N+1}$ will again lead to cancellations when we consider the difference $\sigma_{N}=\sigma_{\geq N}-\sigma_{\geq N+1}$. These two cross sections will have different series for their double logarithms since the number of active partons and their color structure differ. In this situation $\Delta_{\geq N+1}$ will again give a better estimate for the extra $\Delta_{\text {cut }}$ type uncertainty that arises from separating $\sigma_{\geq N}$ into $\sigma_{N}$ and $\sigma_{\geq N+1}$.

### 12.33 Perturbative Uncertainties for Method C

In method C we assess the perturbative uncertainties using resummed predictions for variables $p^{\text {cut }}$ that implement a jet veto, following Refs. [375, 26]. An advantage of using resummed predictions is that they contain perturbation theory scale parameters which allow for an evaluation of two components of the theory error, one which is $100 \%$ correlated with the total cross section (as in method A), and one related to the presence of the jet-bin cut which is anti-correlated between neighboring jet bins (as in method B).

The resummed $H+0$-jet cross section predictions of Ref. [375] follow from a factorization theorem for the 0 -jet cross section [374], $\sigma_{0}\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)=H \mathcal{I}_{g i} \mathcal{I}_{g j} \otimes S f_{i} f_{j}$, where $H$ contains hard virtual effects, the $\mathcal{I}_{\text {s }}$ and $S$ describe the veto-restricted collinear and soft radiation, and the $f$ s are standard parton distributions. Fixed-order perturbation theory is carried out at three scales, a hard scale $\mu_{H}^{2} \sim m_{H}^{2}$ in $H$, and beam and soft scales $\mu_{B}^{2} \sim m_{H} \mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$ and $\mu_{S}^{2} \sim\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)^{2}$ for $\mathcal{I}$ and $S$, and are then connected by NNLL renormalization group evolution that sums the jet-veto logarithms, which are encoded in ratios of these scales. The perturbative uncertainties can be assessed by considering two sources: i) an overall scale variation that simultaneously varies $\left\{\mu_{H}, \mu_{B}, \mu_{S}\right\}$ up and down by a factor of two which we denote by $\Delta_{H 0}$, and ii) individual variations of $\mu_{B}$ or $\mu_{S}$ that each hold the other two scales fixed [375], whose envelope we denote by the uncertainty $\Delta_{S B}$. Here $\Delta_{H 0}$ is dominated by the same sources of uncertainty as the total cross section $\sigma_{\text {total }}$, and hence should be considered $100 \%$ correlated with its uncertainty

Fig. 31: Relative uncertainties for the 0 -jet bin cross section from resummation at NNLL+NNLO for beam thrust $\mathcal{T}_{\mathrm{cm}}$ on the left and $p_{T}^{\text {jet }}$ on the right.
$\Delta_{\text {total }}$. The uncertainty $\Delta_{S B}$ is only present due to the jet-bin cut, and hence gives the $\Delta_{\text {cut }}$ uncertainty that is anti-correlated between neighboring jet bins.

If we simultaneously consider the cross sections $\left\{\sigma_{0}, \sigma_{\geq 1}\right\}$ then the full correlation matrix in method C is

$$
C_{C}=\left(\begin{array}{cc}
\Delta_{S B}^{2} & -\Delta_{S B}^{2}  \tag{98}\\
-\Delta_{S B}^{2} & \Delta_{S B}^{2}
\end{array}\right)+\left(\begin{array}{cc}
\Delta_{H 0}^{2} & \Delta_{H 0} \Delta_{H \geq 1} \\
\Delta_{H 0} \Delta_{H \geq 1} & \Delta_{H \geq 1}^{2}
\end{array}\right),
$$

where $\Delta_{H \geq 1}=\Delta_{\text {total }}-\Delta_{H 0}$ encodes the $100 \%$ correlated component of the uncertainty for the ( $\geq 1$ )jet inclusive cross section. Computing the uncertainty in $\sigma_{\text {total }}$ gives back $\Delta_{\text {total }}$.

Eq. (98) can be compared to $C_{A}$ for method A in Eq. (95), which corresponds to taking $\Delta_{S B} \rightarrow 0$ and obtaining the analog of $\Delta_{H 0}$ by up/down scale variation without resummation ( $\mu_{H}=\mu_{B}=\mu_{S}$ ). It can also be compared to $C_{B}$ for method B in Eq. (97), which corresponds to taking $\Delta_{S B} \rightarrow \Delta_{\geq 1}$ and $\Delta_{H \geq 1} \rightarrow 0$, such that $\Delta_{H 0} \rightarrow \Delta_{\text {total }}$. The numerical dominance of $\Delta_{S B}^{2}$ over $\Delta_{H 0} \Delta_{H \geq 1}$ in the 0 -jet region is another way to justify the preference for using method B when only given a choice between methods A and B. For example, for $p_{T}^{\mathrm{cut}}=30 \mathrm{GeV}$ and $\left|\eta^{\text {jet }}\right| \leq 5.0$ we have $\Delta_{S B}^{2}=0.17$ and $\Delta_{H 0} \Delta_{H \geq 1}=0.02$.

In Fig. 31 we show the uncertainties $\Delta_{S B}$ (light green) and $\Delta_{H 0}$ (medium blue) as a function of the jet-veto variable, as well as the combined uncertainty adding these components in quadrature (dark orange). From the figure we see that the $\Delta_{H 0}$ dominates at large values where the veto is turned off and we approach the total cross section, and that the jet-cut uncertainty $\Delta_{S B}$ dominates for the small cut values that are typical of experimental analyses with Higgs jet bins. The same pattern is observed in the left panel which directly uses the NNLL+NNLO predictions for $\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$, and the right panel which shows the result from reweighting these predictions to $p_{T}^{\mathrm{cut}}$ as explained in Sec .12 .34 below.

### 12.34 Comparison of Uncertainty Methods

In Fig. 32 we compare the uncertainties for the 0 -jet bin cross section from methods A (medium green), B (light green), and C (dark orange). In the upper panels we use $\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$ as the jet-veto variable and full results for the NNLO and NNLL+NNLO cross sections, while in the lower panels we use $p_{T}^{\text {cut }}$ as the jet-veto variable with the full NNLO and the reweighted NNLL+NNLO results (as explained below). The upper panels use a cut on beam thrust, $\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$ while the lower panels use $p_{T}^{\mathrm{cut}}$. The right panels show the same results as those on the left, but are normalized to the highest-order result to better show the relative differences and uncertainties. The uncertainties in methods $\mathrm{A}, \mathrm{B}$, and C are computed from the upper left entry of the matrices $C_{A}, C_{B}$, and $C_{C}$, respectively.

Fig. 32: Comparison of uncertainties for methods A, B, C for the 0 -jet bin cross section for beam thrust $\mathcal{T}_{\text {cm }}$ (top) and $p_{T}^{\text {jet }}$ (bottom). Results are shown at NNLO with uncertainties from methods A and B and for the NNLL+NNLO resummed result using method C (reweighted for $p_{T}^{\mathrm{cut}}$ ). On the right all curves are normalized relative to the NNLL+NNLO central value.

From Fig. 32 we see that in method A (medium green bands) for small values of $p_{T}^{\text {cut }}$ the cancellations that take place in $\sigma_{0}\left(p^{\text {cut }}\right)$ cause the error bands to shrink and eventually almost vanish at $p_{T}^{\text {cut }} \simeq 25 \mathrm{GeV}$, where there is an almost exact cancellation between the two series in Eq. 88). This is avoided by using method B (light green bands). For large values of $p_{T}^{\text {cut }}$ method B reproduces the method A scale variation, since $\sigma_{\geq 1}\left(p^{\text {cut }}\right)$ becomes small. On the other hand, for small values of $p_{T}^{\text {cut }}$ the uncertainties estimated using method B are more realistic, because they explicitly estimate the uncertainties due to the presence of higher order large logarithmic corrections.

The features of this plot are quite generic. In particular, the same pattern of uncertainties is observed for the Tevatron, when using $\mu=m_{H}$ as our central scale (with $\mu=2 m_{H}$ and $\mu=m_{H} / 2$ for the range of scale variation), whether or not we only look at jets at central rapidities, or when considering the exclusive 1 -jet cross section. We also note that using independent variations for $\mu_{f}$ and $\mu_{r}$ does not change this picture, in particular the $\mu_{f}$ variation for fixed $\mu_{r}$ is quite small.

For method C with $\mathcal{T}_{\mathrm{cm}}$ we make use of resummed predictions for $H+0$ jets from gluon fusion at next-to-next-to-leading logarithmic order (NNLL+NNLO) from Ref. [375]. This includes the correct NNLO fixed-order corrections for $\sigma_{0}\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)$ for any cut. The resulting cross section $\sigma_{0}\left(\mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}\right)$ has the jet veto implemented by a cut $\mathcal{T}_{\mathrm{cm}} \leq \mathcal{T}_{\mathrm{cm}}^{\mathrm{cut}}$. This cross section contains a resummation of large logarithms at two orders beyond standard LL parton shower programs. A similar resummation for the case of $p_{T}^{\text {jet }}$ is not available. Instead, we use MC @ NLO and reweight it to the resummed predictions in $\mathcal{T}_{\mathrm{cm}}$, doing so for both the central curve as well as each of the six scale variation curves needed for the uncertainty

Fig. 33: In the left panel we show the same three curves as in the bottom-left panel of Fig. 32, but for the event fraction $f_{0}\left(p_{T}^{\mathrm{cut}}\right)$ treated as a derived quantity from the jet-bin cross sections. In the right panel we contrast the uncertainties obtained using Eqs. (92) and (93) together with method A, with the uncertainty obtained using method B.
determination in method $C{ }^{24}$ We then use the reweighted Monte Carlo sample to obtain cross section predictions for the standard jet veto, $\sigma_{0}\left(p_{T}^{\mathrm{cut}}\right)$. We will refer to this as the reweighted NNLL+NNLO result. Since the Monte Carlo here is only used to provide a transfer matrix between $\mathcal{T}_{\text {cm }}$ and $p_{T}^{\text {jet }}$, and both variables implement a jet veto, one expects that most of the improvements from the higherorder resummation are preserved by the reweighting. However, we caution that this is not equivalent to a complete NNLL+NNLO result for the $p_{T}^{\text {cut }}$ spectrum, since the reweighting may not fully capture effects associated with the choice of jet algorithm and other effects that enter at this order for $p_{T}^{\text {cut }}$. The dependence on the Monte Carlo transfer matrix also introduces an additional uncertainty, which should be studied and is not included in our numerical results. The transfer matrix is obtained at the parton level, without hadronization or underlying event, since we are reweighting a partonic NNLL+NNLO calculation.

From Fig. 32 one observes that the resummation of the large jet-veto logarithms (dark red central curve) lowers the cross section for both $\mathcal{T}_{\mathrm{cm}}^{\text {cut }}$ and $p_{T}^{\text {cut }}$. Comparing to NNLO for cut values $\gtrsim 25 \mathrm{GeV}$ the relative uncertainties in the resummed result of method C (dark orange bands) and the reduction in the resummed central value are similar for both jet-veto variables. Since one expects resummation to decrease the uncertainties, one can also see that the NNLO uncertainties from method B are more consistent with the higher order NNLL+NNLO resummed method C results than those in method A . We observe that the uncertainties in method C are reduced by about a factor of two compared to those in method B. Since the zero-jet bin plays a crucial role in the $H \rightarrow W W$ channel for Higgs searches, and these improvements will also be reflected in uncertainties for the one-jet bin, the improved theoretical precision obtained with method C has the potential to be quite important.

In Fig. 33 we show results for the 0 -jet event fraction $f_{0}$, with $p_{T}^{\text {cut }}$ as the jet-veto variable. In the left panel we compare the uncertainties in $f_{0}\left(p_{T}^{\text {cut }}\right)$ that result from propagating the uncertainties from the jet-bin cross sections obtained from methods A (medium green), B (light green), and C (dark orange). The conclusions are analogous to the corresponding cross-section results in the bottom-left panel of Fig. 32, namely that method B provides a better estimate for the perturbative fixed-order uncertainties than method A, and that the higher-order logarithmic summation present in method C leads to a slightly smaller central value together with the decrease to the uncertainty one expects from incorporating the resummation. In the right panel of Fig. 33 we show the results of the different perturbative schemes for $f_{0}$ defined in Eq. 92) (middle dark green band) and Eq. 93) (lower narrow blue band and upper wide

[^210]|  | method A | method B | method C |
| :---: | :---: | :---: | :---: |

yellow band) each at NNLO and in each case obtaining the uncertainties using method A (direct scale variation) [376](Sec. 5.3). For comparison, the middle light green band shows the uncertainties obtained from method B. The different method A schemes have a wide spread, which demonstrates the large size of the higher-order perturbative corrections in the total and inclusive 1-jet cross sections. The central values of the alternative methods $A_{2}$ and $A_{3}$ are not covered by the method $A_{1}$ uncertainty band, but all three central curves are covered by the larger uncertainty band from method B (except at small $p_{T}^{\text {cut }}$ where scheme 3 starts to diverge earlier than the other schemes). This can be taken as a confirmation that method A tends to underestimate the perturbative uncertainties in the fixed-order results [376](Sec. 5.3), while method B produces more realistic fixed-order uncertainties.

To appreciate the effects of the different methods on the correlation matrix we consider as an example the results for $p_{T}^{\text {cut }}=30 \mathrm{GeV}$ and $\left|\eta^{\text {jet }}\right| \leq 5.0$. The inclusive cross sections are $\sigma_{\text {total }}=(8.76 \pm$ $0.80) \mathrm{pb}$ at NNLO, and $\sigma_{\geq 1}=(3.31 \pm 0.64) \mathrm{pb}$ at NLO. The relative uncertainties and correlations at these cuts for the three methods are shown in Table 9 . The numbers for the cross sections are also translated into the equivalent results for the event fractions, $f_{0}\left(p_{T}^{\text {cut }}\right)=\sigma_{0}\left(p_{T}^{\text {cut }}\right) / \sigma_{\text {total }}$ and $f \geq 1\left(p_{T}^{\text {cut }}\right)=$ $\sigma_{\geq 1}\left(p_{T}^{\text {cut }}\right) / \sigma_{\text {total }}$. Note that method A should not be used due to the lack of a contribution corresponding to $\Delta_{\text {cut }}$ in this method, and the resulting underestimated $\delta \sigma_{0}$. In methods B and C we see, as expected, that $\sigma_{0}$ and $\sigma_{\geq 1}$ have a substantial anti-correlation due to the jet-bin boundary they share.

### 12.4 Conclusion

To summarize, we have discussed the implications of separating LHC cross sections into jet bins, using Higgs production from gluon fusion as a concrete example. The jet binning induces logarithmic dependences on the jet-bin boundary which is important to properly take into account when making predictions and estimating perturbative uncertainties. When using fixed-order predictions only, the additional logarithms at higher orders in perturbation theory caused by the jet binning can be taken into account in the perturbative uncertainty estimate using method B. By resumming the jet-binning logarithms one can obtain improved predictions with reduced (and more sophisticated) uncertainties using method C.

Here we have focused our discussion on $\sigma_{0}$ and $\sigma_{\geq 1}$ and how to take into account the resulting jet-bin boundary. To further separate $\sigma_{\geq 1}$ into a one-jet bin $\sigma_{1}$ and a $\sigma_{\geq 2}$ one can use method B for this boundary by treating $\Delta_{\geq 2}$ as uncorrelated with the total uncertainty for $\sigma_{\geq 1}$ from either methods B or C. Examples of utilizing method B for this jet bin boundary can be found in Ref. [26]. Once it becomes available one can also use a resummed prediction with uncertainties for this boundary with method C .

## 13. A NLO BENCHMARK COMPARISON FOR INCLUSIVE JET PRODUCTION AT HADRON COLLIDERS ${ }^{25}$

#### Abstract

We present a benchmark comparison of two next-to-leading order (NLO) calculations for inclusive jet and jet pair production at hadron colliders. A new version of the NLO code EKS is adapted for computation of differential cross sections and compared to an independent calculation based on the FastNLO code. A percent-level agreement between the two codes is observed for specified settings of computations at typical transverse momenta and rapidities of Tevatron and LHC measurements. We identify theoretical prerequisites for achieving such level of agreement and comment on the stability of NLO calculations with respect to the factorization scale choice.

### 13.1 INTRODUCTION

Inclusive jet production at hadron colliders provides an excellent opportunity to test perturbative QCD (PQCD) and look for possible new physics beyond the Standard Model (SM) over a wide range of energy scales. Single inclusive jet production in the Tevatron Run-2 has been recently used to determine the QCD coupling constant [377] and constrain parton distribution functions (PDF) in the proton in global QCD analyses by several groups [255, 378, 262, 311]. Jet production data provide constraints on the gluon PDF at large $x$ values, possibly in a combination with small- $x$ quark PDFs, as discussed in Section 7. Invariant mass distributions of dijets [379], angular distributions [380, 381], and other jet observables at the LHC [382, 293, 292] provide a unprecedented opportunity to extend searches for quark compositeness and new particle resonances toward the highest energies attainable.

In this contribution, we examine agreement between the computer programs that are available for NLO calculations of jet production cross sections. NLO QCD predictions for jet production work remarkably well in a wide kinematical range and across many orders of magnitude of the cross sections. Nonetheless, the latest PDF analysis evaluates many scattering processes up to NNLO in perturbative QCD. Jet production observables are pivotal for constraining the large- $x$ gluon PDF, but remain known to NLO only. We identify and document main factors affecting NLO jet cross sections at a few-percent level of accuracy and compare the numerical results for typical collider kinematics. Differences between the programs used, and choices for the theoretical inputs made, may be responsible for some differences observed between CT10 and other PDFs, as explained below. Such NLO benchmark comparison will be useful for quantifying or reducing the uncertainties on the resulting PDFs and for the future implementation of NNLO and higher-order resummed contributions to the jet cross sections.

From the experimental point of view, jet production has an advantage of very high statistics and a drawback of sizeable systematical errors associated with complexities of jet reconstruction. NLO theoretical uncertainties due to the QCD scale dependence and the fixed-order model for the jet algorithm are comparable to the experimental errors. Control of numerical accuracy involves, in particular, careful tuning of Monte-Carlo integration to handle steeply falling jet cross sections.

An early numerical code (EKS) for the NLO calculation of single-inclusive jet and dijet distributions was developed by S. D. Ellis, Z. Kunszt and D. E. Soper in 1990's [383] based on the subtraction method. Two other widely used numerical programs are NLOJET++ [384, 385] and FastNLO [290, 291].

[^211]The latter provides a fast interface to obtain NLO predictions in kinematical bins of already published experimental jet cross sections by interpolating table files produced by NLOJET++. Besides these fixedorder calculations, POWHEG combines the NLO jet production cross sections with leading-logarithm QCD showering effects [386]. Some phenomenological studies also include partial NNLO contributions to jet cross sections obtained by threshold resummation [387].

The agreement between the above NLO numerical programs is not automatically met, which motivates the present benchmark comparison. The past CTEQ PDF analyses computed NLO jet cross sections using NLO K-factor tables produced by the EKS code, while other PDF analysis groups use FastNLO. Since the CT10 NLO gluon PDF behaves somewhat differently at large $x$ than the gluon PDF from MSTW'08 or other groups [262], one must compare the EKS and FastNLO computations for the same input values to confirm that these programs do not cause the observed disagreement.

Here we show that the results for the Tevatron $(\sqrt{s}=1.96 \mathrm{TeV})$ and LHC $(\sqrt{s}=7 \mathrm{TeV})$ from EKS and FastNLO agree well when the computation parameters are chosen as described in the next section. These settings must be consciously controlled in order to reach acceptable agreement. As a result of this work, the EKS code has been revised to improve its stability and efficiency and to implement output into new differential cross sections [388].

### 13.2 Theoretical setup and inputs

Several theoretical inputs must be matched exactly between the EKS and FastNLO programs in order to reach the level of agreement shown in the figures below.

- Jet algorithm. When calculating the distribution of jet observables, we need to use the same jet algorithms as the ones in the experimental measurements. In this comparison, we utilized the cone-based Midpoint algorithm [389] for the Tevatron observables and cluster-based anti- $k_{T}$ algorithm [341] for the LHC. The only difference between the Midpoint algorithm and modified Snowmass algorithm [389] used in the original EKS program is that the Midpoint algorithm always starts with the middle point between the two partons' directions as a seed for a new protojet, no matter how large their separation is. In the NLO theoretical calculations for single-jet or dijet production that include at most three final-state partons, the cluster-based $k_{T}$ [390], anti- $k_{T}$, and Cambridge-Aachen (CA) [391] algorithms are equivalent.
- The recombination scheme is a procedure for merging two nearby partons into one jet. For example, the energy scheme (4D, based on adding the 4-momentum) or $E_{T}$ scheme (based on adding the scalar $E_{T}$, then averaging over the partons' directions using $E_{T}$ as the weights) can be employed to find the momentum of the merged jet [392]. Our comparison uses the energy scheme for both the Tevatron and LHC measurements, as it is often used by the recent experiments. Different choices of the recombination scheme can cause differences of up to ten percent in the NLO distributions, as will be shown later. Note that, with the energy scheme, the jet could be massive, which means that the jet's pseudorapidity will not be equal to its rapidity.
- The jet trigger imposes acceptance conditions on each jet's $p_{T}$ or rapidity when deciding if this jet's contribution is included into the jet observable. In NLO calculations of single-inclusive jet distributions, the jet trigger conditions have no influence. In dijet production, they may change the cross sections by small amounts by affecting the selection of two leading jets in some cases. In our dijet calculations we choose $p_{T}>40 \mathrm{GeV},|y|<3$ for each jet at the Tevatron and $p_{T}>30 \mathrm{GeV}$, $|y|<3$ at the LHC.
- Renormalization and factorization scales. The scale choice is only related to theory and has no correspondence in experiment. It is conventional to choose the renormalization and factorization scales to be of order of the typical transverse momentum $p_{T}$ of the jet(s): $\mu_{R} \sim \mu_{F} \sim p_{T}$. In contributions with two resolved jets, $p_{T}$ naturally corresponds to the transverse momentum of either of the final-state jets (which are equal by momentum conservation). More ambiguity
is present in contributions with three resolved jets, when $p_{T}$ can correspond to the transverse momentum of either of the jets in each event or to a combination of three transverse momenta. A meaningful comparison must use equivalent definitions of " $j$ et $p_{T}$ " in the renormalization and factorization scales of both NLO calculations.
When FastNLO interpolates tables of NLOJET++ cross sections for single inclusive-jet production, it sets $\mu_{R}$ and $\mu_{F}$ proportional to the $p_{T}$ value at a fixed point in each $p_{T}$ bin of the experimental data. Given the high precision of the latest PDF analyses, the FastNLO scale convention produces a numerically different result than the scale proportional to the $p_{T}$ of the leading jet or the average $p_{T}$ of two leading jets in each event. It depends on the binning of the experimental data and is numerically close to the average $p_{T}$ in each bin for small enough bins.
In the EKS calculations for single-jet production, we set the scale proportional to $p_{T}$ of each individual jet in any $p_{T}$ bin, which means that we repeat the evaluation of the matrix elements with three resolved jets (contributing to three $p_{T}$ bins) by successively setting $\mu_{R, F}$ to be proportional to the $p_{T}$ of each jet in the event. Such matrix elements are thus evaluated three times. This event-level scale setting of EKS turns out to be numerically close to the bin-level scale setting of FastNLO if the bin sizes are small. However, a few-percent differences are still observed at the largest rapidities and $p_{T}$. For dijet production, FastNLO and EKS choose the $\mu_{R}$ and $\mu_{F}$ scales that are proportional to the average $\left|p_{T}\right|=\left(\left|p_{T 1}\right|+\left|p_{T 2}\right|\right) / 2$ of the two leading jets.
- Monte-Carlo integration. Precision calculations for jet production are numerically challenging because of the rapid falloff of the cross sections with the jet's $p_{T}$ and rapidity, and also because of large numerical cancellations occurring between some $2 \rightarrow 2$ and $2 \rightarrow 3$ contributions. Both EKS and NLOJET ++ evaluate differential cross sections by Monte-Carlo integration, which requires to generate of order $10^{9}$ of sample points to achieve percent-level accuracy for the whole kinematical region. The upgraded EKS code performs the Monte-Carlo integration using the VEGAS method from the CUBA2.1 library [393]. The EKS output is produced in the form of two-dimensional cross sections ( $\left.d^{2} \sigma /\left(d p_{T} d y\right), d^{2} \sigma /\left(d M_{j j} d y\right), \ldots\right)$ and stored in finely binned two-dimensional histograms. Such output is "almost fully differential" in the sense that the finely grained histograms can be rebinned into any set of coarse bins of the given experiment at the stage of the user's final analysis. This format is different from the FastNLO format, which provides the cross sections in coarse bins taken from pre-existing experimental publications.
The fine binning in EKS is introduced at the stage of Monte-Carlo integration in order to improve convergence and to better handle the NLO cancellations. The Monte Carlo sampling pattern is tuned automatically to ensure that all fine bins are filled with comparable numbers of sample points, regardless of the momentum and scattering angle values associated with each bin. Then we get uniform relative errors on the cross sections in all bins without consuming too much CPU time, and despite the dramatic variation of cross sections across the bins. Finally, EKS includes a module to allow for flexible choices of scales $\mu_{R}$ and $\mu_{F}$, and another module for calculating differential cross sections of user-provided jet observables.

### 13.3 RESULTS

Figs. 3439 compare our representative numerical results with the ones provided by FastNLO for $p_{T}$ distributions of single jets, invariant mass distributions of dijets, and (in the case of D0 Run-2) angular distributions ( $\chi$ ) of dijets. Kinematical bins of the Tevatron $(\sqrt{s}=1.96 \mathrm{TeV}$ ) [287, 285, 289, 394] and LHC $(\sqrt{s}=7 \mathrm{TeV})$ [293, 292] measurements, and CTEQ6.6 PDFs [256] were used. The cone sizes $R$ of the jets are indicated in the figures.

Left panels in the figures show ratios of EKS to FastNLO cross sections, $\sigma_{\text {EKS }} / \sigma_{\text {FastNLO }}$, at the LO (red points) and $\mathrm{NLO}=\mathrm{LO}+\mathrm{NLO}$ correction (blue points), in kinematical bins provided by the experiments. The horizontal axis indicates the ID of each bin, which are arranged in the order of increasing jet rapidity $y$ and then jet's $p_{T}$ for inclusive jet production, $y$ and then $M_{j j}$ for dijet production, and $M_{j j}$
then $\chi$ for dijet angular dependence. Vertical lines indicate the boundaries of each rapidity interval for single-jet and dijet distributions, and of each dimass interval for the $\chi$ distribution. For example, Fig. 34 shows $\sigma_{\text {EKS }} / \sigma_{\text {FastNLO }}$ in 6 bins of jet rapidity, with bins $1 . . .23$ corresponding to the first rapidity bin ( $|y|<0.4$ ), bins $24 \ldots 45$ corresponding to the second rapidity bin $(0.4<|y|<0.8$ ), and so on.

The left panel includes, from top to bottom, three plots obtained with the renormalization and factorization scales equal to $1 / 2,1$, and 2 times the center scale. We can see a good overall agreement between EKS and FastNLO both at LO and NLO. The only significant discrepancies are found in the highest $p_{T}$ bins for both the Tevatron and LHC single inclusive jet production, which may be due to the difference in the scale choices used in EKS and FastNLO. [These differences reduce when going to NLO]. In the EKS single-jet calculation, we use the actual $p_{T}$ of the partonic jet filled into the bin as the scale input. FastNLO sets the scale according to a fixed $p_{T}$ value in each experimental bin, which tends to be different from the EKS scale in the highest $p_{T}$ bins, which have large widths. The same reason causes a small normalization shift in the other $p_{T}$ bins.

For dijet production, we only observe random fluctuations at highest $M_{j j}$ that are mainly due to numerical integration errors.

In the right panels of Figs. 34 39, we present plots of the NLO K factor from EKS for each distribution, defined as the ratio of the NLO differential cross section to the LO one. The value of the K factor and its stability with respect to the scale choice may provide an indication of the magnitude of yet higher-order corrections.

To minimize the potential effect of higher-order terms, one might opt to choose the renormalization and factorization scales that bring the K factor close to unity in most of the kinematical region. An alternative approach for setting the scale is based on the minimal sensitivity method, which suggests to choose the $\mu_{R}$ and $\mu_{F}$ values (taken to be equal and designated as $\mu$ in the following) at the point where the scale dependence of the NLO cross section is the smallest.

In (di)jet production at central rapidities at the Tevatron, both requirements ( $K \approx 1$ and $d \sigma_{N L O}(\mu) / d \mu \approx 0$ ) could be satisfied by choosing $\mu \approx 0.5 p_{T}$; see, e.g., the appendix in Ref. [395]. For this reason, the scale $p_{T} / 2$ was used in the CT10 study. However, the point of the minimal sensitivity shifts to higher values (close to $p_{T}$ or even higher) at forward rapidities at the Tevatron or at all rapidities at the LHC. For such higher scales, however, it is hard to satisfy the requirement that $K$ remains close to unity at the same time.

This point is illustrated by our plots of the $K$ factors. At the central rapidities and $\mu_{R}=\mu_{F}=$ $0.5 p_{T}$ at the Tevatron (the lowest 3 rapidity bins in Figs. 34.37), $K \approx 1$ and is relatively independent of $p_{T}$, as seen in the top subpanels. However, with this scale choice the K factor deviates significantly from unity and has strong kinematic dependence if the rapidity and $p_{T}$ are large. If one chooses the scale that is equal to $p_{T}$ or even $2 p_{T}$ (the middle and bottom figures), in accord with the minimal sensitivity method for the forward bins, the kinematical dependence of the K factor reduces, but its value increases to 1.3-1.6 in most of the bins.

For CMS kinematics (Figs. 38|39), the $K$ factor has significant kinematical dependence for all central scale choices, however, the choice $\mu_{R}=\mu_{F}=p_{T}$ (the middle subpanels) results in a comparatively flatter $K$ factor that is also closer to unity. We can see that it is hard to find a fixed scale (or a scale of the type $p_{T} \times($ a function of $y)$ [383]) that would simultaneously reduce the magnitude of the NLO correction and stabilize its scale dependence and kinematical dependence. The scale $0.5 p_{T}$ may be slightly more optimal at the Tevatron, and the scale $p_{T}$ may be slightly better at the LHC. In the absence of a clearly superior scale choice, it may be necessary to vary the scale of jet cross sections in the global fit in order to estimate its effect on the PDF errors.

In Figs. 40 and 41, we plot the ratios of the NLO distributions calculated using different recombination schemes, where $\sigma_{4 D}$ is obtained with the energy scheme, and $\sigma_{E_{T}}$ is with the $E_{T}$ scheme. For single inclusive jet production at both the Tevatron and LHC, $\sigma_{E_{T}}$ is larger then $\sigma_{4 D}$. An opposite trend
is observed in dijet production. Differences of the predictions based on the two schemes are larger with the Midpoint algorithm (used at the Tevatron) than with the anti- $k_{T}$ algorithm (used at the LHC). In an NLO calculation, the Midpoint algorithm allows a larger maximal angular separation $(2 R)$ between the two partons forming a jet, compared to the anti- $k_{T}$ algorithm that only allows the angular separation up to $R$. This produces the shown kinematical differences between the two schemes.

## CONCLUSIONS

Jet production plays an important role at hadron colliders and is a main background process in the bulk of new physics searches. A benchmark comparison of NLO QCD predictions for jet production from different numerical codes can be useful for both the ongoing phenomenological studies and upcoming higher-order calculations. In this work we modify the original EKS program and compare the singlejet and dijet cross sections that it produces with the ones from the FastNLO program. We find a good agreement between two programs, apart from differences of up to $5-10 \%$ occuring at the highest jet $p_{T}$ 's and rapidities. We document the exact combination of theoretical settings in EKS that are needed to reproduce the FastNLO results. Based on the EKS calculation, we attempted to identify the choice of the renormalization and factorization scales that could simultaneously reduce the magnitude of NLO $K$ factors and/or scale dependence of the NLO cross section. Since we could not easily find such a scale combination, we propose to vary the factorization and renormalization scales in future (N)NLO PDF fits to better estimate theoretical uncertainties in the resulting PDFs. There is a plan to publish the updated EKS program in the near future [388].

## 14. PHENOMENOLOGICAL STUDIES WITH AMC@ NLO ${ }^{26}$

#### Abstract

We present four phenomenological studies of hadron collider processes performed within the aMC @ NLO framework

### 14.1 Introduction

aMC@NLO (http://amcatnlo.cern.ch) is a fully automated approach to complete event generation and subsequent parton shower at the NLO accuracy in QCD, which allows accurate and flexible simulations for both signals and backgrounds at hadron colliders. All calculational aspects in aMC @ NLO are automated. One-loop contributions are evaluated with MadLoop [8, 396], that uses the OPP integrand reduction method [121] as implemented in CutTools [135]. The other matrix-element contributions to the cross sections, their phase-space subtractions according to the FKS formalism [397], their combinations with the one-loop results, and their integration are performed by MadFKS [398] ${ }^{27}$. The matching of the NLO results with HERWIG [399] or PYTHIA [400] parton showers is performed with the MC@NLO method [401], and it is also completely automatic. Finally, aMC @ NLO can compute scale and PDF uncertainties at no extra CPU-time cost with the help of the process-independent reweighting technique described in [402].

For all technical details we refer to the original publications. We report here on the physics results obtained with aMC @ NLO for observables of interest at hadron colliders [15, 403, 402, 404]. We stress that they are simulated at the hadron level, namely including parton shower and hadronization effects. In Sects. 14.2, 14.3, and 14.4 we present results for the production of $t t H, V b b$, and four-lepton final states at the LHC, respectively. Section 14.5 reports on a study of the $W j j$ process at Tevatron. Finally, in sect. 14.6 we draw our conclusions. The list of the processes considered here should convince the reader that one can perform realistic analyses of experimental data, for signals and backgrounds, entirely within the aMC@NLO framework.

### 14.2 The $t t H$ process at the LHC

The production process of a $H$ boson in association with a top pair [15] is a classic mechanism for Higgs production at the LHC [24, 405], where the large $t t H$ Yukawa coupling and the presence of top quarks can be exploited to extract the signal from its QCD multi-jet background. As an example of the use of aMC @ NLO for this process we present, in Fig. 42, the Higgs transverse momentum distribution and the transverse momentum of the $t t H$ or $t t A$ system at the $\sqrt{s}=7 \mathrm{TeV}$ LHC for a Standard Model (scalar) Higgs with $M_{H}=120 \mathrm{GeV}$ and for a pseudoscalar one with $M_{A}=120 / 40 \mathrm{GeV}$. The total NLO cross sections in the three cases are $\sigma_{\mathrm{NLO}}\left(M_{H}=120\right)=103.4 \mathrm{fb}, \sigma_{\mathrm{NLO}}\left(M_{A}=120\right)=31.9 \mathrm{fb}$, and $\sigma_{\mathrm{NLO}}\left(M_{A}=40\right)=77.3 \mathrm{fb}$, respectively. At moderate values of the Higgs transverse momentum, the scalar and pseudoscalar cases are clearly distinguishable, while at larger values the three distributions tend to coincide. Parton shower effects give in general small corrections with respect to the a pure NLO calculation, except for variables involving all produced particles, such as the transverse momentum of the $t t H$ or $t t A$ system shown in the right panel of Fig. 42.

### 14.3 The $V b b$ process at the LHC

With $V b b$ we understand $\ell \nu b b$ and $\ell^{+} \ell^{-} b b$ final states [403], which are the main backgrounds to searches for SM Higgs production in association with vector bosons $(W H / Z H)$, with the subsequent Higgs decay into a $b b$ pair. The aMC @ NLO framework allows a realistic study including

- NLO corrections;

[^212]

Fig. 42: Higgs transverse momentum distributions (left) and transverse momentum of the $t t H$ or $t t A$ system (right) in $t t H / t t A$ events at the LHC ( $\sqrt{s}=7 \mathrm{TeV}$ ), with aMC @ NLO in the three cases: Scalar (blue) and pseudoscalar (magenta) Higgs with $m_{H / A}=120 \mathrm{GeV}$ and pseudoscalar (green) with $m_{A}=$ 40 GeV . In the lower panels of the left part, the ratios of aMC @ NLO over LO (dashed), NLO (solid), and aMC@LO (crosses) are shown. Solid histograms in the right panel are relevant to aMC@NLO, dashed ones to a pure NLO calculation.

- bottom quark mass effects;
- spin-correlation and off-shell effects;
- showering and hadronization.

As an example we show, in Fig. 43, the invariant mass of the pair of the two leading b-jets, compared with the signal distributions for a standard Higgs with $m_{H}=120 \mathrm{GeV}$. Fig. 43 is interesting because both signal and background are studied at the NLO accuracy. It should be noted that, since completely hadronized events are simulated, sophisticated studies of the jet sub-structure are possible within the aMC@NLO framework, as presented in Fig. 44 , where the fractions of events containing zero $b$-jets, exactly one $b$-jet, and exactly two $b$-jets are plotted. The $b$-jet fractions are fairly similar for $W b b$ and $Z b b$ production, and the effects of the NLO corrections are consistent with the fully-inclusive $K$ factors. On the other hand, the $b b$-jet contribution to the $b$-jet rate is seen to be more than three times larger for $\ell^{ \pm} \nu b b$ than for $\ell^{+} \ell^{-} b b$ final states. This fact is related to the different mechanisms for the production of a $b b$ pair in the two processes. At variance with the case of $\ell^{ \pm} \nu b b$ production, in a $\ell^{+} \ell^{-} b b$ final state the two $b$ 's may come from the separate branchings of two initial-state gluons, and thus the probability of them ending in the same jet is much smaller than in the case of a $g \rightarrow b b$ final-state branching, which gives the only possible contribution to a $\ell^{ \pm} \nu b b$ final state.

### 14.4 Four-lepton production at the LHC

Vector boson pair production is interesting in at least two respects. Firstly, it is an irreducible background to Higgs signals, in particular through the $W^{+} W$ and $Z Z$ channels which are relevant to searches for a standard model Higgs of mass larger than about 140 GeV . Secondly, di-boson cross sections are quite sensitive to violations of the gauge structure of the Standard Model, and hence are good probes of scenarios where new physics is heavy and not directly accessible at the LHC, yet the couplings in the vector boson sector are affected. We consider here the neutral process [402]

$$
p p \rightarrow\left(Z / \gamma^{*}\right)\left(Z / \gamma^{*}\right) \rightarrow \ell^{+} \ell^{-} \ell^{(\prime)+} \ell^{(\prime)-},
$$

Fig. 43: Invariant mass of the pair of the two leading $b$-jets. $W H(\rightarrow \ell \nu b b), Z H\left(\rightarrow \ell^{+} \ell^{-} b b\right), \ell \nu b b$, and $\ell^{+} \ell^{-} b b$ results are shown, with the former two rescaled by a factor of ten.

| Process | Cross section (fb) |  |  |
| :---: | :---: | :---: | :---: |
|  | $q \bar{q} / q g$ channels |  |  |
|  | $\mathcal{O}\left(\alpha_{s}^{0}\right)$ | $\mathcal{O}\left(\alpha_{s}^{0}\right)+\mathcal{O}\left(\alpha_{s}\right)$ | $g g$ channel |
| $p p \rightarrow e^{+} e^{-} \mu^{+} \mu^{-}$ | 9.19 | $12.90_{-0.23(1.8 \%)-0.22(1.7 \%)}^{+0.27(2.1 \%)+0.26(2.0 \%)}$ | $0.566_{-0.118(20.8 \%)-0.014(2.5 \%)}^{+0.162(28.5 \%)+0.012(2.1 \%)}$ |
| $p p \rightarrow e^{+} e^{-} e^{+} e^{-}$ | 4.58 | $6.43_{-0.13(2.0 \%)-0.10(1.6 \%)}^{+0.13(2.1 \%)+0.1(1.7)}$ |  |

Table 10: Total cross sections for $e^{+} e^{-} \mu^{+} \mu^{-}$and $e^{+} e^{-} e^{+} e^{-}$production at the $\mathrm{LHC}(\sqrt{S}=7 \mathrm{TeV})$ within the cuts $M\left(\ell^{ \pm} \ell^{(1) \mp}\right) \geq 30 \mathrm{GeV}$. The first and second errors affecting the results are the scale and PDF uncertainties (also given as fractions of the central values).
which, although smaller than the $W^{+} W^{-}$channel, may provide a cleaner signal due to the possibility of fully reconstructing the decay products of the two vector bosons. aMC @ NLO predictions for the cross sections are given in Tab. 10, which also includes aMC @ NLO estimates for scale and PDF uncertainties. The four-lepton invariant mass and the transverse momentum distribution are presented in Fig. 45, where comparisons between the results obtained with aMC @ NLO matched to HERWIG and to PYTHIA are also given. We stress that these results include the contributions due to $g g$-initiated processes, which have also been computed automatically. These are formally of NNLO, but may play a non-negligible phenomenological role owing to their parton-luminosity dominance at a large-energy collider such as the LHC.

### 14.5 Wjj at Tevatron

In [406] CDF reported an excess of events in two-jet production in association with a $W$ boson, in the form of a broad peak centered at $M_{j j}=144 \mathrm{GeV}$ in the dijet invariant mass ${ }^{28}$. Motivated by this fact, we present in Fig. 46]the aMC @ NLO prediction [404] for the dijet invariant mass in $W j j$ events, using the same cuts as CDF and D0 in the signal region, also comparing with a pure NLO computation and with the Alpgen [408] findings (one-, two-, and three-parton multiplicities have been consistently matched to

[^213]

Fig. 44: Fractions of events (in percent) that contain: zero $b$-jets, exactly one $b$-jet, and exactly two $b$-jets. The rightmost bin displays the fraction of $b$-jets which are $b b$-jets. The two insets show the ratio of the aMC @ NLO results over the corresponding NLO (solid), aMC @ LO (dashed), and LO (symbols) ones, separately for $W b b$ (upper inset) and $Z b b$ (lower inset) production.
obtain the latter). Perturbative, parton-level results agree well with those obtained after shower, and PDF and scale uncertainties (also reported in Fig. 46) are well under control. In summary, we do not observe any significant effects in the shape of distributions due to NLO corrections, which therefore cannot be responsible for the excess of events observed by the CDF collaboration.

### 14.6 Conclusions

The results we have presented in this contribution are based on the strategic assumption that, for the word automation to have its proper meaning, the only operation required from a user is that of typing-in the process to be computed, and other analysis-related information (such as final-state cuts). In particular, the codes that achieve the automation may only differentiate between processes depending on their general characteristics, but must never work on a case-by-case basis. The aMC@NLO framework is based on such an assumption, providing a very powerful tool to compare, at the NLO accuracy including showering and hadronization, theory and experiment in high energy collisions. As an example of the flexibility of aMC@NLO we have presented results for the processes $p p \rightarrow t t H, p p \rightarrow V b b, p p \rightarrow$ $\ell^{+} \ell^{-} \ell^{(1)+} \ell^{(1)-}$ at the LHC, and a study of $p \bar{p} \rightarrow W j j$ at Tevatron.

## 15. PROBING CORRECTIONS TO DIJET PRODUCTION AT THE LHC ${ }^{29}$

## Abstract

We compare and discuss a few kinematic distributions for dijet production at the LHC, computed with a fixed next-to-leading order code, with the

[^214]

Fig. 45: Four-lepton invariant mass and the transverse momentum distributions for aMC@NLO $+g g$ HERWIG (solid black) and PYTHIA (dashed blue) results. The rescaled $g g$ contributions with HERWIG (open black boxes) and PYTHIA (open blue circles) are shown separately. Middle insets: scale (dashed red) and PDF (solid black) fractional uncertainties. Lower insets: aMC@NLO/(aMC@NLO+gg) with HERWIG (solid black) and PYTHIA (dashed blue).

POWHEG BOX and with HEJ. Previous experimental studies have dealt with kinematic distributions where the predictions of the three approaches were very similar. In this proceeding, we investigate kinematic distributions where the resummed effects in POWHEG and HEJ are clearly shown and enhanced with respect to the fixed NLO result, since different QCD-radiation regimes are probed.

### 15.1 Introduction

Dijet production is one of the cornerstone processes at the LHC. The cross section for jet production is very large, making it an important testing ground for our understanding of QCD at high-energy scales. In addition, jet production is an important background for many searches for new physics. It is therefore essential to probe and test our theoretical predictions. Dijet-production studies can bring insights in jet production in association with other particles too: for example, Higgs boson production plus two jets in gluon fusion, a key process for assessing the CP properties of the Higgs boson, can benefit from these studies.

There have been a number of very interesting experimental studies in dijet production by both the ATLAS [410, 411, 294] and CMS [412, 413, 414, 415] Collaborations. It is already clear that higher order QCD contributions beyond a fixed order, low multiplicity calculation can be important because the large available phase space for jet emission at the LHC compensates for the suppression of extra powers of the strong coupling constant.

In this contribution, we compare two theoretical approaches to dijet production that include higher order effects: POWHEG [416, 417, 386, 13] and HEJ [418, 419, 64]. The POWHEG method successfully merges a fixed next-to-leading order (NLO) calculation with a parton shower program, that resums leading logarithmic contributions from collinear emissions. In this study, the POWHEG results obtained with the POWHEG BOX [13] are interfaced with the transverse-momentum-ordered shower

Fig. 46: Invariant mass of the pair of the two hardest jets, with CDF/D0 cuts of [406] (left) and of [409] (right).
provided by PYTHIA 6.4.21 [400]. In contrast, the starting point for HEJ is an all-order approximation to the hard scattering matrix element in the regime of wide-angle QCD emissions. HEJ is accurate at leading logarithmic precision in the invariant mass of any two jets. This is then supplemented with the missing contributions (through a merging and reweighting-procedure) necessary to also ensure tree-level accuracy for final states with up to four jets. The tree-level matrix elements are taken from Standalone Madgraph [163].

The POWHEG and HEJ approaches are clearly very different in their description of QCD radiation. Nevertheless, for several kinematic distributions (see for example ref. [410]) the predictions from POWHEG and HEJ are very similar. In this study, we investigate various observables which can expose the differences in the two approaches and we compare them with the fixed NLO results.

### 15.2 A comparison between NLO, POWHEG and HEJ in dijet production

In order to avoid biasing our event sample, we impose a minimal set of cuts, avoiding symmetric cuts on the jet transverse momenta that would give an unphysical cross section at fixed NLO level [420, 421], due to the presence of unresummed logarithms. Neither the POWHEG or HEJ descriptions suffer from this instability. However, in order to have a sensible fixed NLO cross section to compare with, we impose asymmetric cuts

$$
\begin{equation*}
p_{\mathrm{T}}^{j}>35 \mathrm{GeV}, \quad p_{\mathrm{T}}^{j_{1}}>45 \mathrm{GeV}, \quad\left|y_{j}\right|<4.7, \tag{99}
\end{equation*}
$$

i.e. all jets are required to have a minimum transverse momentum of 35 GeV , and the hardest-jet transverse momentum, $p_{\mathrm{T}}^{j_{1}}$, is required to be greater than 45 GeV . In order to comply with the experimental acceptance, all jets are further required to have an absolute rapidity $\left|y_{j}\right|$ less than 4.7. Jets are defined according to the anti-kt jet algorithm, with radius $R=0.5$. Only events with at least two jets fulfilling Eq. (99) are kept.

In the following, we compare the fixed NLO cross section with the POWHEG first emission results, with the POWHEG results showered by PYTHIA and with the HEJ predictions. The renormalization and factorization scales have been chosen equal to the transverse momentum of the hardest jet in each event, for the HEJ predictions. For the NLO computation (and for computing the POWHEG $\bar{B}$ function), scales are set to the transverse momentum of the so called underlying Born configuration. Scale-uncertainty bands obtained by varying these scales by a factor of two in each direction are shown for the NLO and HEJ results. The scales entering in the evaluation of parton distribution functions and

Fig. 47: The average number of jets as a function of $\Delta y_{\mathrm{fb}}$ (left plot) and of $H_{\mathrm{T}}$ (right plot), as predicted by a fixed NLO calculation, by POWHEG first emission, by POWHEG+PYTHIA and by HEJ. The dotted red lines around the HEJ prediction and the green ones around the NLO result are obtained by varying the renormalization and factorization scales by a factor of two around their central value.
of the strong coupling in the POWHEG Sudakov form factor are instead evaluated with a scale equal to the transverse momentum of the POWHEG hardest emission [417, 386].

In Fig. 47 we plot the average number of jets as a function of the rapidity difference between the most forward and most backward of the jets fulfilling Eq. (99), $\Delta y_{f b}$, on the left-hand side, and as a function of $H_{\mathrm{T}}=\sum_{j} p_{\mathrm{T}}^{j}$ on the right-hand side. The wide-angle resummation implemented in HEJ produces more hard jets than POWHEG and the fixed NLO calculation, as the rapidity separation between the most forward and the most backward jet in the event increases. Both the NLO and the firstemission POWHEG results have at most 3 jets, so that the average number of jets cannot exceed 3 , and give similar results. Additional jets are instead produced by the PYTHIA shower, so that the average number of jets is increased by roughly $20 \%$ with respect to the NLO one, for $\Delta y_{\mathrm{fb}} \approx 7$. For the same separation in rapidity, the HEJ prediction is $45 \%$ larger than the NLO result, with a chance to distinguish among the three approaches.

The dependence of the average number of jets from $H_{\mathrm{T}}$ (right plot) displays a different behaviour: here the showered events have on average more jets than HEJ and the NLO results, as the sum of the transverse momentum of all the final-state jets increases. It is interesting here to comment on the NLO result obtained with the factorization and renormalization scales set to $p_{\mathrm{T}}^{\mathrm{UB}} / 2$, i.e. half of the transverse momentum of the underlying Born configuration. In fact, from the plot, an unphysical behaviour of this quantity emerges: the average number of jets is greater than 3 above $H_{\mathrm{T}} \approx 270 \mathrm{GeV}$. This is due to the fact that the high $H_{\mathrm{T}}$ region is populated mostly by events with 3 jets, two of which have approximately the same high transverse momentum, and the third one is softer with respect to the other two (the cuts in Eq. (99) are always in place). In this configuration, the exclusive two-jet cross section becomes negative, due to incomplete cancellation of the virtual (negative) contribution, now enhanced by a higher value of the strong coupling constant, evaluated at a lower renormalization scale. A more detailed discussion can be found in ref. [422].

As a last example of a kinematic distribution that displays different behaviour if evaluated at NLO or using POWHEG or HEJ, we plot in Fig. 48 the average value of $\cos \left(\pi-\phi_{\mathrm{fb}}\right)$, where $\phi_{\mathrm{fb}}$ is the azimuthal angle between the most forward and backward jets, as a function of their rapidity separation $\Delta y_{\mathrm{fb}}$. For dijet events at tree-level, $\phi_{\mathrm{fb}}=\pi$ since the two jets must be back-to-back, and the average value of the cosine is 1 . Deviation from 1 then indicates the presence of additional emissions, so that

Fig. 48: The average value of $\cos \left(\pi-\phi_{\mathrm{fb}}\right)$ as a function of $\Delta y_{\mathrm{fb}}$, where $\phi_{\mathrm{fb}}$ is the azimuthal angle separation between the most forward and most backward jet. The dotted red and green lines are obtained by varying the renormalization and factorization scales by a factor of 2 in both directions.
this kinematic distribution carries information on the decorrelation between the two jets. This quantity is more inclusive than the average number of jets as it is sensitive also to emissions below the jet $p_{\mathrm{T}}$ cut. The higher radiation activity in POWHEG+PYTHIA and in HEJ, with respect to the fixed NLO and the POWHEG first-emission results, is clearly visible in the figure: the stronger jet activity produced by HEJ at higher rapidity separation (see the left plot of Fig. 47) lowers the average value of the cosine below the POWHEG+PYTHIA result. As expected, the average value predicted by the POWHEG first-emission and the NLO calculation is closer to 1 , since they contain at most one radiated parton.

## Conclusions

In this proceeding, we have discussed the results obtained using a fixed NLO calculation, HEJ and POWHEG+PYTHIA, in the description of three kinematic distributions, selected in order to display more clearly the differences among the three approaches: the average number of jets and azimuthal decorrelation between the most forward and the most backward jet, plotted as a function of the rapidity separation of the most forward and the most backward jet, and the average number of jets plotted as a function of the sum of the transverse momenta of all the jets in the event.

While the limitations of the NLO calculation are clearly visible when we probe regions of the phase space where multi-jet emissions becomes important, the predictions of POWHEG+PYTHIA and HEJ are distinguishable when dealing with the average number of jets as a function rapidity span. Less marked differences are found as a function of Ht , and in the study of the azimuthal decorrelation of the most forward and backward jet.

An experimental analysis of the dijet data, collected at the LHC, should then follow to investigate to which extent our theoretical knowledge for these kinematic distributions is under control.

## 16. W+JETS PRODUCTION AT THE LHC: A COMPARISON OF PERTURBATIVE TOOLS 30

#### Abstract

In this contribution, we discuss several theoretical predictions for $W$ plus jets production at the LHC, compare the predictions to recent data from the ATLAS collaboration, and examine possible improvements to the theoretical framework.

### 16.1 Motivation

Experimentalists are reliant on a number of tools, at LO and NLO, at parton level and at hadron level, in order to understand both simple and complex final states at the LHC. One of the benchmark processes, for both signals to new physics and for their backgrounds, is the production of $W$ plus jets. In this contribution, we discuss several different predictions for the $W$ plus jets final state, concentrating on the $H_{T}$ distribution. We examine where the predictions agree, and where they disagree and compare the predictions to LHC data. We introduce the idea of NLO 'Exclusive Sums', and discuss the performance of this technique and consider also how LoopSim may be able to improve the predictions. We document the use of ROOT ntuples for $W$ plus jets predictions produced by the BlackHat+Sherpa collaboration, indicating how they can be used to examine the variation of the cross sections with jet size/algorithm, PDFs, and scale choices. We also study the possibility of using the LoopSim method together with BlackHat+Sherpa type ntuples, since this may offer the opportunity to improve on the results from NLO Exclusive Sums.

### 16.2 Theory tools: strengths and weaknesses

NLO is the first order at which the normalization (and sometimes the shape) of LHC cross sections can be realistically calculated. The state of the art is in parton-level programs such as BlackHat+Sherpa, where $W+n$-jet cross sections are available, with $n$ up to 4 at NLO [70, 51, 22] (and soon up to 5 [423]). Of course, such parton-level final states do not allow for the full comparisons to the data allowed by the full parton shower Monte Carlo programs such as Sherpa. NLO matrix elements have been included into parton shower Monte Carlos, but only for relatively simple final states (although we note that the NLO matrix elements for $W+2$ jets [404] and $W+3$ jets [424] have recently been implemented in parton shower Monte Carlo programs).

The Sherpa Monte Carlo program [146, 425] includes the exact LO $W+n$-parton ( $W+n$ jet) matrix elements, with $n$ up to 4 (in this study), using the newer ME\&TS scheme as introduced in Refs. [426, 427, 428] for the addition of states with different jet multiplicities with the correct normalizations. The newer matrix-element plus parton-shower merging scheme improves over the CKKW [429, 430] formalism by allowing for a better interplay between the matrix-element and partonshower descriptions. This in particular required the implementation of truncated showers ('TS'). As before, additional jets are, of course, then produced by the parton shower. Both BlackHat+Sherpa and Sherpa rely on DGLAP-based evolution of gluon emission, on the assumption that the gluon emissions are strongly ordered in transverse momentum. For an alternative prediction, we use the program HEJ [418, 419, 431]. The High Energy Jets (HEJ) framework provides a leading-log resummation of the dominant terms in the limit of large invariant mass between jets. In addition, HEJ contains a merging procedure to ensure tree-level accuracy for final states with two, three or four jets.

[^215]A NLO $n$-jet prediction produces events with with either $n$ or $n+1$ partons. For observables for which higher multiplicities have a significant impact, this limitation can be detrimental. If one has predictions for different multiplicities, one can try to combine them by avoiding double counting by requiring that the $n$-jet prediction is used only to describe $n$-jet events (except for the highest multiplicity where ( $n+1$ )-jets configurations are allowed). This procedure is crude and does not increase the formal accuracy of the prediction which is that of NLO of the smallest multiplicity. The idea is that, in observables where higher multiplicities events dominate, a better prediction might be obtained. This has been denoted as the 'Exclusive Sums' technique. The impact of the Exclusive Sums approach depends on the kinematic variable under consideration. For this contribution, we consider only the $H_{T}$ variable, defined as the sum of the transverse momenta of all of the leptons (including neutrinos) and jets in the event. The impact of the approach is expected to depend on the observable under consideration and it may be more beneficial for variables sensitive to multi-jet radiation, such as $H_{T}$, than for more inclusive variables such as $p_{t, W}$. Comparisons for the latter are left to a study now in progress.

### 16.3 Use of BlackHat+Sherpa ntuples

As has been partially detailed in these proceedings, there have been many advances in the computation of the NLO corrections for multi-parton final states. Often such calculations do not exist in a compact user-friendly form, and other means must be taken to allow experimentalists to have access to the results. The BlackHat+Sherpa collaboration has chosen to make available ROOT tuples that contain all of the parton-level information needed to form flexible predictions. The ROOT ntuple framework is a very efficient way to store such information and the use of ROOT tuples is very familiar to experimentalists.

The ROOT ntuples store the four-vectors for the final state partons, as well as their flavor information. The calculation is originally performed using a specific choice of PDF, $\alpha_{s}\left(m_{Z}\right)$, renormalization scale $\mu_{R}$ and factorization scale $\mu_{F}$, but weight information is also stored in the ntuples that allows each event to be easily re-weighted to any other (reasonable) values for the above parameters. (PDFs are varied through calls to LHAPDF [432].) No jet clustering has been performed on the final state partons; jet reconstruction is left to the user, for any jet algorithm/size for which the correct counter-events are present in the ntuple. For the results presented here, the SISCone [433], $k_{T}$ [361] and anti- $k_{T}$ [341] algorithms, with jet radii $R$ of $0.4,0.5,0.6$ and 0.7 can be used. Each of the above jet algorithms were run and the results stored in SpartyJet ntuples ${ }^{31}$ The SpartyJet tuples were 'friended' with the BlackHat+Sherpa ntuples, allowing the analysis script access to all jet information. Such a flexibility allows for an investigation of the dependence of the physics on the details of the manner in which the partons are combined into jets, in a manner difficult to achieve prior to this.

The four-vector information stored in the BlackHat+Sherpa ntuples is shown in Table 11. Note the variety of entries needed for the re-weighting of the cross section results, especially for the case of the variation of the two scales $\mu_{R}$ and $\mu_{F}$. Information is stored in separate ntuples for the different categories of events, which are typically Born, loop (leading color and sub-leading color), real and subtraction terms. For large $n$, in $W+n$-parton final states, there are many divergences present when two partons become collinear or one parton becomes soft. These divergences are controlled using the traditional Catani-Seymour approach [236], which involves the generation of many counter-events. Many of the events have negative weights; only the sum is guaranteed to be positive-definite. Predictions with reasonable statistical precision may require the sum of billions of events. The resultant tuples may amount to several Terabytes. However, the output can be subdivided into ROOT files of order 5-10 GB, allowing for simultaneous parallel processing of the events over multiple nodes, such as in the Tier3 facility at Michigan State University used for these comparisons.

[^216]
### 16.4 BlackHat+Sherpa predictions

We have generated NLO predictions with the BlackHat+Sherpa predictions implementing the cuts used in the 2010 ATLAS $W$ plus jets paper [436]. For completeness, the cuts are reproduced below:

- $p_{T}^{\text {lepton }}>20 \mathrm{GeV}$,
- $\left|\eta^{\text {lepton }}\right|<2.4$,
- $E_{T}^{\text {miss }}>25 \mathrm{GeV}$,
- $m_{T, W}>40 \mathrm{GeV}$,
- $p_{T}^{\text {jet }}>30 \mathrm{GeV}$,
- $\left|y^{\text {jet }}\right|<4.4$,
- $\Delta R^{\text {lepton-jet }}>0.5$.

In Figure 49, we show the NLO BlackHat+Sherpa prediction for the $H_{T}$ distribution for $W+\geq 1$ jets (left) using the anti- $k_{T}$ jet algorithm with $R=0.4$. As the prediction is an inclusive NLO calculation for $W+\geq 1$ jets, there are contributions from both the one-jet and the two-jet final states. Note that as $H_{T}$ increases, the contributions from the $W+2$-jet subprocess also increases. On the right, we again show the $H_{T}$ distribution, but now compute the prediction using the 'Exclusive Sums' technique, adding in the NLO $W+2$-jet information. Now there is a significant contribution at high $H_{T}$ from the $W+3$ -

| branch name | type | notes |
| :---: | :---: | :---: |
| id | I | id of the event. Real events and their associated counter-terms share |
| nparticle | I | number of particles in the final state |
| px | F[nparticle] | array of the x components of the final state particles |
| py | F[nparticle] | array of the $y$ components of the final state particles |
| pz | F[nparticle] | array of the z components of the final state particles |
| E | F[nparticle] | array of the energy components of the final state particles |

Table 11: Branches in a BlackHat+Sherpa ROOT file.

Fig. 49: The $W$ plus jets cross section, as a function of $H_{T}$, for the NLO inclusive $W+\geq 1$-jet prediction (left) and for the Exclusive Sums approach, adding in $W+2$-jet production at NLO (right). The cross sections have been evaluated at a central scale of $H_{T} / 2$ and the uncertainty is given by varying the renormalization and factorization scales independently up and down by a factor of 2 , while ensuring that the ratio of the two scales is never larger than a factor of 2 .
jet final state as well. In Figure 50, the $H_{T}$ prediction is shown using the Exclusive Sums approach, adding $1+2+3$ jets at NLO (left) and $1+2+3+4$ jets at NLO (right). It is evident that as $H_{T}$ increases, contributions from higher jet multiplicities that are only present implicitly in a traditional inclusive NLO $W+\geq 1$-jet calculation, become important. The Exclusive Sums $H_{T}$ predictions agree with that for the inclusive NLO $W+\geq 1$-jet calculation at low $H_{T}$, but are larger at higher $H_{T}$, and in better agreement with the ATLAS data (as discussed below).

However, it can also be noticed that the scale dependences for the Exclusive Sums predictions apparently get better when the 2 -jet NLO information is added, but significantly worse when the 3 -jet and 4 -jet information is added. As discussed in the Appendix, the reduction in scale dependence with the addition of the 2-jet NLO terms may be due to the stabilization of the predictions for the $q q \rightarrow W q^{\prime} q$ topologies. Adding the 3 -jet and 4 -jet NLO terms seems to destabilize the predictions. There are missing Sudakov terms needed to properly 'stitch' the different multiplicity samples together; it is hoped that the LoopSim technique may offer one way in supplying those missing terms.

Below in Figure 51, we show the NLO BlackHat+Sherpa predictions for the $H_{T}$ distribution for $W+\geq 2$ jets: the inclusive calculation to the left, the Exclusive Sums result adding $2+3$-jet NLO information in the middle and the Exclusive Sums result adding 2+3+4-jet NLO information to the right. Over the kinematic range covered in these plots, the Exclusive Sums technique adds less to the cross section at high $H_{T}$, although there is still a degradation of the scale dependence.

Fig. 50: The $W$ plus jets cross section, as a function of $H_{T}$, for $W+\geq 1$-jet production using the Exclusive Sums approach, and adding up to 3 jets at NLO (left) and 4 jets at NLO (right). The cross sections have been evaluated at a central scale of $H_{T} / 2$ and the uncertainty is given by varying the renormalization and factorization scales independently up and down by a factor of 2 , while ensuring that the ratio of the two scales is never larger than a factor of 2 .

Fig. 51: The $W$ plus jets cross section, as a function of $H_{T}$, for $W+\geq 2$-jet production using the inclusive NLO production (left) and the Exclusive Sums approach, adding up to 3 jets at NLO (center) and 4 jets at NLO (right). The cross sections have been evaluated at a central scale of $H_{T} / 2$ and the uncertainty is given by varying the renormalization and factorization scales independently up and down by a factor of 2 , while ensuring that the ratio of the two scales is never larger than a factor of 2 .

### 16.5 Towards interfacing BlackHat+Sherpa ntuples with LoopSim

LoopSim is a method to simulate higher order QCD corrections, in particular those beyond NLO. It is expected to work best for processes with large NLO-to-LO $K$-factor, however it was found to be advantageous even in some cases where the $K$-factor is moderate [437]. The method is based on unitarity and its main ingredient is a procedure that takes events from a process with $n+m$ partons in the final state and produces counter-term events with $n+m-1, n+m-2, \ldots, n$ particles, which approximate 1-loop, 2-loop, etc. contributions. In contrast to the Exclusive Sums method, it enables one to introduce (approximate) virtual corrections beyond 1-loop, thus ensuring that the $\alpha_{s} L^{2}$ type terms cancel for all the orders that are included. While we will not show LoopSim results that are directly comparable to the ATLAS data (the samples were generated before those cuts were made public), we will examine below the dependence on the $p_{t, \min }$ choice (which sets the size of $L=\ln O_{t} / p_{t, \min }$ where $O_{t}$ is a transverse observable) and see that it vanishes as $p_{t, \text { min }} \rightarrow 0$.

To distinguish between the exact result at the order $\mathrm{N}^{p} \mathrm{LO}$ and the result with simulated loops we use a notation in which we replace N by $\bar{n}$ for the orders simulated by LoopSim. So for example, $W+1$ jet at $\bar{n} \mathrm{LO}$ has approximate 1 -loop diagrams and is obtained by combining $W+1$ jet at LO with $W+2$ jet at LO where the latter is passed through LoopSim. Similarly $W+1$ jet at $\bar{n}$ NLO has exact 1-loop diagrams but simulated 2-loop contributions (by using $W+2$ jet at NLO as an input to LoopSim).

As argued in the previous section, the BlackHat+Sherpa ntuples allow one to efficiently perform a broad range of analyses. They have however a limitation. In order to reduce the size of stored files, the only partonic events that are recorded for the $W+n$-jet sample are those in which there are at least $n$ jets above a 20 GeV threshold. Since this threshold is below the jet cuts used by ATLAS and CMS, it is adequate for any NLO study of LHC jet cross sections. The situation is slightly more complex if we want to use the BlackHat+Sherpa ntuples to compute predictions beyond NLO using LoopSim. This is because the cut that is present in the $W+2$-jet BlackHat+Sherpa NLO sample eliminates part of the real contribution to the $W+1$-jet phase space at NNLO, for example $W+3$-parton events in which the 3 partons all form part of a single jet, or in which 2 partons form part of one jet, while the third is well separated in angle but below the 20 GeV jet threshold.

Since we plan to use LoopSim interfaced to BlackHat+Sherpa ntuples in our future study of multijet processes, it is important to directly check the effect of the finite generation $p_{t}$ cut, $p_{t, \mathrm{gen}}^{\min }$, on the predictions of the $p_{t}$ and $H_{T}$ distributions. We have performed such a study for $W^{-}+1$ jet generated with MCFM, where we varied a 'parton'- $p_{t}$ generation cut from 1 to $20 \mathrm{GeV}{ }^{32}$ This is not entirely equivalent to the cut in the BlackHat+Sherpa samples (which is applied to the standard jets, not to the partons), but should be adequate from the point of view of estimating the potential order of magnitude of finite generation cuts. The output from MCFM was interfaced to LoopSim which produced the additional loop diagrams. Then, the events were analyzed with the following set of cuts: $\left|y^{\text {lepton }}\right|<2.5, p_{T}^{\text {lepton }}>$ $20 \mathrm{GeV},\left|y^{\mathrm{jet}}\right|<4.5, p_{T}^{\text {jet }}>25 \mathrm{GeV}, m_{T, W}<20 \mathrm{GeV}$, where the anti- $k_{T}$ algorithm with $R=0.4$ was used for clustering.

The results are presented in Figure 52 where the ratios of cross sections obtained with a range of generation cuts are shown as functions of the $p_{t}$ of the leading jet and $H_{T, \text { jets }}$. At NLO, the only artefact we see is for the $p_{t, \text { gen }}^{\min }$ of 20 GeV in the bin below 40 GeV . This is as expected, since a 20 GeV cut on each of two partons can at most affect jets up to 40 GeV (such an artefact would not be present in the BlackHat+Sherpa samples). At $\bar{n} \mathrm{LO}$ and $\bar{n} \mathrm{NLO}$, however, the dependence on $p_{t, \mathrm{gen}}^{\min }$ is extended to a larger range of $p_{t, \text { lead.jet }} / H_{T, \text { jets }}$ and it is visible also for values of $p_{t, \text { gen }}^{\min }<20 \mathrm{GeV}$. However, even if the $p_{t, \text { gen }}^{\min }$ dependence of the $\bar{n} \mathrm{LO}$ and $\bar{n} \mathrm{NLO}$ results is stronger than at NLO, it dies out quickly with increasing $p_{t, \text { lead.jet }} / H_{T, \text { jets }}$ and becomes irrelevant at $\sim 100 \mathrm{GeV}$, depending on the observable and the

[^217]

Fig. 52: Ratios of cross sections from runs with a certain range of $p_{t, g e n}^{\min }$ values taken wrt. the cross section generated with $p_{t, \mathrm{gen}}^{\min }=1 \mathrm{GeV}$ for the distributions of $p_{t}$ of the leading jet (left) and the scalar sum of jets' transverse momenta, $H_{T, \text { jets }}$ (right).
order. This appears to be consistent with the expectation that the effect of the cut should vanish as a power of $p_{t, \text { gen }}^{\min } / p_{t, \text { lead.jet }}$ or $p_{t, \text { gen }}^{\min } / H_{T, \text { jets }}$.

Therefore we conclude, that in spite of the finite generation cut one should be able to trust the results obtained using BlackHat+Sherpa ntuples, above a moderate $p_{t}$ limit, even for more complex analyses such as those involving LoopSim.

### 16.6 Comparisons to data, Sherpa and HEJ predictions

In Figure 53 (left), we compare the ratio of the 2010 ATLAS $W$ plus jets data for the $H_{T}$ distribution for $W+\geq 1$ jets to predictions using the generic NLO calculation for $W+\geq 1$ jet, the Exclusive Sums approach adding up to 4 jets at NLO and the Monte Carlo event generator Sherpa. The agreement between the data and the pure NLO result is rather poor; it improves substantially with the inclusion of the Exclusive sums up to two jets at NLO, with further small improvements coming from higher multiplicities. As a reminder, we previously noted that the scale dependence improved when adding the 2 -jet NLO information, but degraded when adding higher jet multiplicities. The Sherpa prediction slightly overshoots the data for $H_{T}$ in the inclusive $W+1$-jet bin. We however note that the data versus Sherpa $H_{T}$ ratio has been formed based on the absolute normalization as given by the Monte Carlo simulation. Comparing the inclusive 1-jet cross sections, we find a factor of 0.97 between the data and the Sherpa result.

In Figure 53 (right), we compare the ratio of the 2010 ATLAS $W$ plus jets data for the $H_{T}$ distribution for $W+\geq 2$ jets to predictions using the generic NLO calculation for $W+\geq 2$ jet, the Exclusive Sums approach adding up to 4 jets at NLO, and to predictions from HEJ and from Sherpa. As noted previously, there is some increase in the predictions from the Exclusive Sums approach at the highest $H_{T}$ values, but not nearly as much as in the $W+\geq 1$-jet case. These increases go in the direction of closer agreement with the data, but the statistical error does not allow a clear judgement to be made. The Sherpa and HEJ predictions for this ratio are in reasonable agreement with the data but appear to fall off somewhat more rapidly at large $H_{T}$ than either the data or the various BlackHat+Sherpa predictions. Again this partly is the result of relying on the absolutely normalized Monte Carlo predictions, which yield $W+\geq 2$-jet normalization factors of 0.95 or 0.93 between data and Sherpa or HEJ, respectively.

Fig. 53: The ratios of the ATLAS $W+\geq 1$-jet (left) and $W+\geq 2$-jet (right) cross sections, as a function of $H_{T}$, taken wrt. various theory predictions. The absolute normalization has been kept as given by the calculations. The error bars represent the total fractional error (statistical plus systematic added in quadrature) at each point.

Fig. 54: (left) The fraction of the $H_{T}$ cross section for $W+\geq 1$-jet events arising from the $W+\geq 2$-jet, $W+\geq 3$-jet and $W+\geq 4$-jet final states derived from the Exclusive Sums approach, from Sherpa and from HEJ, compared to the 2010 ATLAS data. (right) The ratio of the cross sections for $W+\geq 3$ jets to $W+\geq 2$ jets, as a function of $H_{T}$, using predictions from the Exclusive Sums approach, from Sherpa and from HEJ, compared to the ratio from the 2010 ATLAS data.

In Figure 54 (left), we show the predictions for the fractions of the $H_{T}$ cross section in the inclusive $W+1$-jet bin arising from the inclusive $W+2$-jet, $W+3$-jet and $W+4$-jet final states as obtained from the Exclusive Sums approach and from Sherpa, compared to the 2010 ATLAS data. In Figure 54
(right), we show the ratio of the cross sections for $W+\geq 3$ jets to $W+\geq 2$ jets, as a function of $H_{T}$, again using predictions from the Exclusive Sums approach and from Sherpa but also from HEJ. We again compare to the ratio given by the 2010 ATLAS data. All three predictions agree with each other and with the data over the range considered, despite the big differences in the approaches. There may be an indication of some separation between the predictions at the very highest $H_{T}$ values.

### 16.7 Conclusions, outlook and future studies

The advances achieved over the last few years in calculating NLO corrections for multi-jet final states allow a more serious consideration of the possibility to combine various $n$-jet NLO predictions into an inclusive jet sample. The Exclusive Sums approach discussed in this contribution is a first promising step into this direction. More studies are required to understand the uncertainties related to this procedure. One way of doing so would be to test the stability of the predictions against variation of the jet algorithm and/or parameters of the jet algorithm used to obtain and separate the different NLO predictions for the fixed-multiplicity sets that eventually make up the sum of exclusive $n$-jet contributions. ${ }^{33}$

For the Exclusive Sums approach, outlined here for the case of $W+\geq 1$ jets, contributions are added proportional to $\alpha_{s}^{2}\left(W+1\right.$ jet at NLO), $\alpha_{s}^{3}$ ( $W+2$ jets at NLO), $\alpha_{s}^{4}(W+3$ jets at NLO) and $\alpha_{s}^{5}\left(W+4\right.$ jets at NLO), i.e. this procedure mixes powers of $\alpha_{s}$ and thus is missing essential Sudakov form factors that effectively bring each term to the same power of $\alpha_{s}$. One could imagine accomplishing this by embedding the NLO matrix elements in a parton shower Monte Carlo framework, however the technology for merging different multiplicities of NLO calculations with a parton shower is still under development. Note that at LO the tree-level matrix-element plus parton-shower merging methods (e.g. as implemented in Sherpa) are designed to satisfy this same- $\mathcal{O}\left(\alpha_{s}\right)$ requirement by including the (allorders) leading-log effects to the 'LO Exclusive Sums' exhibiting the LO analog of the Exclusive Sums discussed here. Compared to the matrix-element plus parton-shower merging, we see that the 'NLO Exclusive Sums' technique only accounts for Sudakov effects up to $\mathcal{O}\left(\alpha_{s}\right)$ while it describes each jet bin at full NLO instead of LO accuracy.

Relying on the parton shower Monte Carlo framework is not the only way to go in refining the Exclusive Sums strategy. Alternatively, the LoopSim method can be used to provide approximations to the higher-loop terms missing in the Exclusive Sums approach. As we have seen here, prospects for using it together with BlackHat+Sherpa ntuples seem promising. A detailed comparison of the LoopSim results to LHC data is however beyond the scope of this Les Houches contribution, though we look forward to it being carried out in the near future.

The ATLAS data taken in 2011 is about a factor of 130 times as large as the data taken in 2010 (the only published data for $W$ plus jets so far). This will allow a much further reach in all kinematic variables. To get an idea, we show in Figure 55 the ratio of the predictions from the Exclusive Sums to the respective inclusive NLO predictions for $W+\geq 1,2,3$ jets. At an $H_{T}$ value of 2 TeV , the ratio for $W \geq 1$ jet is of the order of 2 ; the ratio for $W \geq 2$ jets rises to about 1.4. The NLO-to-LO $K$ factor for $W+\geq 1$ jet rises rapidly with increasing $H_{T}$, while the $K$-factor for $W+\geq 2$ jets increases only moderately (because no new subprocesses are being introduced). It will be interesting to see if (a) the additional factor of 2 (for the $W+\geq 1$-jet case) and (b) the additional factor of approximately 1.4 (for the $W+\geq 2$ jet case) lead to better agreement with the data. The LHC data from 2011 (and the higher statistics expected in 2012) will reach these kinematic values and should shed further light on the necessity and the efficacy of this theoretical technique, not only for $W+\geq 1$ jet, but for higher jet multiplicities as well.

[^218]

Fig. 55: The ratio of the predictions obtained from the NLO Exclusive Sums approach to the inclusive NLO predictions for $W \geq 1$ jets, $W \geq 2$ jets and $W \geq 3$ jets. The ' jitter ' is due to the limited BlackHat+Sherpa statistics for these predictions.

## Acknowledgments

We would like to thank the Les Houches organizers for a very stimulating workshop, and Zvi Bern, Lance Dixon and Kemal Ozeren for useful discussions. GPS and SS gratefully acknowledge support from the Agence Nationale de la Recherche under grant ANR-09-BLAN-0060. JMS is supported by the UK Science and Technology Council (STFC). JH acknowledges support from the National Science Foundation.

## Appendix: a double logarithmic analysis of the Exclusive Sums method

To help understand the structure of the Exclusive Sums method, it can be useful to consider how it works in a simple double logarithmic approximation. We use $p_{t, \min }$ to represent the minimum $p_{t}$ for the jets in the Exclusive Sums sample, and first study the cross section for $W$ production as a function of $p_{t, W}$ at high $p_{t, W}\left(\gg m_{W}\right)$, considering in particular the terms that go as $\alpha_{s}^{n} L^{2 n}$ where $L=\ln p_{t, W} / p_{t, \min }$. The 0 -jet sample does not contribute at all to non-zero $p_{t, W}$, so the first term comes from the exclusive 1 -jet contribution. If calculated to all orders in the double logarithmic approximation (DLA), it would have the form

$$
\begin{equation*}
\sigma_{1, \operatorname{excl}}^{\mathrm{DLA}}\left(p_{t, W}\right)=\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \exp \left(-\frac{2 C \alpha_{s}}{\pi} L^{2}\right) \tag{100}
\end{equation*}
$$

where $C=2 C_{F}+C_{A}$ for the (dominant) $q g \rightarrow W^{ \pm} q^{\prime}$ scattering process. The $n$ exclusive jet rate would be given by

$$
\begin{equation*}
\sigma_{n, \mathrm{excl}}^{\mathrm{DLA}}\left(p_{t, W}\right)=\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \frac{1}{(n-1)!}\left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)^{n-1} \exp \left(-\frac{2 C \alpha_{s}}{\pi} L^{2}\right) \tag{101}
\end{equation*}
$$

and one sees that the sum over all multiplicities is given by

$$
\begin{equation*}
\sigma\left(p_{t, W}\right)^{\mathrm{DLA}}=\sum_{n=1}^{\infty} \sigma_{n, \mathrm{excl}}^{\mathrm{DLA}}\left(p_{t, W}\right)=\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \tag{102}
\end{equation*}
$$

i.e. in the double logarithmic approximation, there are no corrections to the $p_{t, W}$ distribution at high $p_{t, W}$. Now let us consider what happens if we expand each of the exclusive sums to NLO. For the $n$-jet cross section, we have

$$
\begin{equation*}
\sigma_{n, \mathrm{excl}}^{\mathrm{NLO}(\mathrm{DLA})}\left(p_{t, W}\right) \simeq \sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \frac{1}{(n-1)!}\left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)^{n-1}\left(1-\frac{2 C \alpha_{s}}{\pi} L^{2}\right) \tag{103}
\end{equation*}
$$

Performing the sum over $n$, which corresponds to summing an infinite tower of NLO exclusive jet calculations, leads to

$$
\begin{align*}
\sigma\left(p_{t, W}\right)^{\mathrm{DLA}} & =\sum_{n=1}^{\infty} \sigma_{n, \mathrm{excl}}^{\mathrm{NLO}(\mathrm{DLA})}\left(p_{t, W}\right)  \tag{104a}\\
& =\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right) \exp \left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)\left(1-\frac{2 C \alpha_{s}}{\pi} L^{2}\right)  \tag{104b}\\
& =\sigma_{1}^{\mathrm{LO}}\left(p_{t, W}\right)\left(1-\frac{1}{2}\left(\frac{2 C \alpha_{s}}{\pi} L^{2}\right)^{2}+\mathcal{O}\left(\alpha_{s}^{3} L^{6}\right)\right) . \tag{104c}
\end{align*}
$$

As long as $L^{2}$ is not large, the difference between this and the correct answer of Eq. 102 is a straightforward NNLO correction, i.e. small. However when $p_{t, W} \gg p_{t, \min }$ the logarithms become large, the $\alpha_{s}^{2} L^{4}$ term can be of order 1 and the Exclusive Sums method may then no longer be a good approximation. A similar analysis can be performed for an exclusive sum truncated at some finite order, as used in our study.

Given the above discussion, one may wonder then if there are any circumstances in which the Exclusive Sums method will bring benefits. For the observable studied in this contribution, $H_{T}$, the key difference with respect to $p_{t, W}$ is that it is subject to a 'giant' $K$-factor at NLO. This phenomenon is associated with 'dijet' topologies in which a soft or collinear $W$ is radiated off the dijet system, leading to a double logarithmic (electroweak) enhancement. In addition these topologies can be created by $q q$ type scattering (whereas the LO process involves only $g q$ or $q \bar{q}^{\prime}$ scattering), leading to further enhancement in $p p$ collisions at large $H_{T}$. Dijet type topologies contribute significantly to the $H_{T}$ distribution, even when the $W$ is soft, because the variable sums all particles' transverse momenta (whereas the softness of the $W$ limits these topologies' contribution to the $p_{t, W}$ distribution).

Because of the giant $K$-factor, for the $H_{T}$ variable the behaviour of the Exclusive Sums method is more subtle than for $p_{t, W}$ : while the $\sigma_{W+2}^{\mathrm{NLO}}$ contributions destabilize the prediction for the $q g \rightarrow W q^{\prime}$ type topologies, they instead stabilize the prediction for the much larger $q q \rightarrow W q^{\prime} q$ topologies (present only at LO in a NLO $W+1$-jet calculation). Going further in the exclusive sum, however, i.e. including $\sigma_{W+3}^{\mathrm{NLO}}$ and $\sigma_{W+4}^{\mathrm{NLO}}$ contributions can however destabilize the predictions for both kinds of topologies. Traces of this behaviour were visible in the numerical studies shown above.

## 17. $W$ PRODUCTION IN ASSOCIATION WITH MULTIPLE JETS AT THE LHC ${ }^{34}$

#### Abstract

We compare the results from four different theoretical predictions for the production of a $W$ boson in association with at least two jets at the Large Hadron Collider. We discuss a possible method for combining next-to-leading order samples with different jet multiplicity from BlackHAT+SHERPA. We then compare these results with the next-to-leading order $W$ plus two jet calculation, the leading order ME\&TS merged approach of SHERPA and the highenergy resummation approach of High EnERGY JETS in an attempt to determine if these approaches can be distinguished at the LHC.

### 17.1 INTRODUCTION

The production of a $W$ boson in association with jets at the Large Hadron Collider (LHC) is an extremely important process. It contributes to three distinct areas of the rich physics program at the LHC. Firstly, it is a key Standard Model signal and therefore important to test our understanding of the Standard Model in the TeV -scale energy range. Secondly, it is an important background in many searches for new physics where, for example, new heavy coloured particles have cascade decay chains. Thirdly, it provides an ideal testing ground for experimental techniques such as a jet veto: what is learned in the relatively well-understood treatment of $W$ plus jets can be directly applied to Higgs searches for example.

It has been observed that the ratio of $W+(n+1)$-jet events to $W+n$-jet events can be substantially larger than one might naïvely expect by considering the $\alpha_{s}$ suppression only. This is especially true in phase-space regions of large four-momenta, such as the high- $H_{T}$ tail, because the available phase space for extra jet emission at the LHC is extremely large. It can therefore compensate for the effect of an additional factor of the strong coupling. This effect is more visible in distributions where additional radiation leads to a significant change in the value of the observable, as is the case for the $H_{T}$ distribution, the scalar sum of the transverse momenta of identified leptons, jets and missing energy. The change will be more moderate in an observable like $H_{T, 2}$, whose definition differs from that of $H_{T}$ by truncating the jet sum to include only the two hardest jets in the event. To make an impact here requires the radiation to lead to an additional jet with transverse momentum as large as that of the second hardest jet, not only larger than the jet $p_{T}$ threshold. The effects will also be smaller in more inclusive variables like the transverse momentum of the $W$ boson, $p_{T, W}$, or the leading jet, $p_{T, j_{1}}$.

There are a number of different theoretical approaches to describing the emission of large numbers of jets. In order to probe to what extent the differences in these will be accessible at the LHC, we will compare, in this study, the predictions for the jet activity in inclusive $W(\rightarrow e \nu)+2$-jet production from (a) BLACKHAT+SHERPA $(B H S)$ [70, 51, 22], (b) combined $B H S$ samples (to be described below), (c) Sherpa [146, 425] run in ME\&TS mode (S-MEPS) [426, 427, 428] and (d) High Energy Jets (HEJ), an all-order resummation of wide-angle radiation [418, 419, 438].

The current state-of-the-art next-to-leading order (NLO) predictions for $W$ production in association with jets are those of $B H S$, which have been calculated up to $W$ plus four jets with a leading-colour approximation for the virtual part [22], and up to $W$ plus three jets with a full color treatment [70, 51]. In this study, we consider the inclusive $W+2$-jet prediction at NLO accuracy, and further, discuss and show predictions from an inclusive sample where $W+2,3,4$-jet events generated by $B H S$ are combined in a simple manner, nevertheless without introducing any double counting of phase-space regions.

The $S$-MEPS predictions are obtained from merging at leading order (LO) tree-level Matrix Elements for $W+0, \ldots, n$-parton final states with (Truncated) parton Showers (hence the name ME\&TS) preserving the leading logarithmic accuracy to which soft and collinear multiple emissions are described by the parton shower. The newer ME\&TS merging scheme was introduced in Ref. [426] and optimised

[^219]as documented in Refs. [427, 428] to improve over the original SHERPA implementation based on the CKKW approach [429, 430]. ME\&TS guarantees a better matching regarding the usage of scales as occurring in the evaluation of the matrix elements and those scales driving parton showering. The $S$-MEPS sample used in our study was generated by including $W(\rightarrow e \nu)$ production matrix elements with up to five extra partons (massless quarks, $u, d, s, c, b$, and gluons).

The HEJ framework is a resummation of the leading logarithmic terms occurrung in pure, or $W$, $Z$ or $H$ plus, multi-jet production in the limit of large invariant mass between each pair of jets, to all orders in $\alpha_{s}$. This is then matched to tree-level accuracy for final states with two, three or four jets. In principle, the HEJ framework can be merged with a parton shower to add the collinear pieces which are not included in the HEJ description (HEJ does include soft emissions down to around 2 GeV ). First steps in this direction for pure jet production were taken in [431]. Here, the HEJ predictions are calculated at the parton level.

In the 17.2 section, we will elaborate on the method (b) for combining NLO samples of different jet multiplicities. Then, in the 17.3 section, we will first show explicit results of the sizable impact of large multiplicity events by comparing predictions from the combined BHS sample and the S-MEPS merged sample. Secondly, we will study variables chosen to probe the differences in the treatment of the QCD radiation. We will show and compare the predictions for all four descriptions mentioned above focusing on the following observables:

- the average number of jets as a function of $H_{T}=\sum_{i} p_{T, j_{i}}+p_{T, e}+p_{T, \nu}$ and $\Delta y$, the rapidity difference between the most forward and most backward jets, and also
- the ratio of the inclusive 3-jet rate to the inclusive 2-jet rate as a function of $H_{T}$ and $\Delta y 35$

We will then discuss the areas of agreement and difference that we find, before we finally conclude in the 17.4 section.

### 17.2 NLO EXCLUSIVE SUMS

An NLO $n$-jet prediction contains events with $n$ or $n+1$ partons. For observables for which higher multiplicites have a significant impact, this limitation can be detrimental. If one has predictions for different multiplicities ( $m, m+1, \ldots, M$ ), one can try to combine them by avoiding double counting by requiring that the $n$-jet prediction is used only to describe $n$-jet events (except for the highest multiplicity where ( $n+1$ )-jets configurations are allowed). The total cross section can be rewritten as a decomposition based on exclusive (exc) and inclusive (inc) jet bins:

$$
\begin{equation*}
\sigma^{\mathrm{tot}} \equiv \sigma_{m}^{\mathrm{inc}}=\sum_{n=m}^{M-1} \sigma_{n}^{\mathrm{exc}}+\sigma_{M}^{\mathrm{inc}} \tag{105}
\end{equation*}
$$

The exclusive-sums procedure describes each jet bin at NLO accuracy, i.e. at $\mathcal{O}\left(\alpha_{s}^{n+1}\right)$, or, alternatively, only the $(M+1)$-th (inclusive) jet bin is predicted with LO precision. We hence note that the combination of the terms shown in Eq. 105) occurs at different orders of the strong coupling. Furthermore, the definition of an exclusive $n$-jet sample requires a detailed treatment of jet vetoing. For these reasons, the simple combination procedure is crude and does not increase the formal accuracy of the prediction, which is that of NLO of the smallest multiplicity. However, one can hope that the procedure will lead to a better prediction in observables where higher multiplicity events dominate.

More studies are required to understand the uncertainties related to this procedure. One way of doing so would be to vary the jet algorithm and/or parameters of the jet algorithm used to separate the different NLO predictions into fixed multiplicities sets and test the stability of the prediction ${ }^{36}$ This is left to a future study.

Fig. 56: The average number of jets as a function of $p_{T, W}$ (left) and $p_{T, j_{1}}$ (right). The $p_{T, W}$ plot shows the $B H S$ exclusive sums prediction, while the $p_{T, j_{1}}$ plot is obtained from $S$-MEPS.

### 17.3 RESULTS OF THE COMPARISON

In this section, we compare the results of different theoretical descriptions for $W+n$-jets production at the LHC. The number $n$ can take values from 2 and above, as we will mostly consider inclusive samples. The four descriptions, which we will compare here in more detail, are

- the $B H S$ calculation of $W+2$-jets at NLO,
- the combined sample of $W+2,3,4$-jet events at NLO from $B H S$, as described in the 17.2 section,
- the $S$-MEPS merged $W+n$-jets sample using LO tree-level matrix elements up to $n=5$, and
- the approach of HEJ.

Throughout this study, we will consider inclusive samples of $W^{-}$boson production in association with at least two hard jets identified by the anti- $k_{T}$ jet algorithm using $R=0.4$. The jets are required to have $p_{T, j}>25 \mathrm{GeV}$. We look only in the $W^{-} \rightarrow e^{-} \bar{\nu}_{e}$ decay channel and use the cuts given in Tab. 12 where $M_{\perp, W}$ is defined as $M_{\perp, W}=\sqrt{\left(\left|\vec{p}_{T, e}\right|+\left|\vec{p}_{T, \nu}\right|\right)^{2}-\left(\vec{p}_{T, e}+\vec{p}_{T, \nu}\right)^{2}}$.

The HEJ predictions use the geometric mean of the jet transverse momenta to determine the renormalisation and factorisation scale, i.e. $\left(\prod p_{T, j}\right)^{1 / n}$. This central choice will be varied by a factor of two in either direction to provide an envelope (marked by dotted lines in the corresponding figures) around the HEJ default prediction. The BHS predictions instead use $\hat{H}_{T}^{\prime} / 2$ as the NLO calculation becomes unstable for a scale which is too low. In the $S$-MEPS calculation, scales are chosen according to the default prescription given by ME\&TS [426].

The variables $H_{T, 2}, p_{T, W}$ and $p_{T, j_{1}}$ are less sensitive to the presence of additional radiation than $H_{T}$, as discussed in the introduction. The plots, which we present in Figs. 56 and 57 address the alternative question: given a particular value of $H_{T}, H_{T, 2}$ etc. how many jets are typically found in the event?

Figs. 56 and 57 show the stacked results for the average number of jets as a function of $p_{T, W}, p_{T, j_{1}}$, $H_{T}$ and $H_{T, 2}$ visualising the contributions from each exclusive 2,3,4-jet sample and the inclusive 5 -jet

Fig. 57: The contribution from different multiplicities to the average number of jets as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the BHS exclusive sums prediction, while the lower ones are extracted from S-MEPS.
sample. The left (right) plot in Fig. 56 and the upper (lower) rows of plots in Fig. 57 depict the results as obtained from the combined BHS sample (the $S$-MEPS sample). In all cases the different colours correspond to the terms in the numerator of the formula for the average number of jets,

$$
\begin{equation*}
\langle N\rangle_{5}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{106}
\end{equation*}
$$

where blue, green, red and magenta stand for $i=2,3,4$ and $i=5$, respectively. The subscript to $\langle N\rangle$ clarifies that we truncate the determination of the average after the fifth jet bin, noting that $\langle N\rangle_{k} \rightarrow\langle N\rangle$ for a sufficiently large number of jet bins. This makes no difference for the BHS predictions employed here since the jet multiplicity de facto is limited to five, but it does for the $S$-MEPS and HEJ computations where events with $i>5$ jets do occur. We have defined $n_{k}^{\text {exc } / \mathrm{inc}}=d \sigma_{k}^{\text {exc } / \mathrm{inc}} / d O$ where $O$ denotes an observable like $H_{T}$, or $\Delta y$ presented later on. Note that in Fig. 57 the 5 -jet part contributes to the average number of jets with a factor of 5 , while the 2 -jet part, for example, contributes with a factor of 2 only.

The layout of Fig. 58 (including the colour coding) is the same as before: here, we however display, wrt. $n_{2}^{\text {inc }}$, the relative fractions of the different multiplicities corresponding to the terms in the denominator of Eq. (106). In other words, in Fig. 58 we consider the partitioning of

$$
\begin{equation*}
1=\frac{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{107}
\end{equation*}
$$

Fig. 58: The fraction of the total rate from different multiplicities as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the $B H S$ exclusive sums prediction, while the lower ones are extracted from $S$-MEPS.

Although there is just a $30 \%$ fraction of inclusive 5 -jet events to the total cross section, we observe that their contribution to the build-up of $\langle N\rangle\left(H_{T}\right)$ for very large $H_{T}$ gets close to $50 \%$. Also, for an $H_{T} \sim$ 500 GeV , the average number of jets is composed evenly between the 2,3 -jet and 4,5 -jet contributions, while the relative fraction of the 2,3 -jet events is nearly $70 \%$. This emphasizes the dominance of multijet events in forming large $H_{T}$ values. It also can be seen that for medium $H_{T}$ values, $400<H_{T}<$ 700 GeV , all the multiplicities give roughly the same contribution to the variable $\langle N\rangle\left(H_{T}\right)$, while for low $H_{T}$, the average is primarily described by 2-jet events.

Going clockwise through Figs. 56 and 57 we see that the average number of jets is indeed sensitive to higher multiplicities when considered as a function of $p_{T, W}, p_{T, j_{1}}$ and $H_{T, 2}$, but in all these cases this happens to a lesser extent as if considered as a function of $H_{T}$. As expected, the dependence is mildest for $p_{T, W}$, the most inclusive observable studied here. We also observe that the jet-bin decomposition of $p_{T, j_{1}}$ and $H_{T, 2}$ turns out very similar. Most strikingly we note the increase in the contribution from the highest multiplicity events, the ones containing more or at least five jets. For $H_{T, 2}$, we furthermore display to the right of Fig. 58 the relative fractions as done in the $H_{T}$ case. Even for largest $H_{T, 2}$ values, the fraction arising from 2,3 -jet events remains close to $65 \%$ stressing once more the lower sensitivity of $H_{T, 2}$ versus $H_{T}$ regarding multiple jet production.

Finally, we compare the plots from the combined BHS samples in all figures to the corresponding ones generated with the $S$-MEPS sample. Interestingly, the outcome looks very similar although ME\&TS handles the single terms in Eq. (105) rather differently. They are calculated at least at leading (soft/collinear) logarithmic accuracy improved by LO $n$-jet effects. Presumably, for the exclusive jet bins, this description (which allows a better treatment of jet vetoes) is not too far off the exclusive sums

Fig. 59: Average number of jets as a function of $H_{T}$ (left) and $\Delta y$ (right) in two BHS descriptions, from $H E J$ and from $S$-MEPS, the latter using the $\langle N\rangle_{7}$ definition. The bands shown with dotted lines for the HEJ prediction are a result of varying the scale by a factor of 2 in each direction.
approach, since the unresolved $\mathcal{O}\left(\alpha_{s}\right)$ corrections are also present in the Sudakov form factors applied in the ME\&TS approach. Also, the combined BHS samples as well as the $S$-MEPS sample use the same tree-level matrix elements, namely up to $W+5$-parton matrix elements. Clearly, it has to be studied further whether this similarity in the results is a coincidence or not.

It is clear that the impact of the higher multiplicity samples is significant throughout, especially in the high $H_{T}$ tail. This is precisely the region, which would be probed for signs of new physics, and therefore it is essential that we fully understand our theoretical descriptions in this region. This is the subject of the remainder of this contribution, where we compare all four different methods of modelling hard QCD radiation in inclusive $W+2$-jet events.

The left plot of Fig. 59 shows the final comparison plot between the exclusive sums and inclusive 2-jet $B H S$ results as well as the $H E J$ and $S-M E P S$ predictions for the average number of jets as a function of $H_{T}$. The differences in the descriptions are significantly larger than the scale uncertainty band on the $H E J$ prediction. For the $W+2$-jet NLO result, the number of jets rises to 2.6 already at $H_{T}=500 \mathrm{GeV}$ but that levels off significantly below the $S-M E P S$, exclusive $B H S$ sum and $H E J$ results. The $H E J$ results level off at a higher value of about 3.0 , starting to clearly disagree with the exclusive sums and $S$-MEPS predictions above 500 GeV , from where those two curves keep rising to a final level of around 3.7 to 4.0. The $S$-MEPS comes in highest at largest $H_{T}$, where $\langle N\rangle_{7}$ is shown, cf. Eq. (106), in order to determine the average number of jets for this $S$-MEPS result. The reason for giving slightly higher $\langle N\rangle$ than the exclusive sums lies in the contribution of additional parton-shower jets present in the $S$-MEPS calculation and more accurately accounted for by the use of the $\langle N\rangle_{7}$ definition as compared to the earlier result based on $\langle N\rangle_{5}$ presented in Fig. 57 to the lower left.

In the right panel of Fig. 59, we have plotted the average number of jets as a function of the rapidity span, $\Delta y$, instead of $H_{T}$ as before. Again the differences are larger than the scale variation shown on the HEJ result, but the ordering is different to that of the left plot of Fig. 59. All four descriptions increase linearly with $\Delta y$ but the gradient is steepest for the HEJ predictions where the average rises above 3.0 for $\Delta y$ values as large as 6.0. The BHS exclusive sum result is consistently below this, reaching about 2.8 at $\Delta y=6.0$, and agrees pretty well with the $S$-MEPS result based on $\langle N\rangle_{7}$. The NLO $W+2$-jet prediction given by $B H S$ is lower still, between 2.4 and 2.5 for $\Delta y \sim 5.0$.

It may seem surprising that on the plot on the left-hand side the exclusive sums and S-MEPS lie higher for most of the distribution whereas on the right-hand side these approaches as well as $H E J$ give predicitions that are commensurate. The region of high $H_{T}$ and that of high $\Delta y$ however are largely distinct as it is very expensive to have both a large rapidity and large $p_{T}$ for the jets. Also while radiating

Fig. 60: The ratio of the inclusive 3 -jet and 2 -jet rates in the inclusive $W+2$-jet NLO and exclusive sum description of $B H S$ as well as in the $S$-MEPS and $H E J$ approaches as a function of $H_{T}$ (left) and $\Delta y$ (right). Again, the dotted lines indicate the uncertainty band from varying the scale in $H E J$ by a factor of 2 in each direction.
an additional jet automatically moves an event towards the higher $H_{T}$ direction, radiating an additional jet tends to not change the rapidity difference. So, we expect the higher multiplicies to have a smaller effect on the average number of jets as a function of $\Delta y$ compared to as a function of $H_{T}$. This is indeed the case in Fig. 59.

Lastly, in Fig. 60 we plot the ratio of the inclusive 3 -jet to the inclusive 2 -jet rate as a function of $H_{T}$ (left) and $\Delta y$ (right), again for all four descriptions used here. The predicted $\left(d \sigma_{3}^{\text {inc }} / d H_{T}\right) /\left(d \sigma_{2}^{\text {inc }} / d H_{T}\right)$ all agree very well below 400 GeV . The fixed order $B H S$ result for $W+2$ jets is highest for large $H_{T}$, however is known to become unreliable here, since the probability that an inclusive 2 -jet event is at least a 3 -jet event turns too large, being in conflict with the expected behaviour of an $\mathcal{O}\left(\alpha_{s}\right)$ correction. The BHS exclusive sums, the S-MEPS and the HEJ results, in this order, level off considerably lower with the HEJ fraction staying below $60 \%$ to $70 \%$, which leaves the other predictions again above the $H E J$ uncertainty envelope. In contrast, when the same ratio of jet rates is plotted against $\Delta y$, the $H E J$ prediction is consistently higher throughout. This again emphasises that differences in the descriptions come to light in different kinematic regions. However, in both cases here the magnitude of the differences is relatively small and would be rather difficult to distinguish in present experimental data.

### 17.4 CONCLUSIONS

We have compared a number of theoretical descriptions of $W^{-}$production in association with at least two jets. After outlining one possible method of combining NLO calculations of different multiplicities, we compared this with a pure NLO calculation of $W+2$-jets production obtained by BLACKHAT+SHERPA, a sample of leading-order events merged using the ME\&TS method of SHERPA, and the high-energy resummation of the HEJ framework.

We studied the average number of jets and the ratio of the 3 -jet and 2 -jet inclusive cross sections as a function of $\Delta y$ and of $H_{T}$. We find, with these simple cuts, some clear differences in the predictions when we study the average number of jets as a function of both $\Delta y$ and $H_{T}$. Smaller differences, which would be more difficult to disentangle experimentally, are found when we study the ratio of inclusive rates.

It would be very valuable to have an experimental study, which probed the average number of jets in $W$ production in association with at least two jets, to test our different descriptions of these important Standard Model processes.

## ACKNOWLEDGEMENTS

The authors would all like to thank the organisers and participants for the extremely stimulating workshop. JMS is supported by the UK Science and Technology Facilities Council (STFC).

## 18. UNCERTAINTIES IN THE SIMULATION OF $W+$ JETS - A CASE STUDY 37

#### Abstract

In this contribution, uncertainties in the simulation of a large variety of observables related to the production of $W$ in association with jets at the LHC and the Tevatron are discussed. This work aims to - serve as a compendium of currently publicly accessible tools in addition to the ones presented in a previous publication [439] with a similar topic, and to compare their results; - discuss the origin and generic size of various uncertainties in the simulation of perturbative and non-perturbative aspects of this process; - trace the interplay of these uncertainties in various stages of the full event simulation; - hint at those uncertainties in each of the various tools considered here which the respective authors find relevant; - guide their users in how to assess the related uncertainties in a way the authors recommend.

### 18.1 Introduction

The production of $W$-bosons in association with jets constitutes an important process at the Tevatron and the LHC, for a variety of reasons. First of all, it represents a major background to Standard Model signatures such as top-pair and single-top production, and it also plays a role in searches for the Higgs boson in the Standard Model. Furthermore, this reaction, together with the fairly similar channel of $Z$ production in association with jets, provides one of the most important backgrounds in those searches for new physics where large missing transverse energy and high jet multiplicities characterise the respective signal. Thirdly, this process has become a standard reaction for QCD studies at hadron colliders, ranging from the validation of simulation tools for multijet signatures to measurements related to multiple parton scattering. Finally, this process also provides one of the main testbeds for novel techniques in the automation of higher-order QCD corrections and their matching or merging with subsequent parton showers in the framework of event generators.

In the spirit of this last point, providing a testbed for the combination of fixed order calculations with the parton shower, this process has been analysed in quite some depth in [439] about five years ago. A number of reasons provide motivation to update and extend this previous study, namely

- the LHC being up and running and starting to provide highly precise data such that a proper treatment of uncertainties becomes an important issue;
- major improvements in the ability to calculate higher-order corrections including up to four jets in the final state accompanying the $W$ bosons [51, 117, 22];
- the advent of such next-to leading order calculations - albeit for lower final state multiplicities fully matched to the parton shower [440, 404, 424];
- an improved understanding of the leading order merging prescription for towers of multijet multiplicities with the parton shower [426, 441];

[^221]- the combination of matching and merging methods [442, 443];
- and new methods to simulate multijet topologies based on the high-energy limit [64].

Therefore this study aims at being a first step towards a more complete update of [439], with a shift in focus towards a discussion of theoretical uncertainties in different approximations, including perturbative and non-perturbative effects. Apart from tracing the origin and determining the generic size of various uncertainties in the theoretical description of various observables related to this process, also the interplay of them at various stages of the simulation, from the matrix element to the hadron level will be discussed. Consequently, the most important causes for theory uncertainties in various tools are highlighted. Therefore, one of the more practically relevant goals is to also provide methods to reliably and robustly estimate such uncertainties for the various tools used in this study, as recommended by authors or users.

The outline is as follows: After briefly presenting the various tools included in this study and discussing the way they have been used here in Sec. 18.2 , example results for them will be presented individually, tool by tool in Sec. 18.3 . In Sec. 18.4 these results are compared in order to see and quantify relative differences. In this endeavour, experimental results have not yet been included. We reserve this comparison with relevant data for a later, full-fledged analysis, which will hopefully include even more tools.

### 18.2 Codes

In this work a variety of different codes has been employed, which allow to study the process at various different stages:

1. Fixed order matrix elements:

By now, the description of $W$ boson production in association with jets is possible for up to 4 additional jets at NLO. Here, results from two NLO codes, GoSAM+SHERPA [12, 425, 146] and BLACKHAT+SHERPA [70, 51, 22], which are either publicly available or provide publicly available event files, are presented. The corresponding results therefore are on the matrix element level.
2. All-order resummed matrix elements:

Approximations to the partonic matrix elements for the processes of $n$-jet production, and $W, Z, H+n$-jets, $n \geq 2$, was recently calculated to any multiplicity, and including all-order resummations for the leading virtual corrections. The all-order scheme [418, 419], implemented in the HEJ [64] code, becomes exact in the limit of large invariant mass between each parton (the MRK limit of BFKL). The resummation scheme is merged with LO matrix elements (much like in MEPS, see later). The resummation of HEJ can also be interfaced to a parton shower [431]; the results presented here, however, are on the matrix element level. It should also be stressed that due to the nature of the approximation of HEJ, the simulation here are relevant for the production of at least two jets in addition to the $W$ boson.
3. Parton showers:

The pure parton shower code relies on the collinear approximation to produce additional jets. By using a matrix element reweighting, however, in the process of $W$ production, typically one additional jet can correctly be described. For this simulation, PYTHIA8 [348] has been used here, with results available on the parton shower level, hadron level and hadron level including UE.
4. LO matrix elements merged with the parton shower (MEPS):

By now, the use of towers of multijet matrix elements with increasing multiplicity merged to the parton shower following ideas presented in [444, 429, 445, 430] is common practise in the experimental collaborations. In fact, a first comparison of different codes and implementation has been presented a while ago [439]. Here, three implementations of these ideas are included, namely the ones in MADGRAPH+PYTHIA [165, 446, 163, 191, 400], PYTHIA8+ME [441] and SHERPA [146]. Here results are available on all levels matrix element level, parton shower level, hadron level,
hadron level including UE, and hadron level including UE and QED final state radiation in different combinations of codes.
5. NLO matrix elements matched to the parton shower ( $\mathrm{NLO} \otimes \mathrm{PS}$ and MENLOPS):

In principle two methods by now have been proposed and fully implemented which consistently match full NLO calculations to the parton shower, namely Mc@NLO [401] and Powheg [416, 417]. Here the latter is being used, with its implementation in the Powheg Box [13], and interfaced to the PYthia [400] parton shower in its $k_{T}$-ordered version [447]. In addition, a combination of such matching with the merging methods described in the previous point is available [442, 443], ranging under the name MENLOPS. In this paper we use an implementation of such methods provided in the SHERPA framework. In both cases, results are available on all levels matrix element level, parton shower level, hadron level, and hadron level including UE.

### 18.21 BLACKHAT + SHERPA

The NLO predictions are obtained by combining BLACKHAT [4] for the virtual part and SHERPA [147, 448] for the real part. It is currently possible to obtain predictions at NLO for a $W$-boson in combination with up to four jets [70, 51, 22].

The plots have been produced by re-analysing large event files produced by the combination of BLACKHAT and SHERPA. These files contain particle four-momenta as well as the coefficients of all scale dependent functions, including the PDFs so that it makes it possible to easily change factorisation and renormalisation scales as well as the PDF set.

We used a common factorisation and renormalisation scale $\mu_{F}=\mu_{R}=\hat{H}_{T}^{\prime} / 2$ with $\hat{H}_{T}^{\prime}=$ $\sum_{j} p_{T}^{j}+E_{T}^{W}$ where the sum runs over all jets and $E_{T}^{W}=\sqrt{M_{W}^{2}+\left(p_{T}^{W}\right)^{2}}$.

Estimation of uncertainties The estimation of the uncertainties for the NLO calculation obtained with BLACKHAT+SHERPA is obtained by combining in quadrature the pdf uncertainties obtained using the pdf error set and the uncertainties obtained by varying the factorisation and renormalisation scales simultaneously by factors of $1 / 2$ and 2 . To this error we also add in quadrature the integration error estimate. Another way of estimating the uncertainties due to the choice of scales is to compare predictions obtained using different choice of basis scales, but this has not been done for this study.

We used the CTEQ6.6 PDF set. The value of $\alpha_{s}$ used for this calculation has also been taken as that provided with this PDF set. The PDF uncertainties are estimated using the hessian method and PDF 'error' set provided with the CTEQ6.6 PDF set.

### 18.22 GOSAM + SHERPA

GOSAM [12] is a new framework which allows the automated computation of one-loop scattering amplitudes for multi-particle processes. The one-loop scattering amplitudes are generated in terms of algebraic $d$-dimensional unintegrated amplitudes, which are obtained via Feynman diagrams. This allows to perform symbolic manipulations of the expressions prior any numerical step. For the reduction, the program offers the possibility to use either a $d$-dimensional extension of the OPP method [121, 122, 119], as implemented in SAMURAI [6], or tensor reduction as implemented in golem95 [130, 131] interfaced through tensorial reconstruction at the integrand level [124].

The GoSAM framework can be used to calculate one-loop corrections within both QCD and electroweak theory. Beyond the Standard Model theories can be interfaced using FeynRules [137] or LanHEP [136].

To produce results for a certain process specified by the user, the program must be fed with an "input card" with the details of the process. Alternatively, when interfacing the program with a Monte

Carlo (MC) event generator which supports the Binoth-Les-Houches-Accord (BLHA) interface [145], the specific order file produced by the MC event generator can be passed to GoSAM.

The analysis presented here was performed using this latter generation mode and SHERPA [425] 146] was chosen as MC event generator. SHERPA provides therefore the matrix elements for the production of $W$ and exactly one jet at the Born-level and the NLO real corrections to it, together with the needed subtraction terms and their integrated counter-parts. GOSAM provides the NLO virtual-part. The generation of the code follows the standards of the BLHA-interface [145]. During the first call of Sherpa an "order file" is written by the MC program. This file is read-in by GOSAM to produce the code for the one-loop evaluation of needed process. If this happens successfully, a contract file with information on the different possible subprocesses is produced by GoSAM and can be later read by the MC generator to recognize the numbering of the different partonic subprocesses. At running time all information between GoSAM and SHERPA is also passed using the BLHA-interface standards.

The steering of the event generation and the analysis interface with RIVET [360] is done using SHERPA cards. Each curve in the analysis consists of 100 combined runs of 50 million events. The renormalisation and factorisation scales are set according to the choice made for this analysis in Les Houches to

$$
\mu_{F}=\mu_{R}=\hat{H}_{T}^{\prime} / 2
$$

where $\hat{H}_{T}^{\prime}$ is defined in the previous section.

Estimate of uncertainties The estimation of the uncertainties for the NLO calculation obtained with GoSAM+SHERPA is done combining in quadrature the PDF uncertainties with the uncertainty coming from the separate variation of factorisation and renormalisation scale by factors of $1 / 2$ and 2 . Ideally also the integration error should be added in quadrature to the previous estimate, however the MC integration error obtained with RIVET at NLO is not reliable because of the incapacity of RIVET to take into account properly the correlation between real and subtraction events. For this reason and because of the very high statistics of the MC sample, the MC integration error is neglected. To assess the PDF uncertainty we compute the envelope of the results obtained using the three different PDF sets CT10 [255], used as nominal set, MSTW08 [262] and NNPDF2.1 [312]. The total scale uncertainty is determined by adding in quadrature the factorisation and renormalisation scale uncertainties. Each of them is found by computing the maximum between the nominal value and the up and down variations.

### 18.23 HEJ

The High Energy Jets (HEJ) framework [418, 419] provides an alternative description of collider events to the standard fixed order calculations (possibly interfaced to a parton shower). Instead, HEJ uses approximations to the hard scattering matrix element to all orders in $\alpha_{s}$ which become exact in the High Energy limit. The approximation results in sufficiently simple matrix elements, that these can be explicitly regulated, integrated and summed over any (relevant) multiplicity. This results in an explicit all-order resummation of the dominant contributions from wide-angle QCD radiation.

The building blocks of the HEJ framework ensure the correct leading logarithmic behaviour in the Multi-Regge Kinematic limit (aka. the High Energy Limit) of large invariant mass between all partons, for both the real and virtual corrections. The resummed $n$-jet rate is then further matched to tree-level accuracy for events with up to and including four jets, using a merging procedure for the soft radiation.

This procedure has so far been applied to the production of jets [64], $W$ plus jets [449], $Z$ plus jets and Higgs boson plus jets and has currently been implemented in a fully flexible Monte Carlo for the first two of these processes. The implementation integrates explicitly over any number of QCD emissions from a $(W, Z, H+)$ dijet system, and hence produces event samples for processes with two jets or more. Note that one has access to the momenta of all final state particles for every event and it is therefore extremely simple to restrict to a subset of the events if required, e.g. 3-jet exclusive events.

The HEJ resummation includes emissions at large transverse momentum which are increasingly important as the centre-of-mass energy of particle collisions increases. HEJ is currently the only available flexible Monte Carlo generator to obtain leading logarithmic accuracy in the limit of large invariant mass between emissions. However, the HEJ framework does not include any systematic resummation in the collinear limit. This is included in a parton shower, but a careful merging procedure is required to link one with HEJ, as there is significant overlap between the soft emissions included in each approach; the first steps in this direction have been taken for jet production [431] and are ongoing. In the current study though, only parton level predictions are given.

Estimate of Uncertainty The HEJ framework does not contain any tunable parameters other than the choice of renormalisation and factorisation scale (just like any fixed order calculation). In this study, in common with other approaches, we choose both of these to be given by the geometric mean of the transverse momentum of the jets:

$$
\begin{equation*}
\mu_{R}=\mu_{F}=\left(\prod_{j=1}^{n} p_{T}^{j}\right)^{1 / n} \tag{18.2.1}
\end{equation*}
$$

where the jets are defined according to the relevant cuts in each analysis. This is however only an arbitrary choice, as the framework admits any choice for the scale, including $H_{T}, p_{T}$ of the hardest jet and a fixed scale. For a given scale, $\alpha_{s}$ is evaluated according to the relevant PDF.

In common with standard convention, we calculate the scale variation by changing this scale by a factor of two in both directions. In principle, one could also include the PDF uncertainty, but this is not done in this study (as the scale uncertainty dominates). As described above, HEJ contains matching to tree-level accuracy for up to four jets. However, unlike the merging procedure in a showered sample, the merging scale here is not a free parameter. There is only one rational choice for the merging scale: the minimum $p_{T}$ of a jet in the relevant analysis. However, in an inclusive sample with at least two jets, one could use as a further estimator of uncertainty the variation obtained when matching to three and four jet LO matrix elements. This procedure will be studied in detail in Ref. [449], but in the present study, we quote the uncertainty only from the scale variation.

### 18.24 MADGRAPH + PYTHIA

MADGRAPH [165, 446, 163, 191] is a general purpose leading order matrix element (ME) generator, with a broad variety of models available and easily extensible thanks to its modular structure. The event generation is performed by the MADEVENT component, a tool implementing the Single Diagram Enhanced algorithm for multi-channel phase space integration. When a user provided process is specified, MADGRAPH automatically generates the amplitudes for all the relevant subprocesses and produces the mappings for the integration over the phase space. This process-dependent information is then used by MADEVENT, where the process specific code generated allows the user to calculate cross sections and to produce unweighted events. Once the parton level events have been generated, a traditional parton shower (PS) Monte Carlo library can be run on top of the MADGRAPH output to describe additional QCD radiation, and possibly allow to produce hadron level generated events if a suitable hadronisation model is then applied.

In order to avoid double counting of QCD radiation from the matrix element and the parton shower, the MLM matching approach is used in its ktMLM implementation provided by the MADGRAPH team [191].

For the present study MADGRAPH-5.1.1 [191] has been used for the matrix element generation, while the parton shower and hadronisation has been provided by PyTHIA 6.4.2.4 [400]. The $W+n$ jet process has been simulated up to 4 additional partons. The PDF used in both calculations has been

CTEQ6L1, and in the matrix element calculation the strong coupling costant has been setup to be equal to the one from the PDF used. The factorisation scale and the hadronisation scale are set to the W transverse mass, $m_{\perp, W}$. The parton level clusterisation scale xqcut has been set to 10 GeV , while the ME - PS matching scale qcut has been set to the optimal value of 20 GeV , determined ensuring the smoothness of the differential jet rate.

The Pythia settings have been defined according the so called Tune Z2, an adjustment of Tune Z1 described in [450] for CTEQ6L1, where the $p_{\perp}$ cutoff for the multiple parton interactions is set to $\operatorname{PARP}(82)=1.832$ obtained on top of LHC data as far as the underlying event and multiple parton interactions are concerned, while the fragmentation parameters are those optimized on LEP data by the Professor [451] team.

Estimate of uncertainties To estimate the uncertainties due to the factorisation scale and the renormalisation scale, which are set to $m_{\perp, W}$, we varied them simultaneously by a factor two. In addition we have independently varied by a factor two the ME - PS matching scale.

While applying these modifications, the total cross-section is kept fixed to the value obtained with the default parameters, 27.77 nb . That is because we are only interested in shape variations of the distributions, rather than in the total cross-section of the process calculated by MADGRAPH, which is accurate only at the leading order.

### 18.25 PoWhEG BOX + PYTHIA8

The Powheg Box [13] is a computer framework to ease the Powheg [416] implementation of new processes. It only requires as input the individual components of the NLO calculation under consideration, i.e., the Born process, its virtual radiative corrections and the real emission contributions. Then it automatically combines them, canceling the emerging soft and collinear singularities in the Frixione-Kunszt-Signer (FKS) subtraction scheme, and produces the required events. The Powheg Box is also a library, where previously implemented processes are available in a common framework.

For the present study we make use of the $W+$ jet implementation presented in [440].
The produced events are passed to PYthia8 [348] through the Les Houches interface [452] and showered with the default transverse-momentum ordered shower, vetoing further emissions harder than the one already present in the input events. This is achieved by setting the starting scale of the shower as the transverse momentum of the hardest emission 38

When multiple partonic interactions (MPI) are turned on, these are allowed to be harder than the first Powheg emission. Indeed, since the $W+1$ jet process is not accounted for in MPI, there is no over-counting.

Eventually, the relevant distributions are evaluated by interfacing the MonteCarlo output to the RIVET [360] analysis, for the two given sets of ATLAS and CMS cuts.

Since we have simulated events starting from a hard process where a $W$ is produced in association with one jet, only observables built from events where at least 1 jet is present will be shown.

Generation of predictions and estimate of uncertainties Predictions presented here are based on a merged sample of $4 \mathrm{M} W^{+}+j$ and $4 \mathrm{M} W^{-}+j$ weighted events, produced with the default Powheg Box choice of parameters. In particular, we have required a minimum cut $p_{\mathrm{T}}=5 \mathrm{GeV}$ on the associated jet at the generation level and, in order to enhance the statistical sampling of the high- $p_{\mathrm{T}}$ tail, we have further suppressed the rapidly rising contribution at low jet $p_{\mathrm{T}}$ by the factor $p_{\mathrm{T}}^{2} /\left(p_{\mathrm{T}, \text { supp }}^{2}+p_{\mathrm{T}}^{2}\right)$, with $p_{\mathrm{T}, \text { supp }}^{2}=100 \mathrm{GeV}$. The inverse of this factor enters the event weight.

[^222]We have adopted the Powheg Box default values for EW parameters, namely

$$
\begin{equation*}
M_{W}=80.398 \mathrm{GeV}, \quad \Gamma_{\mathrm{W}}=2.141 \mathrm{GeV}, \quad\left(\mathrm{ff}_{\mathrm{em}}\right)^{-1}=128.89, \quad \sin ^{2}{ }^{`} \mathrm{~W}=0.222645 \tag{18.2.2}
\end{equation*}
$$

and we have assumed a CKM matrix with a mixing between the first two generations only

$$
\begin{equation*}
\left|V_{u d}\right|=\left|V_{c s}\right|=0.975, \quad\left|V_{u s}\right|=\left|V_{c d}\right|=0.222, \text { and }\left|V_{t b}\right|=1 . \tag{18.2.3}
\end{equation*}
$$

Finally, we have resctricted the integration region to the interval $0<M_{W}<2221 \mathrm{GeV}$.
For the computation of the Powheg $\bar{B}$ function, the renormalisation and factorisation scale was chosen equal to

$$
\begin{equation*}
\mu_{R}=\mu_{F}=p_{\perp, j} \tag{18.2.4}
\end{equation*}
$$

where $p_{\perp, j}$ corresponds to the transverse-momentum of the (single) parton recoiling against the $W$ boson in the so-called underlying Born kinematics [417]. We have also run the code using

$$
\begin{equation*}
\mu_{R}=\mu_{F}=1 / 2\left(\sqrt{M_{W}^{2}+p_{\perp, W}^{2}}+p_{\perp, j}\right) \tag{18.2.5}
\end{equation*}
$$

but no relevant differences were observed with respect to the aforementioned choice, being the two scales similar for the $W+1$ jet processes at hand.

The scales entering in the evaluation of parton distribution functions and of the strong coupling in the Powheg Sudakov form factor are chosen to be equal to the transverse momentum of the PowHEG hardest emission [417, 386].

Scale-uncertainty bands obtained by varying the factorisation and renormalisation scales entering the $\bar{B}$ function by a factor of two in either directions are used as an estimate of the theoretical error associated to higher order missing effects.

The uncertainty due to the PDF choice was estimated generating events using three different sets (CT10 [255], MSTW2008 [262], and NNPDF2.1 [312]). The value of the strong coupling constant at $M_{Z}$ is consistently read from the PDF table used. The further showering performed by PYTHIA8 is instead performed with default PDF and $\alpha_{s}$ definitions, the difference being beyond the claimed accuracy of the calculation. In this study, we have used PYthia8, version 8.153.

### 18.26 Pythias

Pythia8 [348] is the latest incarnation of event generators of the Pythia family. At the heart of the generator are parton showers that evolve high-scale processes to the scale of hadronisation, by generating splittings with DGLAP splitting kernels. The splitting scales are ordered in relative transverse momentum [348, 447], and the phase space is constructed in a dipole-like manner in order to capture soft gluon coherence effects [453]. A key point of the evolution of partonic states in PYTHIA8 is that all perturbative components are interleaved [348, 447, 454], i.e. multiple partonic interactions, space-like and time-like showers are all generated in one transverse-momentum ordered evolution sequence. This means that due to the competition for phase space, all steps in the event generation are correlated. For a detailed discussion how parameters of the interleaved shower evolution are tuned to collider data, see [455]. Pythia8 with additional matrix element corrections has so far not been tuned to data. Since in [441], only very small differences were seen for LEP between PYTHiA8 with and without matrix element merging, we expect only small re-tuning effects in the parameters of the Lund string model [456]. Similarly, since we keep the low-scale modelling of PYTHIA8 largely intact, only small changes in the underlying event tuning are expected. We however expect that some re-tuning will be needed for jet shape data.

It should be noted that Pythia8 includes a selection $2 \rightarrow 1$ and $2 \rightarrow 2$ processes, as well as a limited variety of $2 \rightarrow 3$ processes, but does not contain a general ME generator. New processes, particularly for higher jet multiplicities, have to be made available in form of Les Houches Event (LHE)
[452] files. By virtue of matrix element corrections, Pythia8 describes the first emission in $\mathrm{W}+$ jets with the full matrix element probability. When introducing matrix elements with one additional jet within matrix element merging, this allows to fully cancel the merging scale dependence for the first emission, while small merging scale dependencies enter when including further jets. Current versions of Pythia8 include a general implementation of the CKKW-L matrix element merging prescription [445]. Please consult [441] for a detailed discussion of the implementation in PYTHIA8.

Generation of the predictions To generate predictions with stand-alone Pythia8 (i.e. without inclusion of matrix elements for W production in association with two or more jets), the built-in $q \bar{q} \rightarrow \mathrm{~W}$ matrix element in Pythia8 was used to generate the initial configuration. This was then evolved with to the hadronisation scale and the ensemble of partons hadronised using the Lund string model. For this study, we use the publicly available PyTHIA 8.157, with CTEQ6L1 parton distribution functions, and the associated Tune 4C. Since [441] showed a large dependence of the quality of the matrix element merging on whether rapidity-ordered emissions are explicitly forbidden in space-like showers, results are presented with and without enforced rapidity ordering.

The inclusion of matrix elements for additional jets into PYTHIA8 is achieved with Cккw-L merging. All merging tasks are handled internally in PYthiA 8.157, allowing for a high degree of automation. This means that the user only needs to supply

- Matrix element configurations in form of LHE files.
- An identifier giving the hard process of interest.
- A value of the merging scale. Facilities to allow the user to implement a her/his own merging scale definition are available.
For this report, matrix element configurations with additional jets were generated with MADGRAPH/ MadEvent [163], and read into Pythia8 in form of Les Houches Events. Pythia8 then derives all possible parton shower histories for an event, probabilistically chooses a history, and uses the reconstructed states and splitting scales to perform a re-weighting with Sudakov factors and $\alpha_{s}$ values. This means each event will have a weight

$$
\begin{aligned}
w_{\mathrm{CKKWL}}= & \frac{x_{n}^{+} f_{n}^{+}\left(x_{n}^{+}, \rho_{n}\right)}{x_{n}^{+} f_{n}^{+}\left(x_{n}^{+}, \mu_{F}^{2}\right)} \frac{x_{n}^{-} f_{n}^{-}\left(x_{n}^{-}, \rho_{n}\right)}{x_{n}^{-} f_{n}^{-}\left(x_{n}^{-}, \mu_{F}^{2}\right)} \\
& \times \prod_{i=1}^{n}\left[\frac{\alpha_{s}\left(\rho_{i}\right)}{\alpha_{\mathrm{SME}}} \frac{x_{i-1}^{+} f_{i-1}^{+}\left(x_{i-1}^{+}, \rho_{i-1}\right)}{x_{i-1}^{+} f_{i-1}^{+}\left(x_{i-1}^{+}, \rho_{i}\right)} \frac{x_{i-1}^{-} f_{i-1}^{-}\left(x_{i-1}^{-}, \rho_{i-1}\right)}{x_{i-1}^{-} f_{i-1}^{-}\left(x_{i-1}^{-}, \rho_{i}\right)} \Pi_{S_{+i-1}}\left(\rho_{i-1}, \rho_{i}\right)\right] \Pi_{S_{n}}\left(\rho_{n}, t_{\mathrm{MS}}\right)
\end{aligned}
$$

where $\rho_{i}$ and $x_{i}^{ \pm}$are the the reconstructed shower splitting scales and momentum fractions of the incoming partons in $\pm$ z-direction, and $\Pi_{S_{+i}}\left(\rho_{i}, \rho_{i+1}\right)$ the parton shower no-emission probability when evolving the state $S_{+i}$ from scale $\rho_{i}$ to $\rho_{i+1} . \alpha_{\text {sME }}$ gives the strong coupling used in the matrix element calculation. All reweighting factors are generated dynamically with help of the shower. The interleaved evolution of PYTHIA8 is accommodated by consistently including effects of multiple interactions into the no-emission probabilities. A detailed description of the formalism is given in [441].

As input for the current analysis, we have produced LHE files for $\mathrm{W}^{+}+$jets with up to four (three) additional jets at Tevatron (LHC) energies. The renormalisation scale in MADGRaPH was fixed to $\mu_{R}=\mathrm{M}_{\mathrm{Z}}$. For hadronic cross sections, CTEQ6L1 parton distributions (as implemented in LHAPDF [457]) have been chosen at a factorisation scale $\mu_{F}=\mathrm{M}_{\mathrm{W}}$, and the strong coupling in the ME was correspondingly fixed to $\alpha_{s}\left(\mathrm{M}_{\mathrm{Z}}\right)=0.129783$. To regularise QCD divergences and act as a merging scale, a cut in

$$
k_{\perp}^{2}=\min \left\{\min \left(p_{T, i}^{2}, p_{T, j}^{2}\right), \min \left(p_{T, i}^{2}, p_{T, j}^{2}\right) \frac{\left(\Delta \eta_{i j}\right)^{2}+\left(\Delta \phi_{i j}\right)^{2}}{D^{2}}\right\} \quad \text { with } \quad D=0.4
$$

and a cut value of $k_{\perp, \min }=t_{\mathrm{MS}}=15 \mathrm{GeV}$ has been applied to the matrix element.

Merged Pythia8 predictions are given for the default settings, i.e. using the parameters of Tune 4C, for Tune A2 [458], and for Tune 4C without enforced rapidity ordering (dubbed Tune X). Again, it should be noted that so far, no tuning including additional jets has so far been conducted.

Estimate of uncertainties To estimate uncertainties of a merged prediction of W+jets, it is interesting to study the dependence on the merging scale value. For this, we have generated LHE files with three different $k_{\perp, \text { min }}=t_{\text {MS }}$ cuts $\left(t_{\text {MS }}=15,30,45\right) \mathrm{GeV}$, and performed CKKW-L merging on these samples. Furthermore, to show the effect of tuning, the $t_{\mathrm{MS}}=15-\mathrm{GeV}$-sample was processed for two adequate tunes, Tune 4C and A2.

Uncertainties related to shower ordering In [441], it was shown that restricting shower emissions in Pythia8 to regions of phase space ordered both in transverse momentum and rapidity leads to nonnegligible effects in merged predictions. This can be seen as an effect of limiting the shower accuracy by reducing the phase space over which splitting kernels are integrated, meaning the accuracy of Sudakov form factors is impaired. Loosely speaking, if above the merging scale, the matrix element, integrated over the full phase space ${ }^{39}$, differs substantially from the splitting probabilities integrated over the allowed parton shower phase space, merged results will exhibit substantial merging scale dependencies. Such problems are obviously introduced if the parton shower phase space is heavily constrained.

Changing the phase space regions in which the shower is allowed to radiate thus allows us to estimate the uncertainties of the merging procedure in conjunction with the underlying shower. Particularly, this procedure can test the quality of the matrix element merging beyond the first few emissions, and give hints on how the shower resummation may be improved.

To emphasise the impact of the shower transition probabilities, we choose a fairly small merging scale ( $t_{\mathrm{Ms}}=15 \mathrm{GeV}$ ) to regularise the tree-level matrix elements for this investigation. Then, for each matrix element state, we generate all possible parton shower histories for a matrix element state, by clustering emissions. This is achieved by inverting the shower momentum- and flavour-mappings.

When merging matrix elements with rapidity-ordered showers, we investigate two ways of biasing the selection of a particular history, from which to generate the necessary Sudakov form factors:

1. In a "y-blind" sample, we do not include an additional discriminant based on rapidity. This means that - just like in the standard case - $\rho$-ordered will be preferred over $\rho$-unordered ones.
2. In a " $y$-conscious" sample, we pick histories with rapidity-unordered splittings only if no rapidityordered histories were found. Adopting this strict ordering criterion, histories ordered in $\rho$ and rapidity will be chosen predominantly, and only if no such history exists, histories un-ordered in either $\rho$ and/or rapidity are picked.
It should be noted that to the accuracy of the parton shower, both these prescriptions are equivalent, and switching the choice of histories gives a real estimate of the quality of the merging in conjunction the underlying shower. We believe that including this uncertainty gives a pessimistic view on how wide the range of predictions of one merged calculation can be, indicating that although standard by now, matrix element merging in Pythia8 should be applied with care. However, with reasonable settings, including additional jets can improve the description of multiple hard jets substantially.

### 18.27 SHERPA

ShERPA [425, 146] is a full-fledged event generator capable of simulating all aspects of particle collisions as they occur at particle accelerators such as the Tevatron or the LHC. It includes two independent matrix element generators, AmEGIC++ [147] and Comix [459], to generate cross sections and distributions

[^223]for final state multiplicities of up to six to ten particles. In the former one, methods to automatically generate dipole subtraction terms in the widely used Catani-Seymour scheme [236, 150] have been incorporated [448]; the SHERPA package also supports the BLHA [145] for the interface to one-loop programs such as BlackHat or GoSam. For parton showering, SHERPA employs an algorithm based on Catani-Seymour subtraction kernels, proposed in [460] and implemented in the SHERPA framework in [461]. For the hadronisation, SHERPA uses either its native hadronisation scheme, based on the cluster fragmentation model [462] and its implementation described in [463] or an interface to PYtHIA [400] providing access to the routines of the Lund string model [456]. Both have been successfully tuned to LEP data within the SHERPA framework, with a similar quality in describing the data. The hadron decays are also fully provided in the SHERPA framework, as well as QED final state radiation to both the $W$-boson and the hadron decays, simulated using the YFS approach [464, 465].

In this work, the most recent, publically available SHERPA version, SHERPA-1.3.1, has been used in two ways of running the simulation, namely

1. in the MEPs mode:

In this method, towers of LO matrix elements with increasing jet multiplicity, in the case at hand $W, W+1, W+2, \ldots, W+n_{J}$ jets, are merged in the spirit of [429, 430] to yield an inclusive sample. In fact, codes relying on such algorithms have been compared in a previous publication [439], which helped to establish and validate the methods and their various implementations. In contrast to the original implementation in SHERPA [466], which used analytical forms of Sudakov form factors etc., the current version of the method [426] directly uses the parton shower for Sudakov rejections etc. and is thus closer in spirit to the variant presented in [445, 467] for multijet merging.
2. in the MENLOPs mode:

This method can be understood as the combination of a matching of the parton shower to a NLO matrix element and a merging of additional towers of LO matrix elements with even higher jet multiplicities. Thus, in the case at hand, inclusive $W$ production calculated at NLO accuracy is merged, as above, with LO matrix elements for $W+1, W+2, \ldots, W+n_{J}$ jets. This method has been pioneered in [442, 443] where the implementation employed within Sherpa has been detailed in the second reference.

The respective settings and relevant details for both simulation modes are described below.

Sherpa in MePs mode In the MEPS mode Sherpa was run with up to $n_{J}=6$ jets in the matrix element evaluation including all possible massless (anti-)quark and gluon initial and final states. All matrix elements were generated using Comix. The MEPS-separation parameter was set to $Q_{\text {cut }}=20 \mathrm{GeV}$, for its precise definition see [426]. The scales are chosen as

$$
\begin{equation*}
\alpha_{s}^{k+n}\left(\mu_{\mathrm{eff}}\right)=\alpha_{s}^{k}(\mu) \cdot \alpha_{s}\left(p_{\perp, 1}\right) \cdot \ldots \cdot \alpha_{s}\left(p_{\perp, n}\right), \tag{18.2.6}
\end{equation*}
$$

wherein the relative transverse momenta $p_{\perp, i}$ are the nodal values of the final state partons of the $W+n$ parton matrix element as obtained from recombining it using the inverted splitting probablities given by the parton shower. The core scale $\mu$ is then chosen as the partonic centre-of-mass energy of the reconstructed core process, i.e. $\mu^{2}=\hat{s}_{2 \rightarrow 2}$ where $k=0$ in the process at hand. In all stricly perturbative setups a parton shower cutoff of $t_{0}=(0.7 \mathrm{GeV})^{2}$ has been used.

The parton shower cutoff and all fragmentation parameters of both the internal cluster hadronisation and the interfaced Lund string fragmentation models have been tuned to LEP data and give a similarly good description. Similarly, the parameters of SHERPA's MPI model have been tuned to Tevatron and LHC data using the CT10 [255] parton density parametrisation. These parameters are given in App. 18.71

Sherpa in Menlops mode In the MeNloPs mode Sherpa is run with essentially the same parameters as in the MEPs mode, described in the previous subsection. Hence, $n_{J}=6$ and $Q_{\text {cut }}=20 \mathrm{GeV}$. To be able to describe the inclusive $W$ production process at NLO accuracy, AmEGIC++ was used for all parts of the NLO $W$ production matrix elements (supplemented with a hardcoded one-loop matrix element from the internal library) and the LO $W+1$ parton matrix element. Consecutively, the scales were chosen as above with $k=0$ for all tree-level parts and $k=1$ for the real and virtual corrections entering the next-to-leading order correction of the core process. All non-perturbative parameters remain unchanged wrt. the MEPS mode.

Estimate of uncertainties In order to estimate the uncertainites of the SHERPA predictions, the following procedures have been applied:
(A) PDF uncertainties:

Unlike in the PDF4LHC presciption [468], here only the central predictions of the three NLO PDFs, CT10 [255], MSTW2008 [262] and NNPDF2.1 [312] are compared to estimate the PDF uncertainties. The different parametrisations of PDFs as well as their corresponding value of $\alpha_{s}$, both its value at $M_{Z}$ and its running, enter in the calculation of the matrix elements, the parton shower and the underlying event.
(B) Scale uncertainties:

In a global manner, all scales, renormalisation and factorisation scales are simultaneously modified by the canonical multiplication with 2 and $1 / 2$. This, however, is not only applied to the evaluation of the matrix elements but also to that of the parton shower, the hadronisation, the underlying event simulation and the hadron decays. Regarding the matrix-element evaluation, the MEPs default scale choice forms the starting point for the scale variations to be executed.
(C) Hadronisation uncertainty:

Here the intrinsic modeling uncertainties are evaluated by changing the hadronisation model operating on SHERPA's parton shower final states, namely switching from SHERPA's default cluster hadronisation to PYTHIA's string fragmentation. For both schemes, an independently tuned set of parameters has been employed to perform the parton-to-hadron transition.
(D) Underlying event uncertainty:

To this end the tune of the underlying event based on using the CT10 PDF has been modified such that the plateau of the number of charged particles and sum of transverse momenta in the transverse region are increased or decreased by $10 \%$. This change in the amount of MPI activity is accomplished by varying the $\sigma_{\mathrm{ND}}$ correction factor (SIGMA_ND_FACTOR) by -0.04 or +0.05 , respectively.

### 18.3 Results

In this section we compile results for the individual codes for a number of representative observables at the different levels of the simulation. It should be noted, though, that in all results presented in this section PDF uncertainties have been estimated by typically varying only over a few different sets rather than employing the full procedure as suggested by the PDF4LHC accord [468].

### 18.31 BLACKHAT + SHERPA

The following results have been obtained with BlackHat+SherPa. Uncertainties due to the factorisation/renormalisation scale variation and the that due to the PDF uncertainties are shown. The yellow band corresponds to the addition in quardature of these two uncertainties and the statistical estimation on the integration error. All observables are defined using the ATLAS cuts, cf. App. 18.6.

Fig. 64 displays the inclusive cross section for a $W$ boson in association with $n$ jets, where $n=1,2,3,4$. A NLO computation of $W+4$ jets also provides a leading order calculation of the $W+5$
jets rate, but since it is not at NLO accuracy we refrain here from including it.
In all the plots presented in this section the uncertainties are dominated by the uncertainty arising from the scale variation (it is not the case when the central scale of the process is chosen close to a local maximum, in which case the upper boundary of the scale variation is very close or identical with the central value, as can be seen from the plots corresponding to $W+3,4$ jets). This is partially due to the fact that for the assessment of the PDF uncertainty only error sets have been employed that are closely related to the central set. In addition, the functional form of the scale definition as given by the kineamtics of the final state has not been changed, but rather the emerging scales $\mu_{F}$ and $\mu_{R}$ have been multiplied in parallel by factors of 2 and $1 / 2$.

Fig. 61: Pseudo-rapidity and transverse momentum distributions for the first jet in inclusive $W+1$ jet production (upper panel), for the second jet in inclusive $W+2$ jet production (central panel), anf for the third jet in inclusive $W+3$ jet production (lower panel).

Fig. 63: HT distributions for event with at least one (top left), two (top right), three (bottom left) or four (bottom right) jets.

Fig. 64: Inclusive cross section for $W+n$ jet production.

### 18.32 GoSAM + SHERPA

The setup described in the previous section for the analysis using GoSAM+SHERPA gives the following theoretical uncertainties. The plots show that in general the scale uncertainties are bigger then the PDF uncertainties and that the renormalisation scale dependence is usually bigger then the dependence on the factorisation scale. To illustrate the decrease in the scale uncertainty given by the NLO calculation we also include the distributions for the pseudo-rapidity and transverse momentum of the second hardest jet, which have only tree-level accuracy. All observables shown are defined using the ATLAS cuts, cf. App. 18.6 Note that errors in the 2 -jet configuration are increased w.r.t. those provided by BLACKHAT+SHERPA, since here only $W+1$ jet configurations are dealt with at NLO, and the 2 -jet configurations therefore are descibed at LO only.

Fig. 65: Pseudo-rapidity and transverse momentum distributions for the hardest jet.

Fig. 66: Pseudo-rapidity and transverse momentum distributions for the second hardest jet. This distribution have formally leading order accuracy and have therefore a much larger scale dependence than the same distribution for the hardest jet, for which a genuine NLO prediction is available.

Fig. 67: HT distributions (left) and $\Delta R$ between lepton and hardest jet (right) for events with at least one jet.

### 18.33 HEJ

This section contains the predictions from the High Energy Jets (HEJ) event generator. This gives predictions for the production of a $W$ boson in association with at least two jets. Throughout, we show results for CTEQ, MSTW and NNPDF parton distributions. We show a scale uncertainty band only for the first of these for clarity. The results for the other two are very similar. The yellow band in the ratio panel shows the statistical uncertainty in each case. The scale variation is seen to be dominant over the statistical uncertainty and the differences in choice of pdf. All observables are defined using the CMS cut definitions, cf. App. 18.6

As discussed in Sec. 18.23, the resummation contained in the HeJ framework is supplemented with a merging procedure to ensure tree-level accuracy for events with up to and including four jets. This leads to the larger drop from the four jet to the five jet cross section, compared to the drop either from

Fig. 68: The Hes prediction for the distribution of the transverse mass of the $W$ boson (top left) and for the angle between the hardest jet and the charged lepton from the decay of the $W$ boson (top right), the transverse momentum of the hardest jet (bottom left) and for the $H_{T}$ distribution (bottom right) in events where a $W$ boson was produced in association with at least two jets.

Fig. 69: The Hes prediction for the cross sections of $W$ plus $n$ jets.
three-jet to four-jet, or from five-jet to six-jet. This can be clearly seen in Fig. 69

### 18.34 MadGraph + PYthia

The following results have been obtained with MadGraph+Pythia. Uncertainties due to the factorisation and renormalisation scale and MEPs matching scale are shown for results on hadron level including UE and QED final state radiation. A comparison of results on parton shower level, hadron level, hadron level including UE, and hadron level including UE and QED final state radiation, is also presented. All observables shown are defined using the CMS cuts, cf. App. 18.6.

From these results we can conclude that the largest uncertainty on all observables is due to the factorisation and renormalisation scale. In addition to that, a large effect is found by switching off the final state QED radiation, while only a small difference is oberved between results at the shower level and all other results prior to the QED radiation.

Fig. 71: MADGraph+PYTHIA results for $\Delta R$ between lepton and hardest jet.

Fig. 72: MadGraph+Pythia results for for $p_{\perp}$ of hardest jet (top), number of jets (middle) and $H_{T}$ of events with at least 2 jets (bottom).

### 18.35 Powheg Box + Pythia8

In this section we show results obtained by running the Powheg Box implementation of $W+1$ jet together with Pythia8. In all the following plots of this section, CMS analysis cuts have been enforced, see App. 18.6. For this study, in the left panels of Figs. 73.75, we show uncertainties obtained from variations of renormalisation and factorisation scales by a factor of two in either directions and by choosing different PDF sets in the computation of the hard scattering. Results are shown at the final level, after the shower, the hadronisation and the inclusion of MPI, all performed by PYTHIA8. In general, we notice that the uncertainty due to scale variations is greater than the changes in the results due to different PDF choices.

In the right panels of Figs. $73 / 75$ we show our results at different stages of the simulation, for a fixed PDF set (chosen to be CT10). The stages considered include from the first emission level up to the full showered events in PYTHIA8, including MPI and also effects due to QED radiation off leptons and quarks. Various stages of the simulation have been obtained setting the PYTHIA8 switches as reported in Sec. 18.73 .

We recall here that results should be considered to be physical only after the the hadron level is reached (possibly including MPI and QED effects). In particular, we stress that the results at the parton level are obtained considering only the POWHEG first emission, and they are therefore only intermediate: indeed at this stage only the hardest radiation has been generated and effects due to further showering are not yet taken into account.

For most of the observables results do not show large variations going from a simulation level to another. In particular, for truly NLO predictions such the plots in Fig. 74 or the bin $n_{\text {jet }}=1$ of Fig. 73 , the major effects that arise at each successive stage of the simulation are a change in the normalisation, due to a slightly different number of events passing the analysis cuts when multiple emissions are allowed, and a moderate shape distortion in the low end of the spectrum. Both these effects may be attributed to multiple QCD radiation due to Sudakov effects introduced by the parton shower. As expected, these effects are of the same size, or smaller, than the theoretical uncertainty due to scale and PDF's variations, when propagated to the hadronic level. Similar effects are also observed when the QED radiation is turned on. In this case, results are lowered as a consequence of the cuts on the lepton transverse momentum and rapidity.

Due to the requirement of having at least two jets, the remaining observables are predicted only at leading order or with leading log accuracy by the Powheg simulation of $W+1$ jet. This is also reflected

Fig. 73: The number of jets, as predicted by Powheg Box + Pythia 8 .

Fig. 74: The hardest jet transverse momentum distribution (upper plots), the $\Delta R$ separation (middle plots) and the invariant mass $m$ (lower plots) of the hardest jets and the hardest lepton, as predicted by Powheg Box + Pythia8.

Fig. 75: The transverse momentum $p_{\perp}$ of the next-to-hardest jet, the scalar sum of the jet transverse energy $H_{T}$ of events with at least 2 jets and the sum of the transverse energies of all the particles in events with 2 or more jets, as predicted by Powheg Box + Pythia8.

Fig. 76: Comparison between predictions using different PYTHIA8 tunes, at hadron level with MPI, as predicted by Powheg Box + Pythia8.
in the larger band associated with the scale variations.
Observables such as $H_{T}$, the scalar sum of the transverse energy of the jets for events with two or more jets, show an enhancement in the high- $H_{T}$ tail. This effect mostly arise as a consequence of the showering, since the successive stages do not change the predictions any longer. The same behaviour, even more enhanced, is also observed in the scalar sum of the transverse energy of all particles, always in events with two or more jets.

In Fig. 76 we instead compare the effect of using different PYTHiA8 tunes on our predictions, obtained in this case at the hadron level, including MPI. Essentially all the observables turned out to be extremely stable under the variations of the PYthia8 tune, as shown in Fig. 76. Major differences only appears for the beam thrust, when it is defined at the particle level (see App. 18.62).

### 18.36 Pythias

For this study, PYthia8 has been run stand-alone and including matrix elements with additional jets. Note that in PYthia8, multiple interactions are interleaved with space- and time-like showers, meaning that in general, MPI and parton showers cannot be disentangled by just switching off secondary scatterings. When referring to "Hadron Level", we mean after the interleaved evolution (including QED

Fig. 77: Tuning variations for Pythia8 at hadron level. The plots show the $H_{T}$-distribution when requiring at least two jets (upper left), the $p_{\perp}$ of the hardest jet (upper right), the $\Delta R$-separation of lepton and the hardest jet (lower left), and the number of jets (lower right). The lower insets show the ratio of the samples in the upper half to ME3PS (Tune 4C, y-blind treatment). All merged plots are produced with a merging scale of $t_{\mathrm{MS}}=15 \mathrm{GeV}$.
splittings), and after hadronisation. For the sake of comparison, "Shower Level" indicates results after (interleaved) final- and initial-state radiation, switching multiparton interactions off. All results presented in this section are generated with CTEQ6L1 parton distributions for protons colliding at $E_{\mathrm{CM}}=7000$ GeV . Cккw-L-merged samples include up to three additional jets, taken from MADGraph/MadEvent.

Fig. 77 exemplifies how changes in the tuning of the event generator can affect the outcome of merged calculations in PYTHIA8. For this, we produce predictions for Tune 4C [455] and Tune A2 [458]. In general we observe only modest shape changes of up to about $20 \%$ in observables, when comparing the two merged predictions, lending confidence to the statement that the tuning did not artificially produce hard scale physics. Normalisation changes between 4 C and A2 can be explained by a difference in Sudakov suppression: Since Tune 4C integrates the splitting kernels over a smaller region of phase space, the suppression generated by trial showers is less pronounced. The increase in the number of jets in Tune A2 with respect to Tune 4C, after the third jet, is expected, because the generation of the fourth jet is handled solely by the parton shower. Since 4C allows less phase space for these emissions by

Fig. 78: Variation of the merging scale value for Pythia8 at shower level. The plots show the $H_{T^{-}}$ distribution when requiring at least two jets (upper left), the $p_{\perp}$ of the hardest jet (upper right), the $\Delta R$-separation of lepton and the hardest jet (lower left), and the number of jets (lower right). The lower insets show the ratio of the samples in the upper half to ME3PS for $t_{\text {MS }}=30 \mathrm{GeV}$. All plots are generated using Tune 4C (y-blind treatment).
enforcing rapidity ordering, A2 will look harder. It is debatable whether including rapidity ordering into the tuning makes the tune mimic hard scale effects. The scales at which the fourth jet is produced are certainly close to the scale of (hard) multiple interactions, which is in turn closely connect to soft physics. Although the enforced rapidity ordering in Tune 4C might be considered questionable, we here take the pragmatic approach of considering the evolution both with and without enforced rapidity ordering. From the fact that up to three jets, the merged predictions of Tune 4C and Tune A2 only differ in normalisation, we anticipate that the effect of rapidity ordering will be reduced by merging more jets, since then, the number of jets above a cut-off will be dictated by the matrix element.

In Fig. 78, we investigate the impact of changes in the merging scale value. Again, we mainly see normalisation changes and only small changes in shape, which in most cases are smaller than changes due to different tunes. The $R$-separation between lepton and hardest jet $\Delta R$ (lepton, hardest jet) shows significant shape changes above $\pi$. This again is an effect of Tune 4C, and is greatly reduced in Tune A2 $2^{40}$, as

[^224]

Fig. 79: Variation of the criterion employed to favour "ordered histories" in Pythia8 at shower level. The plots show the $H_{T}$-distribution when requiring at least two jets (upper left), the $p_{\perp}$ of the hardest jet (upper right), the $\Delta R$-separation of lepton and the hardest jet (lower left), and the number of jets (lower right). The lower insets show the ratio of the samples in the upper half to ME3PS (Tune 4C, y-blind treatment). All merged plots are produced with a merging scale of $t_{\mathrm{MS}}=15 \mathrm{GeV}$.
can be inferred from the tune variation. However, even in Tune A2, small shape changes remain, with the change becoming less pronounced when comparing two large merging scales. We take this as an indication that the shower splitting probability - giving radiative contributions to $\Delta R$ (lepton, hardest jet) $>\pi$ for high $t_{\mathrm{Ms}}$ - and the the matrix element, which fills the same region in for the low merging scale case, are indeed different from the second jet on. This also explains the difference between Tune 4C and Tune A2, which differ by the phase space regions over which the splitting kernels are integrated.

Finally, in Fig.79, we address the interplay of matrix element merging and ordering in the underlying shower more carefully. The effect of different choices manifests itself again mainly in changes of the normalisation of the plots, and is comparable in magnitude to the impact of merging scale variations. At first, the changes may seem counter-intuitive, and need clarification. For this, it is important to remember the definition of " y -blind" and " y -conscious" in section 18.26 . The y -blind treatment will - irrespectively of rapidity configurations - mainly choose histories ordered in the shower evolution variable $\rho$, and only

[^225]pick $\rho$-unordered histories if no other ones have been constructed. However, in the y-conscious approach, once no history ordered both in rapidity and $\rho$ is found, one amongst all un-ordered histories is chosen probabilistically, irrespectively of the history being y-/ $\rho$-/or y- and $\rho$-unordered. Since the ordering criterion is stricter, un-ordered histories will be chosen more frequently, meaning that $\rho$-unordered ones will also contribute more, compared to the y-blind case. Matrix element states with no ordered histories will have a number of jets at very similar scales, so that the Sudakov suppression generated by trial showers will be smaller. Moreover, for matrix element states in which the last reconstructed splitting is unordered, the parton shower will be started at the larger of the unordered scales ${ }^{41}$, which can result in a slightly harder spectrum of resolved parton shower jets. Because $\rho$-unordered states are picked more often when requiring a tighter ordering criterion, this leads in visible differences. The y-conscious method might seem somewhat artificial, considering that it introduces a larger dependence on states outside the range of even the $y$-unordered shower variant. Nevertheless, the $y$-blind and $y$-conscious prescriptions are equivalent to the accuracy of the (y-ordered) shower, so that both should be investigated when assessing the quality of the merging. From the visible changes, we can infer that different treatments of formally sub-leading effects do matter. For the y-ordered evolution, these are more visible since the accuracy of the shower itself is worse, so that the effects of including matrix element states cancel to a lesser degree. It is interesting to note that the deviations between the different prescriptions are considerably smaller if the merging scale is increased, again hinting at a reduced shower accuracy if the evolution is ordered in multiple variables.

Fig. 79 further shows distributions labelled Tune $X$, which have been generated by using Tune 4 C , removing the rapidity constraint on space-like emissions, and treating histories y-blind. Results of these runs, as expected, closely follow Tune A2. The outcome of both Tune A2 and Tune X differs only slightly from the Tune 4 C (y-blind) curves, consolidating the conclusion that shifting fractions of $\rho$-un-ordered histories are responsible for the deviations between the y-blind and y-conscious methods. As in the discussion of tuning variation, the similarity in the results of the merged calculation for Tune 4C and Tune A2 breaks down once we examine jets that are solely produced by the shower, i.e. starting from the fourth jet.

### 18.37 SHERPA

As described in Sec. 18.27 , SHERPA has been run in two modes for this comparison of LHC predictions. The results for the conventional merging of towers of tree-level matrix elements, SHERPA MEPS, are presented in Sec. 18.37 while the results of its enhancement to NLO accuracy in the core $W$ production process, Sherpa MeNloPs, are displayed in Sec. 18.37 . As detailed earlier, all parameters have been chosen identically otherwise. The precise requirements regarding the event selection and the definitions of the observables used in this comparsion follow the CMS cut specifications and can be found in App. 18.6.

SHERPA MEPS Figs. 80,83 show the results as obtained by running SHERPA in the MEPS mode for a variety of inclusive and multi-jet observables at different levels of the event generation. All central results are displayed together with their respective uncertainties related to the different sources listed in Sec. 18.27. The layout in all figures is the same: the upper left and right panels respectively show the matrix element level and parton shower level predictions for a given observable. The matrix element level is defined as the event generation phase right before the parton showering. For the MEPs approach this means that modifications necessary for the procedure to work like $\alpha_{s}$ reweighting and Sudakov rejection have been already included at this level. The predictions presented in all centre panels were generated after enhancing the event generation to include corrections induced by the parton-to-hadron transition and decays of the therein produced primordial hadrons. On top of these soft physics effects, one has to also

[^226]

Fig. 80: SHERPA MEPS. Uncertainty of the transverse mass of the reconstructed $W$ on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 81: Sherpa MePs. Uncertainty of the angular separation of the charged lepton and the hardest jet on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 82: SHERPA MEPS. Uncertainty of the transverse momentum of the hardest jet on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 83: Sherpa MEPs. Uncertainty of the inclusive jet multiplicity on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.
account for multiple parton interactions. The results in the centre right panels of all figures incorporate these additional corrections. Finally, all plots to the lower left show the most complete hadron level predictions, which were obtained by adding to the event generation QED radiation effects as occurring in the decays of the vector boson and the hadrons. To allow a direct comparison of the impact of the consecutive event stages, the way the central results change is summarized in all plots to the lower right of Figs. 80.83 . In these, as in all other panels, the main plots are supplemented by ratio plots stressing the magnitude of the differences and uncertainties. Note that the yellow band throughout illustrates the statistical uncertainty on the central event sample.

Apart from the summary plots at the lower right, all other cases depict predictions documenting the uncertainty of the central predictions at the different levels of event generation. These uncertainty estimates are gained following the procedures outlined in Sec. 18.27. At all event simulation phases, the scales are varied as described under this section's point (B). Note that the variation is applied to all phases used to make up the respective central (or default) sample, which is taken as the reference under all circumstances. For the matrix element level, parton shower level and full hadron level results, PDF variations according to point (A) are shown in addition, whereas for the centre panel plots, the focus is on the outcomes of the model and tune variations instead, as specified in point (C) and point (D) of Sec. 18.27. Notice that the lower left panels also contain the outcomes of scale variations utilizing the alternative PDFs mentioned under point (A); they are much alike the ones stemming from the default set.

As an example for an inclusive observable the transverse mass of the reconstructed $W$ boson is shown in Fig. 80. The scale uncertainties amount to $\sim 15 \%$ at all generation levels, whereas the uncertainties due to the choice of PDF are much smaller. Similarly, the hadronisation uncertainty is negligible. The $m_{\perp, W}$ observable however is more sensitive to the tuning of the MPI model as can be seen from the $\pm 10 \%$ envelope in the centre right plot of Fig. 80. The uncertainty is of the same order as for the scale variations, which generally are more pronounced in the soft region. When considering the impact of each perturbative and non-perturbative event stage (see the plot to the lower right), it is the MPI corrections that are largest in the region of $m_{\perp, W}<m_{W}$, ranging up to $\sim 30 \%$ wrt. the matrix element level prediction. They are small above $m_{W}$. In this region the dominant effect comes from the QED corrections, which themselves are rather small, but they lead to a contamination of the electron isolation. The application of the isolation cuts then yields a reduction of the overall normalisation of the event sample. Finally there is a small shift towards lower transverse masses, pronouncing the deviation in the tail of the distribution somewhat further.

Fig. 81 and Fig. 82 depict observables that require the presence of at least one jet. In the former the geometric separation, $\Delta R$, between the hardest jet and the electron is shown, while in the latter, focus is on the transverse momentum, $p_{\perp}$ of the hardest jet only. As before the dependence of the predictions on PDF and hadronisation model changes remains negligible. While the scale dependence of the $\Delta R$ and $p_{\perp}$ variables increases to $\sim 30 \%$, the uncertainty due to the tuning of the MPI model decreases to $\sim 5 \%$ when compared to the findings concerning the more inclusive observable considered above. In both cases the reason for the sensitivity change obviously lies in demanding at least one (hard) jet. The scale uncertainties primarily result from changes in the overall cross section. Again, comparing the results of the different event stages, one clearly observes the large impact parton showering has on modifying the matrix element level predictions. The non-perturbative effects go in the same direction amplifying the parton shower effects, but as expected this amplification turns out to be rather mild in the well separated and/or hard phase space regions. QED corrections only play a minor role, and are far less important than for the $m_{\perp, W}$ variable.

In Fig. 83 one of the simplest examples of a multi-jet observable is presented, namely the distribution of the inclusive $W+n$ jet cross sections as a function of $n_{\text {jet }}$. Qualitatively, the parameter and model dependencies of the predictions are found to behave as for the inclusive one-jet variables. As one would expect, the scale uncertainties subsequently increase with the order of the jet bin. The same can be noticed for the variation of the PDFs used in the calculation - even though here the effect is considerably
smaller.

Sherpa MeNloPs Following the outline of the previous subsection, Figs. 84.87 compile the results, which were obtained by executing SherPa in the MENLoPs mode, cf. Sec. 18.27. The presentation is based on the same set of figures where the selection of the observables has been taken as in the MEPS case. Again, all (central) predictions are examined towards their scale, PDF, non-perturbative modeling and QED simulation dependence. One small difference has to be pointed out: the plots to the lower left now depict exclusively to what extent the additional QED corrections modify the outcomes including multiple parton interactions and hadronisation effects.

Fig. 84 shows the transverse mass of the reconstructed $W$ boson. In the MENLOPs approach, this observable is described at NLO accuracy, which leads to a reduction of the associated scale uncertainties. The scale variation results for $m_{\perp, W}$ nicely confirm this expectation as can be seen in the upper four plots of Fig. 84. The deviations from the central prediction are much smaller than those found for the MEPs scenario exhibited in Fig. 80, they now are of similar magnitude as the PDF uncertainties. While the scale dependence is reduced, PDF and MPI tune variations as well as QED corrections manifest themselves as in the MEPS case. In particular, the discussion around Fig. 80 explaining the effects of extra QED emissions (as being most relevant in the $W$ decay) can be used to understand the findings illustrated in the bottom left panel of Fig. 84

The MENLOPs method primarily improves the precision of the description of the core process, here the description of the $W$ production process. One also benefits from improving the overall normalisation. However, processes with additional partons in the final state are described in the MENLoPs approach at the same level of accuracy as in the MEPS approach - in both cases by tree-level matrix elements. Thus, the one-jet observables, $\Delta R$ between the lepton and leading jet and the $p_{\perp}$ of the leading jet, and their related uncertainties turn out to be predicted in a very similar manner. This can be clearly observed by comparing Figs. 85486 with Figs. $81 / 82$. Unlike the findings for $m_{\perp, W}$, it particularly can be noticed that the scale dependence associated with the one-jet observables shown here remains unchanged when compared to the respective MEPS results.

Fig. 87 depicts the distribution of the inclusive $W+n$ jet cross sections as obtained for the MeNloPs case. Using the above reasoning, one can understand these results as for the one-jet variables. Note that the scale dependence of the zeroth jet bin shows the expected decrease owing to the NLO accuracy underlying the description of the core process.

Fig. 88 finally, highlights the evolution and uncertainties of two definition of the beamthrust, cf. App. 18.6 a physical observable summing over all final state particles excluding the $W$-constituent lepton and a pseudo-observable including the $W$ itself. For both observables small perturbative uncertainties are completely burried underneath much larger non-perturbative effects and modelling uncertainties, an effect also seen in results from the Powheg Box+Pythia simulation, cf. Fig. 76. This can only be interpreted as this observable being dominated by non-perturbative effects and in particular the underlying event, which somewhat invalidates statements about the merit of this observable in a clean determination of initial state radiation effects made in [469, 26].

Fig. 84: Sherpa MeNloPs. Uncertainty of the transverse mass of the reconstructed $W$ on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 85: Sherpa MeNloPs. Uncertainty of the angular separation of the charged lepton and the hardest jet on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 86: Sherpa MeNloPs. Uncertainty of the transverse momentum of the hardest jet on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 87: Sherpa MENLoPs. Uncertainty of the inclusive jet multiplicity on the matrix element level (upper left), after parton showering (upper right), including hadronisation correction (centre left), multiple parton interactions (centre right), and QED corrections (lower left). The lower right panel shows the evolution of the central value.

Fig. 88: Sherpa MeNloPs. Evolution and uncertainty of two definitions of the beamthrust, calculated using all particles not constituting the $W$ (left) and including the $W$ (right). Exemplary, the combined PDF and scale uncertainty on the matrix element level prediction (yellow) and the modeling uncertainty of the hadron level prediction (blue) are shown.

### 18.4 Comparisons

In this section we compare the results of different tools with each other. While the aim of this study was to have a fairly tuned comparison with as many aspects of the calculations as possible being centrally defined, there are still important residual differences in the various results. Obviously, the different codes produced results at different stages of the simulation, which are not always directly comparable; in addition, some of these stages are not very straightforward to obtain: for instance, running PyTHIA8 without multiple parton interactions included in the interleaved showering obviously changes the overall logic of the parton shower model of this code. In addition, other, more obvious differences occur, ranging from inconsistent choices of PDFs to different strategies in scale setting procedures. For the case of the PDFs, by directly comparing results obtained with BlackHat+SHERPA using CTEQ6.6 and with GoSAM+SHERPA using CT10, it appears as if at NLO these differences are minor. However, it is not clear how much of the differences between MADGraph+PYTHIA and PYTHIA8, which both employ CTEQ6L1, and the other codes, which employ NLO PDFs, can be attributed to differences in PDFs.

In addition, results obtained with the NLO codes typically include at least one jet - Powheg Box+Pythia8 and GoSam+Sherpa take $W+1$ jet at NLO as their core process - while Hej starts at $W+2$ jets, and BlackHat+Sherpa presents results for up to 4 jets accompanying the $W$ boson in different jet bins. Obviously, on the other hand, the multijet merged samples of MadGraph + PYthia, Pythia8 MePs and Sherpa include LO matrix elements for up to 3 to 6 jets.

In the plots in this section each code is shown with a yellow error band, which is the envelope of the variations presented in Sec. 18.3. The only exception is BLACKHAT+SHERPA, which is shown with a blue error band. In the ratio plots the codes are plotted relative to BLACKHAT+SHERPA, also at the parton shower level.

### 18.41 Inclusive observables

In this section we present some inclusive observables, which are typically all obtained from codes employing multijet merging. By and large, all codes agree in the shapes of the $m_{\perp, W}$ distribution at different stages, although there are sizable differences in the respective normalisation of the samples.

Fig. 89: Transverse mass of the reconstructed $W$ on all levels of the simulation, for the exact definition see App. 18.62 and for the cuts employed in the analysis App. 18.61 Note that PyTHIA8 and MadGraph+PyTHia use the CTEQ6L1 pdf, while Sherpa uses CT10.

### 18.42 Observables with at least one jet

As a first and fairly telling observable the $p_{\perp}$-spectrum of the hardest jet is compared, cf. Fig. 90, At the parton level, the results of the NLO calculations - BLACKHAT+SHERPA and GOSAM+SHERPA- agree nearly perfectly with each other and within about $20 \%$ with the multijet merged samples of SHERPA, both at LO (Sherpa MePs) and in the MeNloPs (Sherpa MenloPs) sample. The increase of the latter with respect to the former at relatively low transverse momenta of about 50 GeV or below can probably be related to the different scale definition in the argument of the strong coupling, where the NLO calculations choose $\mu_{R}^{2}=\left(H_{T}^{\prime} / 2\right)^{2} \approx M_{W}^{2} / 4+p_{\perp, j}^{2}$ while in the SHERPA simulation the transverse momentum of the jet has been chosen. Clearly, for small transverse momenta this will lead to visible differences. Going from the matrix element to the parton shower level typically leads to the jets becoming softer and to losing some of them, due to partons emitted outside the jet and a corresponding energy loss. This explains why the SHERPA distribution at the shower level is softer than the NLO result, and thus the SHERPA result at the matrix element level, although the size of the difference seems to be larger than one would naïvely expect. This finding is, however, somewhat at odds with the results obtained from MADGRAPH+PYTHIA, which seem to be slightly harder in shape and significantly larger in normalisation. The PYthia8 MEPS sample, on the other hand, has a smaller one-jet inclusive cross section than SHERPA, but the jet spectrum exhibits a somewhat harder tail, corresponding to a shape difference of about 30$40 \%$ with respect to both the Sherpa results. The same finding, a somewhat harder tail, is also true for the Powheg Box+Pythia8 results. The same trends can be also found at the hadron and hadron + MPI level. For the Powheg Box result the difference can be attributed to the usage of a scale defined at the "underlying-Born" level (cf. Sec. 18.25 for more details). Indeed it has been checked explicitly that a NLO computation performed with the same scale choice used in Powheg Box gives a result in complete agreement with the POWHEG Box result shown here. Clearly, the differences between different

Fig. 90: Transverse momentum of hardest jet on all levels of the simulation, where jets are reconstructed using the anti- $k_{\perp}$ with $R=0.4$ within $|\eta|<4.4$ (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BlackHat+ShERPA (on matrix element level).
calculations and codes exhibited here deserve a more in-depth study, which, unfortunately, is beyond the scope of this comparison.

Similar findings are also true for the next observable, the $\Delta R$ distribution between the lepton stemming from the $W$ decay and the hardest jet displayed in Fig. 91. Again, the two Sherpa samples are compared with the two NLO samples, this time exhibiting a sizable shape difference towards an increase at smaller and a decrease at larger distances of about $40 \%$ relative cross section. While higher jet configurations typically tend to be a bit more central, it seems far-fetched to attribute this difference only to them. At the same time, large differences in $R$ are most likely due to jets which are pretty much forward ${ }^{42}$. This region of phase space for jet production, however, is known to be quite susceptible to mismatches in scale and/or PDF definitions. However, it is worth noting that this difference vanishes almost completely at the parton shower level. The Pythia8 MEPs sample, despite a sizable difference in cross section, appears to follow the shape of the NLO and SHERPA results. Further comparing these results to those of the other codes at the shower level suggests that the MadGraph+Pythia merged sample, apart from a drastically enhanced cross section, also shows an enhancement in shape at smaller $\Delta R \leq 2$ w.r.t. the NLO result. Interestingly enough, the Powheg Box+Pythia8 sample exhibits the

[^227]

Fig. 91: $\Delta R$ between hardest lepton and hardest jet on all levels of the simulation (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).
opposite behaviour: while the cross section seems fairly consistent with the SHERPA and the NLO ones, the shape shows some enhancement of up to $40 \%$ at large distance $\Delta R$, which following the reasoning for the jet $-p_{\perp}$ spectrum may also hint at being due to a difference in the definition of scales. As before, the same trends visible at the parton shower level can also be found at the hadron and hadron + MPI level.

### 18.43 Multi-jet observables

In observables including at least two jets, consider first the case of the $H_{T}$ distribution depicted in Fig. 92 , Over the full range and obscured by large statistical fluctuations both SHERPA samples seem to follow the NLO prediction from BlackHat+Sherpa. The LO result from GoSam+Sherpa, on the other hand, appears to fall off at the hard end of the distribution. The prediction from HEJ is a bit more subtle to judge: at low $H_{T}$ (around 100 GeV ), we see that it is in good agreement with the predictions from the other approaches. However, as higher values of $H_{T}$ are probed, the Hes prediction becomes noticeably larger than the fixed-order descriptions, including those from SHERPA where different multiplicities are merged. This is the region in $H_{T}$ where we would expect high multiplicities to have a noticeable effect, and therefore where we would expect to see the impact of the resummation in Hej. This is, however, slighlty at odds with the fact that the SHERPA prediction included up to 6 jets and that the multijet rates and the $p_{\perp}$ distributions of the fifth and sixth jet from HeJ undershoot those from SHERPA, cf. Fig. 93

Fig. 92: $H_{T}=\sum_{i \in\{\mathrm{jets}\}} E_{\perp i}$ of events with at least 2 jets on all levels of the simulation (for exact definitions and cuts see App. 18.61 and App. 18.62. Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).
and Fig. 95. However, a similar trend concerning the hard tail of this distribution appears also on the shower level in the MadGraph+Pythia sample, which includes up to 4 extra jets, and in the Powheg Box + PYthia8 sample, which includes 2 jets at LO and 1 jet at NLO. The trend is even more pronounced with an even harder tail for the PYTHIA8 MEPS sample, which includes 3 extra jets. At this level, SHERPA more or less follows the NLO result. It should be noted, though, that all approaches remain within the scale variation band indicated on the BlackHat prediction. This findings are consistently carried over to the hadron and hadron+MPI level.

Turning to the $n$-jet rates, at the matrix element level, SHERPA follows fairly closely the NLO results in different jet multiplicity bins, while HeJ seem to overshoot the central value in the 3-and 4-jet bin, but staying inside the NLO scale uncertainty band. going back to the tree-level result of SHERPA in the 5- and 6-jet bins. As discussed in Sec. 18.33, the HeJ framework includes tree-level matching for final states with up to and including four jets in the final state. Therefore it is fair to assume that the absence of matching for five jets and above leads to the larger drop in cross section observed in Fig. 93 from four-jet to five-jet as compared to that from either three-jet to four-jet or from five-jet to six-jet and lends support to the suspicion that in HEJ a matched sample would also provide larger 5- and 6-jet multiplicities. At the shower level, the trend already visible at the $H_{T}$ distribution repeats itself. The smaller cross section in the PYTHIA8 MEPS sample is mainly due to the low multiplicity bins, such that the shape of the $n$-jet distribution also has a relatively harder tail than the SHERPA sample. In contrast,

Fig. 93: Number of jets on all levels of the simulation (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that Powheg Box+Pythia8 and GoSam calculate $W+1$ jet on matrix element level, while Hej starts with $W+2$ jets and that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).
the Powheg Box +Pythia8 result, starting consistently at 1 jet, appear to be at the upper end of the NLO uncertanities throughout.

Looking at the correlation of the two leading jets in Fig. 94 at the matrix element only, both the $\Delta R$ and the $m_{12}$ distribution provided by SHERPA have a slight tilt against the NLO prediction from BLACKHAT+ SHERPA, undershooting the latter result by up to about $40 \%$ for large $\Delta R$ and by up to about $20 \%$ for large $m_{12}$. While HEJ seems to roughly follow the shape of SHERPA for $\Delta R$, it is significantly harder than SHERPA and the NLO result for large values of $m_{12}$. In addition, in both cases, HeJ also predicts a larger cross section that the other tools.

Fig. 95 shows the transverse momentum distributions for the third to sixth jets ordered in $p_{\perp}$, and at the matrix element level. For the third hardest jet, the prediction from HEJ is similar in shape but higher in cross section than the results obtained at NLO from BLACKHAT+SHERPA or the two SHERPA samples. For the fourth jet, the Hej cross section still seems higher than the other ones, but this discrepancy seems to be mainly around comparably low jet $p_{\perp}$. For larger values of $p_{\perp}$ all tree-level type or resummed predictions are below the NLO result. Surprisingly, for the fifth and sixth hardest jets, the HEJ predictions follow the SHERPA ones for low values of $p_{\perp}$ below about 60 GeV , before they fall off nearly instantly. This again may be an artefact of tree-level matching not being included in HeJ for the production of fiveand six-jets or of missing statistical support in this region of phase space.

Fig. 94: $\Delta R$ of two leading jets (left) and invariant mass of two hardest jets (right) matrix element level (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, Pythia8 and MadGraph+Pythia CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BLACKHAT+SHERPA (on matrix element level).

Fig. 95: Transverse momentum of third to sixth hardest jet on matrix element level (for exact definitions and cuts see App. 18.61 and App. 18.62). Note that BlackHat uses the CTEQ6.6 pdf, PYTHIA8 and MadGraph+PyTHIA CTEQ6L1 and all the others use CT10. In both ratio plots the ratio is taken with respect to BlackHat+Sherpa (on matrix element level).

### 18.5 Conclusions

In this study first steps towards an update and extension of the comparison in [439] have been made. In contrast to the older study, a larger variety of tools including fixed-order and resummation tools as well as NLO matched and tree-level merged simulations have been included. Not surprisingly, some observables appear to be described fairly consistently between different tools, while others exhibit large deviations, sometimes clearly beyond the formal accuracy claimed by the different methods, and also beyond the best estimates of intrinsic modelling or calculational uncertainties provided by the authors. In some instances the relative differences are way beyond naïve expectations by most of the authors of this study. This clearly hints at the need to carefully cross-validate different tools before deploying them for large scale simulations, and it also necessitates an increased collaboration of the authors of such tools in order to arrive at a more consistent picture.

We hope that this study triggered some future work towards the latter goal.

## Acknowledgements

We would like to thank the organisers of Les Houches 2012 for repeatedly hosting such a fantastic and fruitful workshop. We would also like to thank all participants for a lively and stimulating atmosphere and lots of inspiring discussions.

Table 13: Cuts used in this study inspired by common ATLAS and CMS cuts.

Tab. 13 presents the cuts applied to define the event selection in both the ATLAS and CMS specifications.

### 18.62 Analysis procedure and definition of observables

A common analysis was implemented within the RIVET framework and used by all codes providing individual events. This analyses is carried out as defined in the following:

1. remove all neutrinos from all final states (i.e. 'all particles' from now on means 'all particles without neutrinos')
2. find hardest isolated lepton (electron or muon) ('lepton' from now on means 'hardest isolated lepton')
3. cut on lepton $p_{\perp}$ and $|\eta|$
4. compute missing transverse energy $E_{\perp}$ :
(a) sum the three-momenta of all particles within $|\eta|<10$, this yields $-\not p$
(b) compute missing energy as $\notin=|\boldsymbol{p}|$
(c) assume resulting four-vector $\not p$ corresponds to neutrino
5. for ATLAS cut on $E_{\perp}$
6. resonstruct $W$ four-momentum as $p^{W}=p^{\text {lepton }}+\not p$
7. compute $W$ transverse mass squared as $m_{\perp, W}^{2}=\left(p_{\perp}^{\text {lepton }}+\not p_{\perp}\right)^{2}-\left(p_{\perp}^{W}\right)^{2}$
8. cut on $W$ transverse mass
9. remove lepton from final state
10. cluster into jets keeping only those passing the $p_{\perp}$ and $|\eta|$ cuts
11. compute $H_{T}=\sum_{i \in\{\text { jets }\}} E_{\perp i}$
12. compute beam thrust $\tau_{B}=\sum_{i \in\{\text { particles }\}}\left(E_{i}-\left|p_{i}^{z}\right|\right)$ using all visible particles

It should be noted that this defintion of the $W$ is infra-red safe only for transverse observables.

### 18.7 Detailed settings

### 18.71 Sherpa

For this study Sherpa-1.3.1 was used. Except for the underlying event, which was tuned for the CT10 [255] parton distribution functions and whose parameters are given below, all other nonperturbative parameters were kept at their default values. The underlying model was tuned for the cluster hadronisation.

| K_PERP_MEAN_1 | 1.17 |
| :--- | :--- |
| K_PERP_MEAN_2 | 1.17 |
| K_PERP_SIGMA_1 | 0.760 |
| K PERP_SIGMA_2 | 0.760 |
| PROFILE_PARAMETERS | $0.576,0.353$ |
| RESCALE_EXPONENT | 0.238 |
| SCALE_MIN | 2.52 |
| SIGMA_ND_FACTOR | 0.465 |

### 18.72 Pythia8

To produce the results, we have used two tunes of Pythia8, Tune 4C and Tune A2, both of which use CTEQ6L1 parton distributions. Tune 4C is the default tune in PYTHIA8- no additional input settings are necessary. For completeness, below we list all parameters that are implicitly set by choosing the default Tune 4C.

```
PDF:pSet = 8
SigmaProcess:alphaSvalue = 0.135
SigmaDiffractive:dampen = on
SigmaDiffractive:maxXB = 65.0
SigmaDiffractive:maxAX = 65.0
SigmaDiffractive:maxXX = 65.0
```

```
TimeShower:dampenBeamRecoil = on
TimeShower:phiPolAsym = on
SpaceShower:alphaSvalue = 0.137
SpaceShower:samePTasMPI = false
SpaceShower:pT0Ref = 2.0
SpaceShower:ecmRef = 1800.0
SpaceShower:ecmPow = 0.0
SpaceShower:rapidityOrder = on
SpaceShower:phiPolAsym = on
SpaceShower:phiIntAsym = on
MultipartonInteractions:alphaSvalue = 0.135
MultipartonInteractions:pT0Ref = 2.085
MultipartonInteractions:ecmRef = 1800.
MultipartonInteractions:ecmPow = 0.19
MultipartonInteractions:bProfile = 3
MultipartonInteractions:expPow = 2.0
BeamRemnants:primordialKTsoft = 0.5
BeamRemnants:primordialKThard = 2.0
BeamRemnants:halfScaleForKT = 1.0
BeamRemnants:halfMassForKT = 1.0
BeamRemnants:reconnectRange = 1.5
```

A detailed discussion of these choices can be found in [455]. All other parameters remain with their default values. For our purposes, it might be interesting to remark that the starting value for $\alpha_{s}$-evolution in time-like splittings is given by

SpaceShower:alphaSvalue $=0.1383$
To investigate the impact of rapidity ordering in space-like showers, we chose to remove enforced rapidity ordering by setting

SpaceShower:rapidityOrder = off
If rapidity ordering is enforced in ISR, the question arises how it should be treated when picking histories. For this purpose, PYTHIA8 supplies the switch

Merging:enforceStrongOrdering
When switched "on", this parameter will result in picking non-rapidity-ordered histories only if no rapidity-ordered paths where found, thus disfavouring non-rapidity-ordered parton shower histories for matrix element states. To have a more complete understanding of the impact of tuning, we also changed to the recently proposed Tune A2 [458]. For this, we have to set

Tune:pp $=7$
Pythia8 will then reset the following parameters:

```
PDF:pSet = 8
SigmaProcess:alphaSvalue = 0.135
SigmaDiffractive:dampen = on
SigmaDiffractive:maxXB = 65.0
SigmaDiffractive:maxAX = 65.0
```

```
SigmaDiffractive:maxXX = 65.0
TimeShower:dampenBeamRecoil = on
TimeShower:phiPolAsym = on
SpaceShower:alphaSvalue = 0.137
SpaceShower:samePTasMPI = false
SpaceShower:pT0Ref = 2.0
SpaceShower:ecmRef = 1800.0
SpaceShower:ecmPow = 0.0
SpaceShower:rapidityOrder = false
SpaceShower:phiPolAsym = on
SpaceShower:phiIntAsym = on
MultipartonInteractions:alphaSvalue = 0.135
MultipartonInteractions:pTORef = 2.18
MultipartonInteractions:ecmRef = 1800.
MultipartonInteractions:ecmPow = 0.22
MultipartonInteractions:bProfile = 4
MultipartonInteractions:a1 = 0.06
BeamRemnants:primordialKTsoft = 0.5
BeamRemnants:primordialKThard = 2.0
BeamRemnants:halfScaleForKT = 1.0
BeamRemnants:halfMassForKT = 1.0
BeamRemnants:reconnectRange = 1.55
```

Apart from not enforcing rapidity ordering in space-like splittings, this tune differs from Tune 4C in that the proton size is considered $x$-dependent. This is in the spirit of Tune $4 C X$, which was introduced in [470]. In general, since we include matrix element states for two and three jets, we do not apply additional matrix element corrections in PYTHIA8 after the first emission, by setting

```
SpaceShower:MEafterFirst = off
TimeShower:MEafterFirst = off
```

### 18.73 Powheg Box + PYtHiA8

For this study we used Powheg Box rev1282 and Pythia 8.153. Except for the specific subprocess requested, the parton distribution functions set and the renormalisation/factorisation scale factors chosen, all the other parameters were kept fixed below during all the runs. Here is a sample Powheg Box input file:

```
! W^+ + jet production parameter
idvecbos 24 ! PDG id of vector boson (24: W+, -24: W-)
vdecaymode 1 ! decay channel (1: electron, 2: muon, 3: tau)
numevts 4000000 ! number of events to be generated
ih1 1 ! hadron 1 (1 for protons, -1 for antiprotons)
ih2 1 ! hadron 2 (1 for protons, -1 for antiprotons)
ebeam1 3500d0 ! energy of beam 1 in GeV
ebeam2 3500d0 ! energy of beam 2 in GeV
lhans1 192800 ! pdf set for hadron 1 (LHA numbering)
lhans2 192800 ! pdf set for hadron 2 (LHA numbering)
ncall1 100000 ! number of calls for initializing the ...
itmx1 5 ! number of iterations for initializing the ...
ncall2 250000 ! number of calls for computing the integral ...
```

| itmx2 | 4 | ! number of iterations for computing the ... |
| :--- | :--- | :--- | :--- |
| foldcsi | 1 | ! number of folds on csi integration |

When interfacing to Pythia8 we have changed the following settings with respect to Pythia8 defaults, for the various stages under investigations:
///Hadron Level w MPI and QED
BeamRemnants:reconnectRange $=1.50000$
MultipleInteractions:alphaSvalue $=0.13500$
MultipleInteractions:bProfile = 3
MultipleInteractions:ecmPow $=0.1900$
MultipleInteractions:expPow $=2.0000$
MultipleInteractions:pT0Ref $=2.0850$
PDF:pSet $=8$
SigmaDiffractive:dampen $=$ on
SigmaDiffractive:maxAX $=65.0000$
SigmaDiffractive:maxXB $=65.0000$
SigmaDiffractive:maxXX $=65.0000$
SigmaProcess:alphaSvalue $=0.13500$
SpaceShower:MEafterFirst $=$ off
SpaceShower:MEcorrections = off
SpaceShower:pTmaxMatch $=0$
SpaceShower:rapidityOrder = on
TimeShower:MEcorrections $=$ off
TimeShower:MEafterFirst $=$ off
TimeShower:pTmaxMatch $=0$
//Hadron Level w MPI (added)
SpaceShower:QEDshowerByQ = off
SpaceShower:QEDshowerByL = off
TimeShower:QEDshowerByQ $=$ off
TimeShower:QEDshowerByL $=$ off
//Hadron Level w/o MPI (added)
PartonLevel:MI = off

```
//Shower Level (added)
HadronLevel:All = off
//Parton Level (added)
PartonLevel:ISR = off
PartonLevel:FSR = off
PartonLevel:Remnants = on
```

and, most important, we have vetoed shower emissions with a transverse momentum greater than the value of SCALUP read from the Les Houches event file for the corresponding event.

### 18.74 MADGRAPH + PYTHIA

For this study MADGRAPH/MADEVENT 5.1.1.0 and Pythia 6.4.2.4 is used. The LHE files are generated for events with a $W$ and up to four additional partons, i.e. for the process:

```
pp>w- -> l-vl~ ; l-vl~~j ; l-vl~~jj ;l-vl~~jjj ; l-vl~~jjjj ;
l-vl~ ; l-vl~j ; l-vl~jj ;
l-vl~jjj ; l-vl~ jjjj ()
```

The mass of the b quark is set to zero. The strong constant $\alpha_{s}\left(M_{Z}^{2}\right)$ is set to 0.1300 both in the matrix element calculation and in the proton PDF, that is the CTEQ6L1.

Pythia is used for the parton shower and the hadronisation with the following parameters modified according to tune Z 2 .

## 19. PHOTON ISOLATION AND FRAGMENTATION CONTRIBUTION ${ }^{43}$

#### Abstract

Photon isolation and its link with the fragmentation contribution is explored via NLO matrix-element generator and parton-shower Monte-Carlo.

Firstly the dependence of the inclusive photon and di-photon NLO cross sections to the choice of isolation criteria are investigated. The isolation criteria used is the discretized version of the Frixione isolation, with parameters chosen for those most practical at an experimental level. As an extention, a more generalized version of the standard Frixione isolation is also studied. The selection of scale is also investigated in search of the 'saddle point', which would give the optimal scale choice. In addition the choice of jet algorithm is investigated for the photon with associated jet cross section. Secondly, properties of the fragmentation contribution in parton-shower Monte-Carlos are investigated. The distance profile of the photon to the other generator level particles in the event is explored in the case of neutral mesons, fragmentation photons and direct photons. Next the impact of a "hollow" or "crown" isolation criterion, expected to enhance the fragmentation contribution, is explored. Then, to complement the NLO inclusive studies, the impact of typical Frixione isolation criteria on the fragmentation component are investigated in the parton-shower Monte-Carlos.

Finally conclusions are made comparing the properties of the fragmentation contribution in NLO generators and parton-shower generators.

### 19.1 INTRODUCTION

Experimental measurements of single photons and di-photons require the application of isolation cuts to reduce the copious backgrounds arising from jet fragmentation. Such cuts also have the impact of reducing the fragmentation contributions of photon production. On the theoretical side, including fragmentation contributions of photon production can greatly increase the complexity of the calculations, while the application of appropriate isolation cuts can effectively remove those fragmentation contributions.

[^228]
### 19.11 Frixione isolation

In the following we will study the Frixione isolation criterion [471], which was designed to suppress the fragmentation contribution. It has been shown to reduce the fragmentation contribution in NLO generators [18]. The question is to know whether or not the behavior is still applicable using parton shower Monte-Carlo and if it can be used experimentally.

We consider the following function for the isolation criterion :

$$
\begin{equation*}
E_{T}^{i s o}(R)<f(R)=\epsilon \cdot p_{T, \gamma} \cdot\left(\frac{1-\cos (R)}{1-\cos \left(R_{0}\right)}\right)^{n} \tag{19.1.1}
\end{equation*}
$$

where $E_{T}^{i s o}(R)$ is the isolation sum of all particles inside a cone of $R=\sqrt{\Delta \phi^{2}+\Delta \eta^{2}}$ around the photon, $\epsilon$ is the strength or the scale of the isolation criterion, $p_{T, \gamma}$ is the transverse energy of the photon, $R_{0}$ is the first considered cone and $n$ the power of the isolation criterion. This formula can be altered by replacing $p_{T, \gamma}$ with a fixed threshold. Functional forms $f(R)$ for different $\epsilon$ and $n$ are shown Fig. 96

Fig. 96: Examples of Frixione functional form for different parameters.

The Frixione isolation is tighter and tighter when decreasing the $R$ cone size. With matrix element NLO generators (as in Jetphox [472, 473] and Diphox [474]), the only contribution possible at a given $R \neq 0$ is the one coming from the suplementary hard jets in the event, while the fragmentation debris are emitted colinearly to the photon at $R=0$ (angle information is lost due to the fragmentation function which is integrated over the angle). With parton-shower generator, fragmentation photons are emitted off quarks at a non-zero angle during the showering process. In the following sections we will study the link between isolation and fragmentation in NLO generators, then with parton-shower Monte-Carlo.

### 19.12 Experimental complications

There are various mismatches between isolation cuts applied to theoretical calculations and isolation cuts applied to data (or to Monte Carlo). First of all, we wish to apply the isolation cut only to energy related to the hard scatter. Experimentally, most of the energy inside an isolation cone is due to the underlying event associated with the hard scatter, or the remnants of additional interactions in the same crossing. Techniques such as jet area subtraction [475, 476] can be used to remove an amount of energy from the isolation cone roughly equal to the expected contamination from underlying event/pileup, leaving only energy related to the hard scatter and specifically to fragmentation processes. Since there is no underlying event/pileup in partonic level theory calculations, only the isolation cut needs to be applied to the theory.

Full details of the use of this correction within the ATLAS collaboration can be found in the inclusive cross section measurement [477]. The ATLAS isolation definition uses a cone around the cluster of cells that are identified as a photon. These photon cluster cells are not included in the sum, so there is first a correction for any leakage of the photon shower into the surrounding cells (typically a few percent of the photon $p_{T}$ ). The pile-up/underlying event correction is then applied by calculating per event the ambient energy from the jet activity in that specific event. This follows the jet area corrections method mentioned above, where all jets are reconstructed without any minimum momentum threshold. The energy density of each jet is calculated and the median density is used for the correction. In 2010 this typically resulted in a correction of around 900 MeV .

The original Frixione isolation scheme assumed that an isolation cut could be applied continuously as a function of R (distance from the photon). Actual detectors have a finite granularity. A solution to this was the adoption of a discretized version of Frixione isolation, allowing this granularity to be taken into account [18]. However, it is not possible to place an isolation cut on the inner-most cone (typically $R \sim 0.1$ ), because of the presence of the photon itself. While the separation between the fragmentation photon and the jet remnants is finite in data (and in Monte Carlo), fragmentation is treated as a collinear process in partonic cross sections. The inability to apply the isolation cut down to $R=0$, results in a greatly reduced ability to discriminate against fragmentation processes in the partonic level theory.

To rectify this the Frixione calculation could be modified into a 'crown' isolation, whereby the last cone is missed from the calculation. Unfortunately as most of the radiation is collinear in the fragmentation events, it is likely to reduce its effect of removing these events. Other studies [478] have shown that the photon quality cuts applied by the experiments will reduce the fraction of fragmentation photons accepted, where substantial fragmentation energy is collinear with the photon. However, the rejection is not $100 \%$, so we are still left with a smaller reduction of fragmentation contributions in the partonic level theory than are actually (presumably) present in the data. In these proceedings, we will discuss how to more properly incorporate the correct level of rejection in the theory.

### 19.13 Choice of fragmentation scale

In addition to the experimental difficulties with applying the isolation criteria there are also difficulties in choosing appropriate scales for the theoretical calculation. This is discussed in the following text, along with other considerations for applying Frixione isolation at a theoretical level.

Fragmentation is treated as a collinear process in partonic calculations. In this framework, the original "continuous" Frixione criterion [471] was designed to inhibit the appearance of final state photonparton collinear singularities which otherwise require absorption in a fragmentation function $D\left(z, M_{F}\right)$. Thus, cross sections for the production of prompt photons isolated with this criterion involve no fragmentation contribution. Discretized variants of this criterion have been proposed which aim at matching better what can be actually implemented experimentally [18]. They consist in a limited number of nested cones $\mathcal{C}_{j=1, \cdots, n}$ with respective radii $R_{1}=R_{\min }<R_{2}<\cdots<R_{n}=R_{\max }$ defined in the azimuthal and rapidity differences with respect to the photon direction, and requiring recursively that the accompanying hadronic transverse energies inside every successive cone $\mathcal{C}_{j}$ be less than an ordered sequence of maximum values ${ }^{44} E_{T j}^{i s o}$ such that $0<E_{T 1}^{i s o}<\cdots<E_{T n}^{i s o}$. However, in contrast with the continuous criterion, such discretized variants still involve a fragmentation contribution, though the latter is expected to be small, since the situation in the innermost cone shares some similarity with the standard cone criterion. When quantifying the magnitude of the fragmentation contribution with such discretized criteria, a potentially tricky issue concerns the fragmentation scale dependence and the "best choice" of scale.

This issue matters for isolation with the standard cone criterion when the radius $R$ of the cone is $\ll 1$ while $E_{T}^{i s o}$ is kept fixed. Whereas the natural fragmentation scale $M_{F}$ in the non-isolated case

[^229]is $\sim p_{T}^{\gamma}$, this choice can lead to very poor theoretical estimates at Next to Leading Order (NLO) in perturbative QCD when $R \ll 1$ [472]. The scale dependence near the choice $M_{F} \sim p_{T}^{\gamma}$ is then large and, worse, the theoretical prediction may eventually exhibit an unphysical violation of unitarity whereby the predicted NLO cross section for photons becomes larger than the inclusive one, so that even for only moderately small $R$ the reliability of the prediction is questionable. On the other hand, as ${ }^{45} D\left(z, M_{F}\right) \sim$ $\log \left(M_{F} / \Lambda_{Q C D}\right)$, with the choice $M_{F} \sim R p_{T}^{\gamma}$ the fragmentation contribution is suppressed compared with $M_{F} \sim p_{T}^{\gamma}$. The situation is improved regarding both scale dependence and unitarity, although it does not solve the problem completely. One actually faces a multiscale problem: $\Lambda_{Q C D} \ll R p_{T}^{\gamma} \ll p_{T}^{\gamma}$, and a one-scale compromise is possibly insufficient depending on the kinematical regime explored. The atypical choice $M_{F} \sim R p_{T}^{\gamma}$ has in principle to be supplemented by a resummation of the logarithmic $R$ dependence coming form outside the cone, if at all possible. At leading-log $R$ (LLR) accuracy at least, such a resummation is actually feasible, which furthermore allows to solve the apparent puzzle why scale choices should be very different in the cases with isolation in a narrow cone vs. broad cone or without isolation.

The concern about the discretized Frixione criteria is that the innermost cone size is quite small. The choice for the fragmentation scale $M_{F}$ shall then arguably be $M_{F} \sim \mathcal{O}\left(R_{\min } p_{T}^{\gamma}\right)$. On the other hand, as the allowed transverse energy deposit $E_{T}^{i s o}\left(R_{\text {min }}\right)$ inside this cone is correspondingly small, the width of the interval in the fragmentation variable on which the fragmentation function is convoluted with the partonic cross section is restricted to a rather narrow range $0<1-z<E_{T}^{i s o}\left(R_{\min }\right) / p_{T}^{\gamma} \sim$ $\epsilon\left(R_{\min } / R_{\max }\right)^{n}$. This leads to a quite suppressed fragmentation contribution. The combination of the two effects: a low fragmentation scale and a narrow $z$-range, is the discrete counterpart of the inhibition of fragmentation by the continuous criterion. We may thus expect that the issue of the narrow cone is less worrying for the reliability of the NLO calculation in this case than if only $R$ were taken small while keeping $E_{T}^{i s o}$ fixed. In order to assess the uncertainty on the fragmentation contribution we may perform the calculation for the "arguably better" scale $M_{F} \sim R_{\min } p_{T}^{\gamma}$ and compare it to the expectedly larger result for the standard choice $M_{F} \sim p_{T}^{\gamma} / 2$.

### 19.2 ISOLATION FOR INCLUSIVE PHOTONS AND DIPHOTONS AT NLO

The study at NLO uses the Jetphox generator to calculate the inclusive photon cross section and Diphox for the di-photon cross section. Details of how to use the software and to obtain predictions with errors can be found in [480] and the selection criteria used are listed in the appendix. Previous results from Les Houches [18] showed that the discretized Frixione isolation criteria did manage to reduce the fragmentation contribution, here we extend that study in several ways. Firstly the cross section returned has been compared to that calculated from using the standard cone isolation, as used in current measurements. A generalized form of the Frixione isolation is discussed, aimed to satisfy both the experimental and the theoretical requirements on the isolation cut for different $p_{T}$ regimes. In addition the effects of changing the number of cones used in the calculation and of choosing an $E_{T}$ cut, rather than relating it to the photon $p_{T}$, are investigated. In addition, further complications to comparing theoretical and experimental isolation calculations are discussed. Finally there are further brief studies using Jetphox to look at scale and jet algorithm choices.

### 19.21 Discretized prescription

The parameters used to define different selections, according to Eq. 19.1.1, were:

$$
\begin{array}{llll}
a: \epsilon=0.05 n=0.2 & b: \epsilon=1 n=0.2 & c: \epsilon=1 n=1 & d: \epsilon=0.5 n=1 \\
e: \epsilon=0.05 n=1 & f: \epsilon=1 n=0.1 & g: \epsilon=1 n=0.5 &
\end{array}
$$

[^230]

Fig. 97: Left: Fragmentation fraction for the cone and Frixione isolation criteria. Right: The applied $E_{T}$ cut on the isolation sum as a function of $p_{T}$ for the 0.4 cone or 0.1 cone in the Frixione criteria.
where all but the last two were based on the previous study. In all cases $R_{0}$ was chosen to be 0.4 , with $R$ being set to either: $0.4,0.3,0.2,0.1$ or $0.4,0.35,0.3,0.25,0.2,0.15,0.1$.

The comparison to the cone isolation in Fig. 97 shows that out of the chosen parameters only 1 set removes the fragmentation contribution more than what is removed by the cone algorithm, although two are lower until high $p_{T}$. It also shows that criteria $b$ and $f$ are not much better than applying no isolation criteria at all. When altering Eq. 19.1 .1 to use a fixed $E_{T}=4 \mathrm{GeV}$ instead of $p_{T, \gamma}$ the results are more promising but this is because it applies a cut in the 0.1 cone that is below the experimental accuracy (of the order 100 MeV due to detector resolution/noise). Unfortunately Fig. 97 also shows that this is also the case for the $p_{T}$ requirements, as case $e$ (the only criteria to perform better than the standard cone) also applies a cut that is not viable experimentally in the 0.1 cone.

There are some positive outcomes from these studies, firstly the Frixione criteria $b$ and $d$ maybe useful criteria to use experimentally as they keep the fragmentation contribution similar and low in all bins, which could help with understanding of the systematic errors/correlation between bins. Secondly the comparison of the number of cones used in the Frixione criteria resulted in a difference of around $1 \%$ on the total cross section and almost no effect on the fragmentation fraction. This means that it is fine to use the lower number of cones case, and that the discrete Frixione criteria is most likely very similar to that of the continuous version.

### 19.22 Generalized prescription

As seen previously, to remove the fragmentation contribution in the theory, a small value of $\varepsilon$ is needed. However, given the effects of finite resolution and granularity on the experimental description of the isolation energy, a minimum threshold has to be allowed in the isolation cone, especially at low $p_{T}$. A typical value of $2-4 \mathrm{GeV}$ is used as experimental cut, to optimize the rejection of hadronic background coming from the decay of light mesons. Now, at high $p_{T}$ this cut might result too tight, particularly on the theoretical side given that an isolation cut much smaller than the photon $p_{T}$ can cause large logs in the calculations, this effect was not observed in the previous Les Houches study.

As a good compromise of these two requirements, it has been proposed [481] to extend the original

Fig. 98: Effect of the two terms in the modified Frixione isolation prescription effects of the different pieces of the generalized Frixione isolation prescription on the isolation cut as a function of $p_{T}$ (left) and the cone radius R (right).

Frixione prescription (Eq. 19.1.1) to a more general form:

$$
\begin{equation*}
E_{T}^{i s o}<\left(\left(E_{0}\right)^{k}+\left(\varepsilon \cdot p_{T}\right)^{k}\right)^{1 / k}\left(\frac{1-\cos R}{1-\cos R_{0}}\right)^{n} \tag{19.2.1}
\end{equation*}
$$

where:
$R_{0}$ is the maximum cone size
$E_{0}$ is the minimum energy pedestal allowed in a cone of size $R_{0}$
$\varepsilon$ is the fraction of the photon $p_{T}$ allowed in the cone of size $R_{0}$
$k$ determines the shape of the isolation profile in $p_{T}$
$n$ determines the shape of the isolation profile in R (see Fig. 98 right])
The extra parameters give enough flexibility to ensure a (finite) tight cut at low $p_{T}\left(\sim E_{0}\right)$ and, at the same time, a loose cut at high end of the spectrum driven by the photon $p_{T}$. The $k$ parameter controls how quickly/smoothly is the transition from one regime to the other (see Fig. 98 left]).

This generalized prescriptior ${ }^{[46}$ has been implemented in Jetphox recently and some possible configurations are explored here. The studied configurations vary $\varepsilon(=0.05,1)$ and $k(=2,5,10)$, and have a fixed value for $E_{0}=4 \mathrm{GeV}$ (the typical cut applied in ATLAS) and $n=0.5$ (given the linear behaviour of isolation distribution width observed for direct photons in ATLAS [482]).

The high- $\varepsilon$ configurations ( $\varepsilon=1$ ), show a worse performance at removing the fragmentation contribution with respect to the fixed cone approach and are practically insensitive to the value of $k$ in the formula. The remaining fragmentation fraction is $\sim 25 \%$ at 45 GeV decreasing to $20 \%$ in the highest $p_{T}$ bin. On the other hand, as seen in Fig. 99, all the configurations for a low value of $\varepsilon(=0.05)$ show an improvement in fragmentation rejection compared to both the no isolation and fixed cone cases, in the whole $p_{T}$ region ( $45 \mathrm{GeV}<\mathrm{p}_{\mathrm{T}}<600 \mathrm{GeV}$ ). The $p_{T}$ profile for the smaller cone ( $R=0.1$ ) in this case (Fig. 99[right]) looks also more promising in terms of its applicability at the experimental level.

[^231]

Fig. 99: Left: Fragmentation fraction for the cone and the (generalized) Frixione isolation criteria. Right: The applied isolation cut as a function of $p_{T}$ for 0.1 cone in the (generalized) Frixione criteria.

### 19.23 Continuous and discretized Frixione criteria in di-photon events

Following the previous studies with inclusive photons, we now consider the production of photon pairs. The aims of this study are i) to assess the effect on the magnitude of the fragmentation contribution by comparing results from using the continuous Frixione criterion with those using several variants of the discretized version, implemented in the NLO programme Diphox, thereby providing a NLO assessment of how much fragmentation may be missing in the NNLO calculation of Catani et al. [78] which includes no fragmentation and therefore uses the continuous criterion; ii) to probe the dependence of the prediction with respect to the fragmentation scale choice. It supplements a similar comparison which had been performed for inclusive photon production in [18].

Fig. 100 provides a comparison of the original continuous criterion to the discretized version of the criterion based on four nested cones with respective radii $R_{\text {min }}=0.1, R_{2}=0.2, R_{3}=0.3$ and $R_{\max }=0.4$. Four variants of the energy profile $E_{T}^{\text {iso }}(R)$ as defined in Eq. 19.1.1 have been considered: $(\epsilon, n)=(0.05,0.2),(0.05,1),(0.5,1)$ and $(1,1)$. Fig. 100 (left) presents the distribution in invariant mass of photon pairs in the range $40 \mathrm{GeV} \leq m_{\gamma \gamma} \leq 300 \mathrm{GeV}$. The discretized criterion $(0.05,1)$ suppresses fragmentation so much that there is practically no difference between the discretized and continuous versions. With the criterion $(1,1)$, the discretized version leads to a distribution $O(10-12 \%)$ larger than the continuous one. The choice $(0.5,1)$ displays a similar feature, though quantitatively less important. The energy profile of the fourth choice is not suited for an efficient isolation unless $\epsilon$ is chosen very small. A similar comparison is shown on Fig. 100 (right) for the distribution in the difference in azimuthal angle $\Delta \phi$ between the two photons. Whereas the distribution in invariant mass is dominated by the direct contribution, the tail of the distribution in $\Delta \phi$ tail at low $\Delta \phi$ is more sensitive to the fragmentation contribution. Therefore, the conclusions are qualitatively similar to the one drawn for the distribution in invariant mass, yet the effects are quantitatively larger.

Fig. 101 assesses the dependence on the fragmentation scale $M_{F}$, for the distributions in invariant mass (left) and in $\Delta \phi$ (right) respectively. Two choices were considered: $M_{F}=R_{\min } \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}=$ $0.1 \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}$ vs. $M_{F}=R_{\max } \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}=0.4 \min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}$ closer to a standard choice ${ }^{47}$. As expected, the distribution in invariant mass, which is not very sensitive to the fragmen-

[^232]

Fig. 100: Comparing continuous and discretized Frixione criterions for the distributions in $m_{\gamma \gamma}$ (left) and $\Delta \phi$ (right) of photon pairs, for four variants of the criterion.

Fig. 101: Fragmentation scale dependence of the distribution in $m_{\gamma \gamma}$ (left) and $\Delta \phi$ (right) of photon pairs, for four variants of the discretized Frixione criterion.
tation contribution, is practically not impacted by the choice. The distribution in $\Delta \phi$ is more sensitive to the fragmentation component and the sensitivity to the fragmentation scale choice is larger than for the distribution in invariant mass. The sensitivity to the fragmentation scale choice is the largest in the case of the criterion $(\epsilon, n)=(1,1)$, for which the predictions are $5-7 \%$ smaller, rather uniformly, with the lower scale choice than with the more standard one.

In conclusion this preliminary study shows that the impact of the fragmentation contribution passing the discretized criterion seems to be almost negligible on the distribution in invariant mass, and remains small even on the tail of the distribution in azimuthal angle. Notwithstanding, the conclusions shall have limited use depending on how isolation is actually implemented experimentally in the innermost cone. We here stick to a discretized version of the Frixione criterion which respects the original idea of a transverse energy deposit decreasing towards zero with the cone radius. If instead any experimental constraint would allow a more permissive condition in the innermost cone, a dedicated study would be mandatory.

### 19.24 Additional studies at NLO

In addition to the isolation studies with Jetphox, we present here two brief studies as an attempt to reduce the theoretical errors from the NLO calculation. These study the choice of renormalizaion and factorization scale parameter and secondly the jet algorithm parameters.

As studied in [480], the scale choice is set to a fraction of the photon $p_{T}$. By altering this fraction around the central value of 1.0 , it is hoped to gain an uncertainty on the terms missed in the NLO calculation. The best selection for this central value would be to be at a 'saddle point', where moving in any direction from this point gives similar changes in the cross section. However, it is found that as the scale is reduced (in steps: $2.0,1.0,0.5,0.25,0.1,0.05$ and 0.01 ) the cross section increases, when moving the two scales coherently or independantly. One difference in this result to the previous study was that it was carried out in three $p_{T}$ bins, but the result remained the same for all (only the highest bin was able to be calculated with a scale of 0.01 ). Similarly the addition of using Frixione isolation instead of the standard cone isolation also resulted in the same cross section behaviour. The summary of this is that there must be large contributions needed from NNLO. However, on the positive side, in all $3 p_{T}$ bins, the variation between 0.5-1.0-2.0 resulted in differences of similar magnitude around 1.0 , so this is likely a safe estimate of the uncertainty.

After the inclusive photon measurements, the next step experimentally is to require the addition of at least one jet. Using a jet of 10 GeV the cross section was calculated for two algorithms each for multiple sizes:

- Kt algorithm with $\Delta R=0.3,0.4,0.5$ or 0.6
- Cone with $\Delta R=0.4,0.5$ or 0.6

These choices had an affect of $<1 \%$ on the cross section computed in 3 photon $p_{T}$ bins, suggesting that this will not increase the error for the NLO calculation when moving from the inclusive cross section to that with an additional jet.

### 19.3 FRAGMENTATION PHOTONS IN PARTON-SHOWER MONTE-CARLO

The second part of this study continues to investigate photon isolation, but now in di-photon events using parton-shower Monte-Carlo generators; again the selection used is listed in the appendix. The study begins by investigating the distance between the photon and other particles. It then moves into studying several different styles of isolation criteria, including Frixione criteria as done in the inclusive NLO studies.
encodes the two photons in a symmetrized way.

### 19.31 Topology of fragmentation photons

We consider three sets of parton-shower Monte-Carlo samples for the $\gamma \gamma+\mathrm{X}$ process:

- Pythia [400] $\gamma \gamma$ Born and Box direct processes, plus the Pythia $\gamma+$ jet process with the jet fragmenting into a photon ( 20 million events were generated for the $\gamma+$ jet sample and 1000 times more would have been needed for the dijet fragmenting to two photons due to the low $q \rightarrow \gamma$ branching ratio for isolated photons).
- Pythia $\gamma \gamma$ Born and Box direct processes, plus the Pythia $\gamma+$ jet process with the jet fragmenting into a photon and the Pythia dijet process with the two jets fragmenting into photons. Both Pythia $\gamma+$ jet and dijet samples were generated with a filter which enhances the presence of events with isolated electromagnetic particles.
- Madgraph [165] $\gamma \gamma+$ up to two supplementary hard jets, with fragmentation/hadronization done with Pythia.
The fragmentation contribution is included as a bremsstrahlung contribution in Madgraph at matrix element level, while it is included as a showering contribution in Pythia $\gamma+$ jet and dijet (in the PYTHIA samples we identify fragmentation photons as those having a quark or gluor ${ }^{48}$ as parent). The fragmentation fraction found is compatible with ref [483]. We consider additionally the case where the two jets fragment into boosted neutral mesons ( $\pi^{0}, \eta, \rho$ and $\omega$ ) that can experimentally mimic direct or fragmentation photons at reconstructed level because of the finite granularity of the detector. These samples include an underlying event but were generated without pile-up.

Fig. 102: $\Delta R$ distance distribution between the photon and the other generator-level particle candidates in the event, for neutral mesons, fragmentation photons and partonic photons.

Fig. 102 shows the $\Delta R$ distance between the photon or neutral mesons and the other particle candidates in the event. Partonic photons, fragmentation photons and neutral mesons have different properties as a function of $\Delta R$. Partonic photons in Pythia have a linear behavior, which is expected because the only contribution that can enter in the isolation sum is the underlying event and pile-up (with also a small contribution from QCD radiation at the shower level) which is expected to be uniform in space. As each bin consists of an annulus with radius growing linearly as a function of $R$, the quantity

[^233]of particles grows linearly with $R$ in the area of the annulus. Neutral mesons have a radically different profile, with a peak of the $\Delta R$ distribution close to 0 . The peak is caused by the decay of particles resulting from jet fragmentation close to the neutral meson direction. Pythia fragmentation photons have a behavior somehow in between that of neutral mesons and partonic photons. The peak at low $\Delta R$ is still present but much reduced with respect to that of neutral mesons. Madgraph partonic photons exhibit a modulation of the Pythia partonic photon $\Delta R$ distribution, probably because Madgraph includes fragmentation as a bremsstrahlung contribution.

From this we can expect that the smaller the $\Delta R$ cone used in Frixione isolation (until $\Delta R \simeq 0.1$ ), the higher the discrimination against the neutral mesons and fragmentation photons. The discrimination against neutral mesons is higher than that against fragmentation photons (as is well-known experimentally). This can be seen in Fig. 103, which shows the isolation sum profile divided by the transverse energy of the photon for different cone sizes.

Fig. 103: Isolation sum normalized to the photon energy computed in cones of size $\Delta R<0.1$ (top left), $\Delta R<0.2$ (top right), $\Delta R<0.3$ (bottom left), $\Delta R<0.4$ (bottom right), for neutral mesons, fragmentation photons and partonic photons.

Table 14: Fraction represented by the 1-fragmentation and 2-fragmentation contributions for various Frixione isolation criteria in Pythia two-prompt photon samples (with electromagnetic enrichment filter).

### 19.32 Impact of hollow cones on the fragmentation contribution

In NLO generators, the products of the quark fragmentation are along the fragmentation photon direction. In parton-shower generators we have seen that this is not necessarily true. In NLO generators, the "hollow" or "crown" isolation, where the energy sum has to be below a fixed threshold in a region $R_{1}<\Delta R<R_{2}$ while in the region $R<R_{1}$ any arbitrary amount of energy is admitted, has been shown to enhance the fragmentation contribution with respect to the usual "solid" isolation. This "hollow" isolation is interesting also because this criterion is closer than the "solid" cone to what is used experimentally (it allows to exclude from the isolation sum the energy deposited by the photon itself). The first two lines of Tables 14 and 15 show that in general the fragmentation fraction does not increase significantly when moving from solid to hollow cone isolation, for the PYTHIA samples.

### 19.33 Impact of Frixione isolation on the fragmentation contribution

Tables 14 and 15 report the fragmentation fraction inside the Pythia two-prompt sample for different Frixione isolation criteria. Eight isolation cones were used : $\Delta R<0.05, \Delta R<0.1, \Delta R<0.15$, $\Delta R<0.2, \Delta R<0.25, \Delta R<0.3, \Delta R<0.35, \Delta R<0.4$. The results are almost identical if instead four cones are used ( $0.1,0.2,0.3,0.4$ ), as found at NLO. The tables show that in both the electromagnetically-enriched samples and non-enriched samples, the discrete Frixione isolation with the usual functional form $f(R)$ does not reduce the fragmentation contribution with respect to the standard isolation criterion (with a cone $\Delta R<0.4$ ) except when the parameter $\epsilon$ is at its smallest value, $\epsilon=$ 0.05 , for which modest reductions of between 5 and $8 \%$ can be achieved. The cause of this apparent non-optimal behavior can be explained by the non-collinearity of the fragmentation debris around the fragmentation photon in PYTHIA. Frixione isolation is designed to apply tighter and tighter isolation criteria $E_{T}^{i s o}<f(R) \rightarrow 0$ as $\Delta R \rightarrow 0$, assuming that most of the fragmentation debris are around $\Delta R \simeq 0$. As it is seemingly not the case in the parton-shower Monte-Carlo studied here, the criterion loses most of its discrimination power.

The previous study suggests that the previous working points studied with the Frixione functional form $f(R)$ might not be optimal for the rejection of fragmentation debris. In figure 104 we compare the performance of three different sets of criteria: 1) non-Frixione isolation in a single cone $\Delta R<0.4,2$ ) optimized working points for the parameters in the Frixione functional form (four cones $0.1,0.2,0.3,0.4$ were used to make the algorithm converge faster), 3) re-optimized 'Frixione' isolation criteria on cones $\Delta R<0.1,0.2,0.3,0.4$ without using the explicit functional form (we no longer constrain the events to satisfy $E_{T}^{i s o}<f(R)$ and let $f(R)$ free). In the second case, an optimization procedure is performed scanning over the parameters $\epsilon$ and $n$ to find the best working points (corresponding to a maximum

Table 15: Fraction represented by the 1 -fragmentation contribution for various Frixione isolation criteria in Pythia two-prompt photon samples (without enrichment filter).

| Criteria | 1-frag fraction |
| :---: | :---: |
| Solid $\Delta R<0.4, E_{T}^{i s o}<5 \mathrm{GeV}$ | 0.455 |
| Hollow $0.1<\Delta R<0.4, E_{T}^{i s o}<4 \mathrm{GeV}$ | 0.458 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=0.05, n=1.0$ | 0.420 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=0.05, n=0.2$ | 0.419 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=0.2$ | 0.514 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=0.1$ | 0.519 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=1.0$ | 0.489 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=1.0, n=0.5$ | 0.503 |
| Frixione 8 cones, $E_{T}=20 \mathrm{GeV}, \epsilon=0.5, n=1.0$ | 0.465 |

efficiency for a given $s / b$ ). In the last case, an optimization code is used to find the best selection criteria to be applied on $E_{T}^{i s o}$ for each $\Delta R$ cone. The optimization takes as input the target value of $s / b$ (partonic signal over fragmentation background ratio), then relaxes and tightens each cut separately with an iterative procedure to find the best signal efficiency for this $s / b$ target. The procedure was performed to find the working points corresponding to the $s / b$ obtained with the first Frixione criterion.

Figure 104 shows that the optimized working points for the Frixione functional form perform slightly better than the standard isolation for a given photon efficiency, and that optimization using no functional form in turn performs slightly better than the Frixione functional form; for the same value of single-photon efficiency, lower values of fragmentation fraction are attainable. It should be noted that this optimisation leads to a looser cut on the first cone, $\Delta R<0.1$, than the usual functional form. Nevertheless, to obtain reductions in the fragmentation fraction of more than $10 \%$, increasingly significant reductions in single photon efficiency are required, since the fragmentation reduction becomes nearly flat.

All in all, with the definition of the isolation in a cone of $\Delta R$ used here, which is a usual way of defining isolation at the experimental level (where one has however to remove the footprint of the photon from the isolation sum and to cope with pile-up), rejecting fragmentation photons can be done only at a cost of a lowered signal efficiency. With this optimization procedure it was found that to decrease the fragmentation fraction by $10 \%$, a signal loss of about $60 \%$ has to be achieved, leading to extremely tight cuts probably not applicable in experimental analysis.

## CONCLUSIONS

Firstly for the NLO cross sections, it was found that only one of the Frixione isolation criteria suggested in [18] actually performs better at removing the fragmentation contribution in the inclusive case than that of the standard cone, although potentially too tight to use experimentally. However, it is useful to see that the results are independent of the number of cones used. This is also the case for the di-photon cross section where it compares well to the continuous criteria. A more promising result in the inclusive case is that the generalized version of Frixione isolation, with small values of $\epsilon$, do significantly reduce the fragmentation fraction without applying too tight a cut in the smallest cone. In addition it is confirmed that the 'saddle point' can not be found when altering the scale choice for the inclusive cross-section, suggesting more corrections needed at NNLO. Finally when moving to the photon with associated jet cross section, from the inclusive cross section, it is reported that the jet algorithm (or size) used at NLO makes little difference to the cross section.

In the study at the parton-shower level it was shown that the isolation profile of fragmentation

Fig. 104: The fraction of the 1 -fragmentation contribution vs single $\gamma$ efficiency for various sets of criteria. Blue : tested working points reported on table 15. Black : selection criteria on isolation in $\Delta R<0.4$. Green : Optimized Frixione isolation using the usual functional form. Red : Re-optimized isolation criteria on cones $\Delta R<0.1,0.2,0.3,0.4$ without using the functional form.
photons is no longer collinear anymore, whereas the modelization of the fragmentation function in NLO generators leads the quark/gluon debris to be collinear to the photon. Furthermore, the hadronization process of the quark/gluon that emitted the photon leads to a $\Delta R$ profile which is no longer peaked at zero (but close to zero). In parton-shower programs isolation still has increasing discriminating power when going lower in $\Delta R$. However, it was found that a $10 \%$ decrease in fragmentation fraction in diphoton events with respect to standard isolation leads to a drop in single photon signal efficiency to approximately $60 \%$ of the initial value. The usual functional form for Frixione isolation was shown to be not completely optimal for suppressing the fragmentation contribution while preserving high signal efficiency. This can be mitigated by re-optimizing the cuts for each $\Delta R$ of the discrete Frixione prescription, which allows a looser cut in the innermost cone. Further studies using other fragmentation modelizations in parton-shower programs like SHERPA [427] (LO matrix-element where photons and jets in the shower are matched to matrix element level) or POWHEG [484] (NLO matrix-element with consistent fragmentation photon matching) would need to be investigated.

In conclusion the results from the two studies show there are differences and similarities at the two levels. Regarding the fragmentation fraction, this is far more reduced at the NLO level than at the parton-shower level. However, the two levels show agreement that the results from Frixione isolation are independant of the number of cones used and that similar shape cuts can be obtained by retuning cuts at the parton-shower level and by using the generalized prescription at NLO.

## ACKNOWLEDGEMENTS

Thanks to the whole of the Les Houches photon subgroup, especially to J.P. Guillet and E. Pilon for their expert input.

## APPENDIX: Selection details

All of the studies are carried out for $p p$ collisions at $\sqrt{S}=7 \mathrm{TeV}$. For simplicity the the inclusive studies are carried out for the region where the photon lies in $|\eta|<0.6$. When calculating the cone isolation around the photon a cone of 0.4 is used with the requirement that the energy in the cone is less than 4 GeV . The renormalization scale $\mu$ and initial state factorization scale $M$ are set to the photon $p_{T}$,
unless stated otherwise, and the CTEQ6.6 PDF[256] is used and the photon fragmentation functions are BFG set II [479]. For the generalized Frixione isolation case, the cones used are: $\mathrm{R}=0.4,0.35,0.3,0.25$, $0.2,0.15$ and 0.1.

In the NLO di-photon studies, the photons have: $p_{T}^{\gamma 1} \leq 25 \mathrm{GeV}, p_{T}^{\gamma 2} \geq 22 \mathrm{GeV}$, in the rapidity range $\left|\eta^{\gamma}\right| \leq 2.5$ for both photons, and a separation $\Delta R_{\gamma \gamma} \geq 0.4$ is required between the two photons. The mass range considered is $40 \mathrm{GeV} \leq m_{\gamma \gamma} \leq 300 \mathrm{GeV}$. In this case the scales $\mu$ and $M$ are chosen equal to $\min \left\{p_{T}^{\gamma 1}, p_{T}^{\gamma 2}\right\}$.

In the parton shower di-photon studies, the photons are selected with: $M_{\gamma \gamma}>80 \mathrm{GeV}, p_{T}>21,20$ $\mathrm{GeV},|\eta|<2.5$ and $E_{T}^{i s o}<5 \mathrm{GeV}$.

## 20. EVENT-BY-EVENT PILEUP SUBTRACTION USING JET AREAS 49

#### Abstract

In these proceedings, we compare the efficiency of several jet-area-based subtraction methods to correct for pile-up contamination at hadronic colliders. We study the dependence on various variables like the $p_{t}$ and rapidity of the jets, the number of pile-up vertices or the Monte-Carlo generator variations. We conclude that estimations of the pile-up density using a median computed over grid-cell patches, including a rescaling to correct for the rapidity dependence, perform particularly well, though alternative methods are possible.

### 20.1 Introduction

With the LHC running at larger and larger luminosities, hard $p p$ interactions are accompanied by an increasing number of pile-up (PU) collisions: from a few PU events per bunch crossing in spring 2011, operation with $\sim 20 \mathrm{PU}$ events is now routine. Considering only in-time PU , this would lead to an extra transverse momentum of $\sim 750 \mathrm{GeV}$ deposited in the event, and a jet of a typical radius $R=0.5$ would see its transverse momentum shifted by $\sim 10 \mathrm{GeV}$. In order to obtain a good energy resolution for the jets it is therefore mandatory to correct for this contamination.

In these proceedings, we review several methods - both existing methods and new refinements - to subtract the contamination due to PU and provide a systematic study of their efficiency.

It is important to note already now that PU has not only the effect to shift the momentum of the jets: it also smears their momentum. Indeed, the number of PU vertices varies from one collision to the next (following a Poisson distribution varying with the beam conditions), all PU interactions, i.e. minimum bias collisions, do not lead to the same energy deposit, and finally, the energy produced in a minimum bias collision is not deposited uniformly across the detector. Altogether, on top of an average shift, PU will add two sources of resolution smearing: event-to-event and in-event fluctuations corresponding respectively to variations of the PU activity from one event to another and from one point to another in a single event.

Here we shall primarily study in-time $P U$, that is the effects coming from multiple $p p$ interactions that occur in the same bunch crossing as the hard interaction one triggers on. Because of the response time inherent to each detector this would come with a second effect, out-of-time $P U$, corresponding to the PU activity in the few bunch crossings preceding the one with the hard interaction. Since these heavily depend on the details of each individual detector - and even varies from one sub-detector to another - it goes beyond the scope of this theoretical study. However, as we shall discuss in further detail later on, the PU subtraction methods proposed here do not make any assumption about a distinction between in-time and out-of-time PU and thus should be robust enough in more complex cases.

[^234]
### 20.2 Subtraction method(s)

We are interested in the situation where a hard event is contaminated by a background coming from additional pileup interactions. A reconstructed jet in that full event (hard event + background), which we shall call a full jet, differs from the hard jet in the original hard event because of the presence of the background. By background subtraction, we mean correcting the full jet in such as to recover the momentum of the original hard jet, i.e. subtract the pileup contamination from the jet's momentum.

### 20.21 Background effects

Our starting point is to realise [485] that a uniform background affects the momentum of a jet in two ways: it shifts its momentum because of the background particles clustered with the jet, and it modifies the way the hard particles themselves are clustered because the background particles are not infinitely soft.

This means that the reconstructed momentum has the form 50

$$
\begin{equation*}
p_{t, \text { full }}=p_{t, \text { hard }}+\rho A \pm \sigma \sqrt{A}+\Delta p_{t}^{B R} \tag{20.2.1}
\end{equation*}
$$

where $p_{t}$ denotes the transverse momentum of the reconstructed jet, $p_{t, \text { hard }}$ the momentum of the original hard jet (in the absence of PU), $A$ the jet area, $\rho$ the background density per unit area within a given event, $\sigma$ the fluctuations of that background (per unit area) from place to place within the event, and $\Delta p_{t}^{B R}$ the back-reaction describing the effect of the background particles on the clustering of the hard ones.

If the background has a positional dependence (e.g. depends on rapidity) then $\rho$ and $\sigma$ will depend on the position of the jet one tries to subtract.

Eq. 20.2.1) characterises the fact that the background has the effects of shifting the transverse momentum of the jet and to degrade its resolution. The shift comes from the " $\rho$ " term in 20.2.1) and from potential back-reaction systematic effects. Using the anti- $k_{t}$ jet algorithm the shift due to backreaction is negligibl ${ }^{51}$. Resolution smearing effects come from various sources: the fluctuations of the background from within an event, i.e. the " $\sigma$ " term in 20.2.1, fluctuations of the background from one event to another, that is the fact that $\rho$ is not the same in every event, and the fluctuations in the back-reaction.

### 20.22 Central subtraction formula

From (20.2.1], the natural way to subtract the background contamination is to define the subtracted jet as [485]

$$
\begin{equation*}
p_{t, \text { sub }}=p_{t}-\rho_{\mathrm{est}} A \tag{20.2.2}
\end{equation*}
$$

where $\rho_{\text {est }}$ is the estimated value for the background density per unit area.
To apply this subtraction we need to compute the jet area and find an estimation $\rho_{\text {est }}$ for the background density per unit area. The jet areas are readily available using FastJet, so we just need to focus on $\rho_{\text {est }}$. The main goal of these proceedings is to investigate various methods of obtaining $\rho_{\text {est }}$ which are listed below. In all cases, it is primordial to realise that the determination of $\rho_{\text {est }}$ is performed event-by-event, and even jet-by-jet when the positional dependence of the background is taken into account.

As we shall see later on, the fact that $\rho$ is estimated for each individual event is crucial: it corrects for the fluctuations of the background from one event to another. If instead one uses an averaged value for $\rho_{\text {est }}$ (over many events), one would get an extra resolution smearing due to the fluctuations of $\rho$ across different events. Similarly, the jet area $A$ in 20.2.2) has to be computed for each individual jet. Using an average area would lead to an additional source of fluctuations of the form $\rho \sqrt{\left\langle A^{2}\right\rangle-\langle A\rangle^{2}}$.

[^235]Using seen vertices Since experimentally it might be possible - within some level of accuracy that goes beyond the scope of this discussion - to count the number of pileup vertices using charged track reconstruction, one appealing way to estimate the background density in a given event would be to count these vertices and subtract a pre-determined number for each of them:

$$
\begin{equation*}
\rho_{\mathrm{est}}^{(n \mathrm{PU})}(y)=f(y) n_{\mathrm{PU}, \text { seen }}, \tag{20.2.3}
\end{equation*}
$$

where we have made explicit the fact that the proportionality constant $f(y)$ can carry a rapidity dependence. $f(y)$ can be studied from minimum bias collisions (see Section 20.32 below) and can take into account the fact that only a fraction of the PU vertices will be reconstructed.

Median subtraction This technique divides the rapidity-azimuthal angle plane in patches and estimates $\rho$ for each event using

$$
\begin{equation*}
\rho_{\text {est }}^{(\text {global })}=\operatorname{median}_{i \in \text { patches }}\left\{\frac{p_{t, i}}{A_{i}}\right\} \tag{20.2.4}
\end{equation*}
$$

This is motivated by the observation that many regions in the event are populated just by the background. In these regions, $p_{t} / A$ is an estimate of $\rho$ and the use of the median, rather than the average, which ensures reduced bias from the hard jets.

This method was originally proposed in [485] using jets (from a $k_{t}$ or Cambridge/Aachen clustering) as patches. Here, we shall also test a new option where the $y-\phi$ plane is simply subdivided into grid cells that we use as patches.

Using a local range Eq. 20.2.4 provides a unique, global, estimate of $\rho$ for the event but does not take into account the positional-dependence of the background. One option, assuming one wants to estimate $\rho$ at the location of a jet $j$, is to limit the computation of the median to the jets in the vicinity of $j$, that i. 5

$$
\begin{equation*}
\rho_{\text {est }}^{(\text {local })}(j)=\underset{\text { jets } i \in \mathcal{R}(j)}{\operatorname{median}}\left\{\frac{p_{t, i}}{A_{i}}\right\} \tag{20.2.5}
\end{equation*}
$$

where $\mathcal{R}(j)$ is a local range around $j$. A typical example, that we shall study later on, is the case of a strip range where only the jets with $\left|y-y_{j}\right|<\Delta$ are included. This option was already proven to be powerful in [486].

Using rescaling Another option to correct for the rapidity dependence of the background ${ }^{53}$ is to introduce a pre-computed rapidity-reshaping function $f(y)$ (see Section 20.32) and use

$$
\begin{equation*}
\rho_{\text {est }}^{(\text {resc. })}(y)=f(y) \operatorname{median}_{i \in \text { patches }}\left\{\frac{p_{t, i}}{A_{i} f\left(y_{i}\right)}\right\} \tag{20.2.6}
\end{equation*}
$$

where now all patches (jets or grid cells) are included in the computation of the median.

### 20.3 Performance tests

### 20.31 Testing framework

The remainder of these proceedings will be devoted to an in-depth comparison of the subtraction methods proposed in Section 20.2. Our testing framework will be very similar to the one used in [486]: we embed a hard event into a pileup background (see again Section 20.2, we reconstruct and subtract the jets in

[^236]both the hard and full event $s^{54}$. for each jet in the hard event, we find the matching jet in the full event and compute the shift
\[

$$
\begin{equation*}
\Delta p_{t}=p_{t}^{\mathrm{full}, \mathrm{sub}}-p_{t}^{\mathrm{hard}, \mathrm{sub}}, \tag{20.3.1}
\end{equation*}
$$

\]

i.e. the difference between the reconstructed-and-subtracted jet with and without pileup. A positive (resp. negative) $\Delta p_{t}$ would mean that the PU contamination has been underestimated (resp. overestimated).

Though in principle there is some genuine information in the complete $\Delta p_{t}$ distribution - e.g. it could be useful to deconvolute the extra smearing brought by the pileup, see e.g. [486] and [487] - we shall focus on two simpler quantities: the average shift $\left\langle\Delta p_{t}\right\rangle$ and the dispersion $\sigma_{\Delta p_{t}}$. While the first one is a direct measure of how well one succeeds at subtracting the pileup contamination on average, the second quantifies the remaining effects on the resolution. One thus wishes to have $\left\langle\Delta p_{t}\right\rangle$ close to 0 and $\sigma_{\Delta p_{t}}$ as small as possible. Note that these two quantities can be studied as a function of variables like the rapidity and transverse momentum of the jets or the number of pileup interactions. In all cases, a flat behaviour would indicate a robust subtraction method.

The robustness of our conclusions can be checked by varying many ingredients:

- one can study various hard processes with the hope that the PU subtraction is not biased by the hard event. In what follows we shall study dijets with $p_{t}$ ranging from 50 GeV to 1 TeV , as well as fully hadronic $t \bar{t}$ events as a representative of busier final states.
- The Monte-Carlo used to generate the hard event and PU can be varied. For the hard event, we have used Pythia 6.4.24 [400] with the Perugia 2011 tune, Pythia 8.150 with tune 4C [348] and Herwig 6.5.10 [488] with the ATLAS tune and we have switched multiple interactions on (our default) or off. For the minimum bias sample used to generate PU, we have used Pythia 8, tune 4C, and checked that our conclusions remain unchanged when using Herwig++ [489] (tune LHC-UE7-2).

Additional details of the analysis For the sake of completeness, we list here the many other details of how the $\Delta p_{t}$ analysis has been conducted: we have considered particles with $|y| \leq 5$ with no $p_{t}$ cut or detector effect; jets have been reconstructed with the anti- $k_{t}$ algorithm with $R=0.5$ keeping jets with $|y| \leq 4$; for area computations, we have used active areas with explicit ghosts with ghosts placed ${ }^{55}$ up to $|y|=5$; for jet-based background estimations, we have used the $k_{t}$ algorithm with $R=0.4$ though other options will be discussed (and the 2 hardest jets in the set have been excluded from the median computation to reduce the bias from the hard event); for grid-based estimations the grid extends up to $|y|=5$ with cells of edge-size 0.56 (other sizes will be investigated); for estimations using a local range, a strip range of half-width 1.5 has been used and we refer to the Section 20.32 below for more information about the rapidity rescaling. Jet reconstruction, area computation and background estimation have all been carried out using FastJet (v3) [361, 435]. Pile-up is generated as a superposition of a Poissondistributed number of minimum bias events and we will vary the average number of pileup interactions. We shall always assume $p p$ collisions with $\sqrt{s}=7 \mathrm{TeV}$. Finally, the matching of a full jet to a hard jet is made by requiring that their common constituents contribute for at least $50 \%$ of the transverse momentum of the hard jet. We shall not discuss matching efficiencies here but they are extremely good: for a reconstructed (full) jet of 50 GeV and 20 PU events, the matching efficiency is $99.9 \%$ and this increases to $99.98 \%$ for $p_{t} \geq 50 \mathrm{GeV}$ and 5 PU events and $99.995 \%$ for $p_{t} \geq 100 \mathrm{GeV}$ and 20 PU events.

### 20.32 Minimum bias and rapidity shape

Before discussing the performances of the subtraction methods described in Section 20.2, there is still a building block that has to be discussed, namely the rapidity dependence of the background $f(y)$ that

[^237]

Fig. 105: Rapidity dependence of the transverse energy per unit area deposited in minimum bias events (obtained from Pythia 8, tune 4C). The normalisation of the fit is such that $f_{\text {seen }}$ is the fraction of seen minimum bias events i.e. the fraction of events which have at least 2 charged tracks with $|y| \leq 2.5$ and $p_{t} \geq 100 \mathrm{MeV}$.
enters in Eqs. 20.2.3) and 20.2.6). Letting aside the question of in-time vs. out-of-time PU and nonlinear effects in the detectors, the shape $f(y)$ can be obtained directly from minimum bias events.

In our case, we have generated minimum bias events with Pythia 8 (tune 4C) and studied the rapidity dependence of the transverse momentum deposited per unit area. The result is shown on Fig. 105 together with a quartic fit. If $f(y)$ is used to rescale median-based estimates of $\rho$, Eq. 20.2.6, any global normalisation factor would cancel, but in the case of Eq. 20.2.3) i.e. for the "seen vertices" method, the normalisation has to match what we mean by a seen PU vertex. In what follows, we shall define that as a minimum bias interaction that has at least 2 charged tracks with $|y| \leq 2.5$ and $p_{t} \geq 100$ MeV , which corresponds to $69.7 \%$ of the event ${ }^{56}$. In these conditions, we have found that the rapidity dependence is well reproduced by

$$
\begin{equation*}
f(y)=1.051141-0.023608 y^{2}+0.000026 y^{4} . \tag{20.3.2}
\end{equation*}
$$

### 20.33 Generic performance and rapidity dependence

Let us begin our performance benchmarks by the study of the rapidity dependence of PU subtraction. First of all, Fig. 106 shows the residual average shift $\left(\left\langle\Delta p_{t}\right\rangle\right)$ as a function of the rapidity of the hard jet. These results are presented for different hard processes, generated with Pythia 8 and assuming an average of 10 PU events per hard interaction. Robustness w.r.t. that choice will be discussed in the next Section but does not play any significant role for the moment.

The first observation is that the subtraction based on the number of seen PU vertices does a very good job in all 3 cases. Then, global median-based (using jets or grid cells) estimations of $\rho$, i.e. the (red) square symbols, do a fair job on average but, as expected, fail to correct for the rapidity dependence of the PU contamination. If one now restricts the median to a rapidity strip around the jet, the (blue) triangles, or if one uses rapidity rescaling, the (black) circles, the residual shift is very close to 0 , typically a few hundreds of MeV , and flat in rapidity.

Note that the strip-range approach seems to have a small residual rapidity dependence and overall offset for high- $p_{t}$ processes or multi-jet situations. That last point, more clearly observed with some

[^238]

Fig. 106: Residual average shift as a function of the jet rapidity for all the considered subtraction methods. For the left (resp. centre, right) plot, the hard event sample consists of dijets with $p_{t} \geq 50 \mathrm{GeV}$ (resp. dijets with $p_{t} \geq 400 \mathrm{GeV}$, and jets above $p_{t} \geq 50 \mathrm{GeV}$ in $t \bar{t}$ events), generated with Pythia 8 (tune 4 C ) in all cases. The typical PU contamination (for unsubtracted jets) is around 5 GeV .

Monte-Carlo generators like Pythia 6 than with others, may be due to the fact that smaller ranges tend to be more affected by the presence of the hard jets (see e.g. Appendix A. 2 of [486]), an effect which is reinforced for multi-jet events. The fact that the residual shift seems a bit smaller for grid-based estimates will be discussed more extensively in the next Section.

Next, we turn to the dispersion of $\Delta p_{t}$, a direct measure of the impact of PU fluctuations on the $p_{t}$ resolution of the jets. Our results are plotted in Fig. 107 as a function of the rapidity of the hard jet (left panel), the number of PU vertices (central panel) and the transverse momentum of the hard jet (right panel). All subtraction methods have been included as well as the dispersion one would observe if no subtraction were performed.

The results show a clear trend: first, a subtraction based on the number of seen PU vertices bring an improvement compared to not doing any subtraction; second, median-based estimations of $\rho$ give a more significant improvement; and third, all median-based approaches perform similarly well.

The reason why median-based estimations of $\rho$ outperform the estimation based on the number of seen PU vertices is simply because minimum bias events do not all yield the same energy deposit and this leads to an additional source of fluctuations in the "seen vertices" estimation compared to all median-based ones. This is the main motivation for using an event-by-event determination of $\rho$ based on the energy deposited in the event. This motivation is further strengthened by the fact that additional issues like vertex resolution or out-of-time PU would affect both $\left\langle\Delta p_{t}\right\rangle$ and $\sigma_{\Delta p_{t}}$ if estimated simply from the number of seen vertices while median-based approaches are more robust.

Note finally that even though local ranges and rapidity rescaling do correct for the rapidity dependence of the PU on average, the dispersion still depends on rapidity. The increase with the number of PU vertices is in agreement with the expected $\sqrt{n_{\mathrm{PU}}}$ behaviour and the increase with the $p_{t}$ of the hard process can be associated with back-reaction, see [486]. These numbers can also be compared to the typical detector resolutions which would be $\sim 10 \mathrm{GeV}$ for 100 GeV jets and $\sim 20 \mathrm{GeV}$ at $p_{t}=400 \mathrm{GeV}$ [490, 491].

### 20.34 Robustness and Monte-Carlo dependence

The last series of results we want to present addresses the stability and robustness of the median-based estimation of the PU density per unit area.

To do that, the first thing we shall discuss is the Monte-Carlo dependence of our results. In Fig.

Fig. 107: Dispersion $\sigma_{\Delta p_{t}}$. Each curve corresponds to a different subtraction method and the results are presented as a function of different kinematic variables: left, as a function of the rapidity of the hard jet for a sample of jets with $p_{t} \geq 100 \mathrm{GeV}$ and assuming an average of 10 PU events; centre: as a function of the number of PU events for a sample of jets with $p_{t} \geq 100$; right: as a function of the $p_{t}$ of the hard jet, assuming an average of 10 PU events

Fig. 108: Dependence of the average $p_{t}$ shift as a function of the number of PU vertices for various Monte-Carlo generators. For the left plot, the hard sample is made of dijets with $p_{t} \geq 100 \mathrm{GeV}$ while for the right plot, we have used a hadronic $t \bar{t}$ sample. For each generator, we have considered both the case with the Underlying Event switched on (filled symbols) and off (open symbols). All results have been obtained using a grid-based median estimation of $\rho$ using rapidity rescaling.

Fig. 109: Average residual shift after PU subtraction. $\left\langle\Delta p_{t}\right\rangle$ is plotted as a function of the $p_{t}$ of the jet for an average of 10 PU events (left panel), or as a function of the number of PU vertices for dijets with $p_{t} \geq 100 \mathrm{GeV}$ (central panel) and for $t \bar{t}$ events (right panel). In all cases, we compare 3 methods: the rapidity-strip range, (red) triangles, the jet-based approach with $y$-rescaling, (blue) circles, and the gridbased approach with $y$ rescaling, (black) squares. Each curve is the result of averaging over the various Monte-Carlo generator options and the dispersion between them is represented both as error bars on the top row and directly on the bottom row.

108 we compare the different Monte-Carlo predictions for the $\left\langle\Delta p_{t}\right\rangle$ dependence on the number of PU vertices in the case of a grid-based median estimate of $\rho$ with rapidity rescaling. For each of the three considered Monte-Carlos, we have repeated the analysis with and without Underlying Event (UE) in the hard event. The first observation is that all the results span a range of $300-400 \mathrm{MeV}$ in $\Delta p_{t}$ and have a similar dependence on the number of PU vertices. The dependence on $n_{\mathrm{PU}}$ is flat for dijet events but shows a small decrease for the busier $t \bar{t}$ events. The $300-400 \mathrm{MeV}$ shift splits into a $100-200 \mathrm{MeV}$ effect when changing the generator, which is likely due to the small but non-zero effect of the hard event on the median computation, and a $100-200 \mathrm{MeV}$ effect coming from the switching on/off of the UE.

This question of subtracting the UE deserves a discussion: since the UE is also a soft background which is relatively uniform, it contributes to the median estimate and, therefore, one expects the UE, or at least a part of it, to be subtracted together with the PU. Precisely for that reason, when we compute $\Delta p_{t}$, our subtraction procedure is not applied only on the "full jet" (hard jet+PU) but also on the hard jet, see Eq. 20.3.1. The $100-200 \mathrm{MeV}$ negative shift observed in Fig. 108 thus means that, when switching on the UE, one subtracts a bit more of the UE in the full event (with PU) than in the hard event alone (without PU). This could be due to the fact (see [492] for details) that for sparse events, as is typically the case with UE but no PU, the median tends to slightly underestimate the "real" $\rho$, e.g. if half of the event is empty, the median estimate would be 0 . This is in agreement with the fact that for $t \bar{t}$ events, where the hard event is busier, switching on the UE tends to have a smaller effect. Note finally that as far as the size of the effect is concerned, this $100-200 \mathrm{GeV}$ shift has to be compared with the $\sim 1 \mathrm{GeV}$ contamination of the UE in the hard jets.

Finally, we wish to compare the robustness of our various subtraction methods for various processes i.e. hard events and PU conditions. In order to avoid multiplying the number of plots, we shall treat the Monte-Carlo (including the switching on/off of the UE) as an error estimate. That is, an average measure and an uncertainty will be extracted by taking the average and dispersion of the 6 Monte-Carlo setups. The results of this combination are presented on Fig. 109 for various situations and subtraction

Fig. 110: Left: relative difference between the reconstructed jet and the reconstructed $Z$ boson transverse momenta. Right: at a given $p_{t}$ of the reconstructed $Z$ boson, difference between the reconstructed $p_{t}$ of the jet and the ideal $p_{t}$ with no UE or PU, i.e. $p_{t}$ shift w.r.t. the "noUE" curve, the (black) triangles, on the left panel. See the text for the details of the analysis.
methods. For example, the 6 curves from the left plot of Fig. 108 have been combined into the (black) squares of the central panel in Fig. 109 .

Two pieces of information can be extracted from these results. First of all, for dijets, the quality of PU subtraction is, to a large extent, flat as a function of the $p_{t}$ of the jets and the number of PU vertices. When moving to multi-jet situations, we observe an additional residual shift in the $100-300 \mathrm{MeV}$ range, extending to $\sim 500 \mathrm{MeV}$ for the rapidity-strip-range method. This slightly increased sensitivity of the rapidity-strip-range method also depends on the Monte-Carlo. While in all other cases, our estimates vary by $\sim 100 \mathrm{MeV}$ when changing the details of the generator, for multi-jet events and the rapidity-strip-range approach this is increased to $\sim 200 \mathrm{MeV}$.

Overall, the quality of the subtraction is globally very good. Methods involving rapidity rescaling tends to perform a bit better than the estimate using a rapidity strip range, mainly a consequence of the latter's greater sensitivity to multi-jet events. In comparing grid-based to jet-based estimations of $\rho$, one sees that the former gives slightly better results, though the differences remain small.

Since the grid-based approach is considerably faster than the jet-based one, as it does not require an additional clustering of the even ${ }^{57}$, the estimation of $\rho$ using a grid-based median with rapidity rescaling comes out as a very good default for PU subtraction. One should however keep in mind local-range approaches for the case where the rapidity rescaling function cannot easily be obtained.

### 20.4 PU v. UE subtraction: an analysis on $Z+j e t$ events

To give further insight on the question of what fraction of the Underlying Event gets subtracted together with the pileup, we have performed an additional study of $Z+$ jet events. We look at events where the $Z$ boson decays into a pair of muons. We have considered 5 different situations: events without PU or UE, events with UE but no PU subtracted or not, and events with both UE and PU again subtracted or not. Except for the study of events without UE, this analysis could also be carried out directly on data.

Practically, we impose that both muons have a transverse momentum of at least 20 GeV and have $|y| \leq 2.5$, and we require that their reconstructed invariant mass is within 10 GeV of the nominal $Z$

[^239]mass. As previously, jets are reconstructed using the anti- $k_{t}$ jet algorithm and the pileup subtraction is performed using the grid-based-median approach with rapidity rescaling and a grid size of 0.55 . All events have been generated with Pythia 8 (tune 4C) and we have assumed an average PU multiplicity of 20 events.

In Fig. 110, we have plotted the ratio $p_{t, \text { jet }} / p_{t, Z}-1$, with $p_{t, \text { jet }}$ the transverse momentum of the leading jet, for the various situations under considerations. Compared to the ideal situation with no PU and no UE, the (black) triangles, one clearly sees the expected effect of switching on the UE, the empty (green) circles, or adding PU, the empty (red) squares: the UE and PU add to the jet $\sim 1.2$ and 13 GeV respectively.

We now turn to the cases where the soft background is subtracted, i.e. the filled (blue) squares and (magenta) circles, for the cases with and without PU respectively. There are two main observations:

- with or without PU, the UE is never fully subtracted: from the original $1-1.5 \mathrm{GeV}$ shift, we do subtract about 800 MeV to be left with a $0-500 \mathrm{MeV}$ effect from the UE. That effect becomes smaller and smaller when going to large $p_{t}$.
- in the presence of PU, the subtraction produces results very close to the corresponding results without PU and where only the UE is subtracted. This nearly perfect agreement at large $p_{t, \text { jet }}$ slightly degrades into an additional offset of a few hundreds of MeV when going to smaller scales. This comes about for the following reason: the non-zero $p_{t}$ resolution induced by pileup (even after subtraction) means that in events in which the two hardest jets have similar $p_{t}$, the one that is hardest in the event with pileup may not correspond to the one that is hardest in the event without pileup. This introduces a positive bias on the hardest jet $p_{t}$ (a similar bias would be present in real data even without pileup, simply due to detector resolution). The "matched" curve in Fig. 110 (right) shows that if, in a given hard event supplemented with pileup, we explicitly use the jet that is closest to the hardest jet in that same event without pileup, then the offset disappears, confirming its origin as due to resolution-related jet mismatching.

### 20.5 Conclusions and discussion

In these proceedings, we have investigated several methods to correct for the pile-up contamination to jets. They are all based on the observation that the average PU contribution to a jet is on average proportional to its area, which directly leads to eq. 20.2.2. The various methods then differ by the method used to estimate the PU activity per unit area, $\rho$. The subtraction efficiency has been studied by embedding hard events into PU backgrounds and investigating how jet reconstruction was affected by measuring the remaining $p_{t}$ shift after subtraction $\left(\left\langle\Delta p_{t}\right\rangle\right)$ as well as the impact on resolution ( $\sigma_{\Delta p_{t}}$ ).

There are 3 broad approaches to the estimation of $\rho$ : (a) using an average contamination per PU vertex, the seen vertices approach, (b) using an event-by-event estimation and, the median approach with jets or grid cells as patches, and (c) using an event-by-event and jet-by-jet method, the local range or rescaling approaches.

The first important message is that, though all methods give a very good overall subtraction $\left(\left\langle\Delta p_{t}\right\rangle \approx 0\right.$ ), event-by-event methods should be preferred because their smaller PU impact on the $p_{t}$ resolution (see Fig. 107). This is mostly because the "seen vertices" method has an additional smearing coming from the fluctuations between different minimum bias collisions. This does not happen in event-by event methods that are only affected by point-to-point fluctuations in an event. Note also that event-by-event methods are very likely more robust than methods based on identifying secondary vertices when effects like vertex identification and out-of-time PU are taken into account.

The next observation is that event-by-event and jet-by-jet methods have the additional advantage that they correct for positional-dependence of the background like its rapidity dependence (see Fig. 106). The median approach using a local range (with jets as patches) or rapidity rescaling (using jets or grid cells as patches) all give an average offset in the $0-300 \mathrm{MeV}$ range, independently of the rapidity of
the jet, its $p_{t}$ or the number of PU vertices, see Fig. 109 and are thus very suitable methods for PU subtraction at the LHC. Pushing the analysis a bit further one may argue that the local-range method has a slightly larger offset when applied to situations with large jet multiplicity like $t \bar{t}$ events (the right panel of Fig. (109) though this argument seems to depend on the Monte-Carlo used to generate the hard-event sample. Also, since it avoids clustering the event a second time, the grid-based method has the advantage of being faster than the jet-based approach.

At the end of the day, we can recommend the median-based subtraction method with rapidity rescaling and using grid cells as patches as a powerful default PU subtraction method at the LHC. But one should keep in mind that the use of jets instead of grid cells also does a very good job and that local-ranges can be a good alternative to rapidity rescaling if the rescaling function cannot be computed. Also, though we have not discussed that in detail, a grid cell size of 0.55 is a good default as is the use of $k_{t}$ jets with $R=0.4$.

To conclude, let us make a few general remarks. First, our suggested method involves relatively few assumptions, which helps ensure its robustness. Effects like in-time v. out-of-time PU or detector response should not have a big impact. Many of the studies performed here can be repeated with "real data" rather than Monte-Carlo simulations. The best example is certainly the $Z+$ jet study of Section 20.4 which could be done using data samples with different PU activity from 2010 and 2011. Also, the rapidity rescaling function can likely be obtained from minimum bias collision data and the embedding of a hard event into pure PU events could help quantifying the remaining $\mathcal{O}(100 \mathrm{MeV})$ bias. Experimentally, it would also be interesting to investigate hybrid techniques where one would discard the charged tracks that do not point to the primary vertex and apply the subtraction technique described here to the rest of the event. This would have the advantage to further reduce fluctuation effects (roughly by a factor $\sim \sqrt{1 /\left(1-f_{\mathrm{chg}}\right)} \approx 1.6$, where $f_{\mathrm{chg}} \approx 0.61$ is the fraction of charged particles in an event). Finally, all the facilities to compute jet areas and background estimation - including jets or grid-cells as patches, local ranges and rescaling functions - are readily available from FastJet (v3.0.0 onward) using e.g. the GridMedianBackgroundEstimator or Subtractor tools.

## Acknowledgements

We thank Andy Buckley, Suzanne Gascon-Shotkin, Paolo Francavilla, Peter Loch, Emily Nurse, and Mark Stockton for very stimulating discussion during and after the workshop. This work was supported in part by grants ANR-09-BLAN-0060, ANR-10-CEXC-009-01 and PITN-GA-2010-264564.

## Part VI

## MC TUNING AND OUTPUT FORMATS

## 21. TUNE KILLING: QUANTITATIVE COMPARISONS OF MC GENERATORS AND TUNES ${ }^{58}$

#### Abstract

We summarise the implementation, status, and scope of the "tune killing" project, which classifies MC generator codes and tunes according to their quality of data description across a range of LHC-relevant observables. The primary aim of the project is to provide sufficiently clear information about generator performance that the current large collection of available tunes may be objectively reduced to a more manageable standard set for common use by LHC experiments and phenomenologists. We make final recommendations as

[^240]to which generators and tunes are in rude health, and those which are obvious candidates for retirement from active service.

### 21.1 INTRODUCTION

Popular MC generators are nowadays associated with a bewildering array of standard parameter configurations, called "tunes". This proliferation of tunes is due to the ongoing project to provide optimised descriptions of LEP, Tevatron and LHC data: as new data and techniques have become available, new tunes have been created, usually but not always with increasing quality of data description. This process looks set to continue, and hence there is a need for agreement on which tunes are of most common interest at a given time.
The PYTHIA6 [400] event generator in particular has been the de facto testbed for tuning due to the wealth of community expertise and its ubiquity of tuning parameters for physical processes. At the time of writing there are 77 tunes available via the built-in PYTUNE routine, and a further 10 or more presented by the ATLAS experiment alone (this counting of ATLAS tunes includes equivalently weighted tunes for multiple PDFs, but not systematic variation tunes, of which there are many more). With such a profligacy of configuration options, it is difficult to objectively decide which are to be preferred for LHC simulation without manually cross-referencing hundreds of plots. It is hence not uncommon for different experimental or phenomenological studies to use entirely disjoint MC generator setups, making comparison difficult. Ideally we would have a much smaller set of agreed-upon generator setups, but choosing such a privileged subset requires clear information on which to base our preferences.
As a first step to addressing this issue, we present here a comparative study of event generator codes and tunes across a range of observables, particularly those of relevance for LHC physics. The study is based on analyses from the Rivet [360] toolkit, and the resulting data descriptions are quantitatively scored based on measures of deviation from the data values, including $\chi^{2}$ and median/maximum binwise deviations (in units of combined experimental, statistical, and theoretical uncertainties). The results are presented as a series of Web pages, using colour coded tables which are hyperlinked to provide the necessary information in a compact, hierarchical form.

### 21.2 Analysis system

The data analysed for this project was produced by individual runs of various generator/tune configurations into the Rivet analysis system. A choice of Rivet analyses was made, intended to cover a number of core QCD modelling aspects for LHC physics: these are documented in Table 16. In some cases only the most relevant range in the distribution is included, as indicated in the Table. The generators and tunes used are documented in Table 17
Note that not all observables are suitable for all generators. For example, AlpGen has not been used for LEP fragmentation, although in a future iteration we will extend the AlpGen coverage to include underlying event observables, where the hard jets could interfere with those from the multiple parton interaction (MPI) mechanism. Several observables, notably hard photon physics, minimum bias observables, and fragmentation/strangeness from RHIC and LHC have not yet been included: this is envisaged as a future extension of the project.
A Python program was written to load the histogram files for each generator/tune combination from a hierarchical directory structure, and to perform some basic statistical characterisation on each bin, histogram, and semantic group of histograms. At the histogram level, specifications are used to determine which bins are to be considered in the statistical comparisons, and to add a nominal "theoretical uncertainty". In this study a $10 \%$ theoretical uncertainty was added to the underlying event and fragmentation observables and a $5 \%$ theoretical uncertainty on the rest. The combined uncertainty for each bin $b$ is then computed from the sum in quadrature of the reference data error, the MC statistical error and the theoretical uncertainty, and is used to compute a MC-data deviation for that bin, expressed in units of

Table 17: Generators and tunes used in the tune killing exercise. (*) Jet and $Z$ boson $\phi^{*}$ observables only.
the total bin error, $\operatorname{dev}_{b}=\left(\mathrm{MC}_{b}-\operatorname{data}_{b}\right) / \operatorname{err}_{b}$.
For each active histogram, the system then reports the $\chi^{2} / N_{\text {bin }}$, and the median, mean, and maximum bin-wise deviation. A total "metric" value for each histogram is reported as the maximum bin-wise deviation if that is greater than $10 \sigma$, otherwise the greater of the median and mean deviations. This hybrid treatment of the metric allows the system to flag up histograms in which there are either widespread moderate deviations or a small number of very discrepant bins which might be missed with a pure median or mean deviation treatment. An HTML table and set of histograms are rendered by the system for each observable, with a continuous colour coding scheme used to highlight the relative quality of data description from ideal (green) to very poor (red).
The histograms are grouped to collect together observables from different sources which reflect related aspects of QCD modelling. The current groups are "Underlying Event (UE)", "Dijets", "Multijets", "Jet shapes", "W and Z", "Fragmentation", and " $B$ fragmentation". In these groups, the same $\chi^{2} / N_{\text {bin }}$, and mean/median/maximum deviation statistics are calculated as before. For visual compactness of classification we again use a hybrid performance metric for each histogram group: again this is the maximum bin-wise deviation found in the contained histograms if that is greater than $10 \sigma$, otherwise the maximum histogram-wise deviation metric in the group if that is greater than $5 \sigma$, otherwise the maximum of the median/mean bin-wise deviation.
The Web pages generated to present this data in a compact way consist of a single top level page containing a colour-coded table of tune performance metrics for each histogram group. Each cell in the table is hyperlinked to a more detailed table for that tune/group where the various $\chi^{2} / N$, max/mean/median deviation and hybrid metric are presented, again colour-coded, for each histogram in the group. The table rows are then hyperlinked to a plot page showing explicitly the tune/generator behaviour for each histogram and indicating the active range of the histograms where appropriate. These pages are shown in Figures 111 to 113 . This form of presentation allows a rapid assessment of generator/tune performance, while still permitting detailed investigation of any flagged-up issues with a few mouse clicks. The system is easily extensible to more observables, groups, and different theory uncertainty / visual classification thresholds.
The classification colours for each performance figure are generated in HSB colour space as a linear variation in deviation $x$ between green (120) and red (0) in the Hue parameter, i.e. $H=120(1-$ $\left.\min \left(x / x_{\text {bad }}, 1.0\right)\right)$, with fixed Saturation and Brightness parameters. The visual threshold $x_{\text {bad }}$ was chosen to be different for each metric type: $5 \sigma$ for maximum deviations, $4 \sigma$ for $\chi^{2} / N$, and $2 \sigma$ for mean and median deviations, and for the hybrid performance metrics. These thresholds were iterated from initial suggestions to the point where distinctions could be made between the models: similar iteration of the discriminating criteria are envisaged while significant model/tune variations exist as the motivation of this study is model discrimination rather than passing or failing a natural performance figure.

### 21.3 Results

As the central theme of this project has been to provide a comprehensible visualisation of the relative performance of generators and tunes, and hierarchical presentation via Web pages was key to achieving this, it would be self-defeating to attempt to present the same information in this summary. Additionally, the nature of tune comparison is that it evolves as new data, tunes, and generator versions become available. Hence, for up-to-date status information we refer the reader to the persistent "tune killing" web page at http:/ /projects.hepforge.org/rivet/tunecmp/.
However, it is worth mentioning some of the most striking features of generators which have been made more evident by this collating of data-MC comparisons:

- The general quality of jet and W/Z data description is in fact better than expected: among PYTHIA tunes in particular there is sufficient variation in parton shower parameters that significant deviations in jet observables would reasonably be expected, but in fact the majority of tunes describe

## Plots for PYTHIA6, AUET2B-LOxx, B frag

Fig. 113: Screenshot of the observable plot page produced by the tune comparison system. This specific example shows the $B$ fragmentation performance of the PYTHIA6 AUET2B LO** tune.
data fairly well.

- The UE in particular has been a focus of tuning activity and this is evident in the consistency of UE data description. The worst performance in this group is from the DW tune of PYTHIA, but even this pre-LHC tune with the "old" PYTHIA MPI model achieves a deviation metric of less than $1 \sigma$ on LHC UE observables.
- PYTHIA D6T outperforms PYTHIA DW - an unexpected result since the MPI energy evolution of D6T is fixed to the default and disfavoured form $p_{\perp}^{0}(s) \sim(\sqrt{s} / 1800 \mathrm{GeV})^{0.16}$, whereas the exponent in DW is closer to the tuned consensus of $\sim 0.25$. This may be a lucky behaviour at 7 TeV , and hence care is needed with extrapolation of D6T to 8,10 , or 14 TeV , but it is clear that the PYTHIA $Q^{2}$-ordered parton shower is not yet dead on purely physics grounds. The best tune of this PYTHIA configuration, however, is Prof- $Q^{2}$, which in addition to general small improvements, is significantly better than DW or D6T at describing the vector boson $p_{\perp}$ distribution.
- Pythia8 is generally seen to perform very well, and provides significant improvements over PYTHIA6 for jet shapes and $B$ fragmentation. Tuning focus is accordingly beginning to shift towards Pythia8, also for minimum bias observables not yet considered here.
- AlpGen interacts strongly with tunes on jet shape and vector boson data descriptions. In particular there appears to be little motivation to use AlpGen with the D6T or Perugia 2010 tunes of PYTHIA6. AlpGen+HERWIG also has significant problems with jet shapes in particular, and the indication of this study is that AlpGen+PYTHIA Perugia 2011 is the most performant configuration, closely followed by AlpGen+PYTHIA Z2. Notably, the Perugia 2011 tune of PYTHIA was specifically developed to minimise ME/PS merging artefacts when used with AlpGen.
- Both HERWIG and Herwig++ have problems describing LEP fragmentation data, but Herwig++ is a very significant improvement over its Fortran cousin. The identified hadron rates are in particular much improved, although $K^{ \pm}$and $\Sigma^{0}$ remain anomalous. However, a known problem with Herwig++ is the poor description of the LEP thrust distribution, which overshoots significantly in the multi-parton region.
- AlpGen seems to have difficulty describing dijet azimuthal decorrelations, even when restricted to the $2 / 3$ parton region of the plot. This is particularly surprising as AlpGen is intended to provide
the multi-parton configurations needed to describe this observable.
- $B$ fragmentation is in general quite poorly described. The best descriptions are by Pythia8, the AUET2B tunes of PYTHIA6, and Herwig++. Other generators and tunes are in decidedly dodgy shape for $B$-specific predictions at the LHC.
Insofar as it is within the scope of this project to make recommendations for canonical generator and tune choices, we note that the Perugia 2011, AUET2B, and Z 2 tunes of PYTHIA6 provide the best data descriptions currently available with that generator and that the Prof- $Q^{2}$ tune is the best available configuration using the $Q^{2}$-ordered PYTHIA parton shower. We hence recommend these 4 PYTHIA tunes as the current minimal set of PYTHIA tunes for general use at the LHC, particularly once an update of the ATLAS AUET2B tune has fixed the tuning issue with the $Z p_{\perp}$.
Among the other generators, where there is not such a proliferation of tunes, we note again the apparent performance issues with AlpGen - this is clearly in need of further pursuit. However, to reduce the amount of comparison needed, we note that Perugia 2011 is the only PYTHIA6 tune now optimised for use with AlpGen with avoidance of the worst effects of ME/PS coupling mismatches: hence future studies can quite happily restrict themselves to this AlpGen+PYTHIA configuration. As AlpGen+HERWIG has several problems with jet description, HERWIG itself has serious problems with both light and $B$ fragmentation, and no further tuning of the JIMMY MPI model is envisaged, the HERWIG generator cannot be recommended for future use in any capacity where an alternative exists.
The "new" C++ generators Herwig++, Pythia8, and Sherpa all perform well, with the exception of Sherpa's $B$ fragmentation and the Herwig++ light fragmentation. Pythia8 generally behaves well but some tuning or development may be needed to improve inter-jet observables and the $Z p_{\perp}$ spectrum. In general, the $\mathrm{C}++$ generators are in good health, and we anticipate further improvements as the focus of tuning studies shifts to them.

### 21.4 Outlook

This project has put in place a system and a set of classification criteria which have proven useful for summarising and investigating MC generator model and tune predictivity for a variety of QCD phenomena. While we claim no mandate to truly "kill" certain tunes or generators, and wish to emphasise that a poor performance in a single observable type (in particular $B$ fragmentation) certainly does not render that generator useless, the results from these comparisons do provide strong arguments for deprecation of at least several PYTHIA6 tunes and of the Fortran HERWIG generator in general.
It is the nature of a project like this that results are continually being updated, and there are many natural avenues for extension which we wish to pursue, in particular:

- Extra observables, e.g. minimum bias and $E_{\perp}$ flow, LHC and Tevatron photon physics, LHC $W / Z$ $p_{\perp}$ data, strangeness data from LHC and RHIC, explicit multijet observables, etc..
- Extra generators and tunes, in particular POWHEG+PYTHIA/HERWIG/Pythia8/Herwig++, MadGraph+PYTHIA/Pythia8, MC@NLO+HERWIG/Herwig++. Comparison between Sherpa with the CTEQ6.6 and CTEQ6L1 PDFs. New Pythia8 and PYTHIA6 tunes from ATLAS.
Greater automation of the data generation will be important, as finding resources (human rather than $\mathrm{CPU}!$ ) to produce and run combinatoric numbers of generator/tune/PDF/observable combinations has been troublesome. We suggest that this project can make use of the output of the CERN LPCC MCplots system (also Rivet-based) for future extension. We also look forward to a forthcoming major upgrade of the Rivet histogramming system which will greatly simplify the treatment of multi-leg generators for which the $n$-parton samples must be explicitly merged, e.g. AlpGen, MadGraph, etc.

## 22. COMPACT ASCII OUTPUT FORMAT FOR HEPMC 59

## Abstract

[^241]We discuss the possibility of reducing the footprint of HepMC event files. Different compression options are discussed, and a suggestion for an update of the HepMC ASCII file format is presented.

### 22.1 Introduction

The HepMC [509] event record has become the de-facto standard for communicating events between event generators and different kinds of analysis programs. HepMC also provides an ASCII-based file format for storing and retrieving events to and from disk, which has also become the standard. This file format is not at all optimized for size, and although disk space today is fairly cheap, there are still problems associated with handling very large files.
A typical minimum-bias 7 TeV LHC HepMC event occupies around 50 kB when written on disk. More interesting events are usually bigger than this and one would typically want to store many events to get anywhere near the statistics collected by any of the LHC experiments; it is clear that such event files will become very large and difficult to handle. Even with standard compression algorithms such as gzip and bzip2, where these file sizes can be reduced by a factor 3 or more, the problem is still substantial.
One could imagine using a binary output format to reduce the event size. Writing a 4 byte floating point number in an ASCII file typically takes 10-12 characters, so here one could expect to reduce file sizes up to a factor 3 . However, standard compression algorithms are rather good at identifying strings of numbers and compressing them, so there is normally not much to be gained by using a compressed binary format compared to a compressed ASCII one. In addition one would lose the advantage of ASCII files that they are (somewhat) readable to the human eye.
Instead the key to reducing file sizes is to remove redundant and unnecessary information stored in the files. This could involve completely reversible operations such as removing the information about the momentum of an intermediate particle, as this can be reconstructed from its decay products. It could also involve irreversible operations such as reducing the precision on the momenta. In the following we describe a number of such operations, which allows us to reduce the file sizes by almost a factor 30 .

### 22.2 The Benchmarking procedure

We started out by generating 1000 non-diffractive QCD events with Pythia 6.425[400] using the AGILe [360] interface. The resulting file size was 48 MB , which can be reduced to 16 MB or 13 MB using gzip or bzip2 respectively. We then investigated several ways of reducing this size.

Removing irrelevant particles The HepMC format contains quite a lot of information about how the event was generated, such as intermediate particles in the hard sub process, which may be generatordependent (and often unphysical) and is not relevant when comparing to experimental data. In principle one could argue that the only thing that should be written out is final-state stable particles (with HepMC status code 1). However, there are circumstances where information about intermediate unstable hadrons (status code 2) is relevant. The AGILe event generator interface already includes facilities for keeping only particle entries with status code 1 or 2.

Reconstructible information Some information in the HepMC file is redundant in the sense that it can be reconstructed from other information in the file. Here are some examples.

- Both energy, momentum and invariant mass of each particle is written out. Clearly, we can eg. reconstruct the energy given the three-momentum and mas $5^{60}$.

[^242]| Format | Status codes | no comp. <br> (MB) | gzip <br> (MB) | bzip2 <br> (MB) |
| :--- | ---: | ---: | ---: | ---: |
| Standard | All | 48 | 16 | 13 |
|  | $1 \& 2$ | 43 | 15 | 13 |
|  | 1 | 17 | 6.0 | 4.8 |
| Compact | All | 18 | 3.3 | 2.1 |
|  | $1 \& 2$ | 13 | 2.9 | 1.9 |
|  | 1 | 4.0 | 1.9 | 1.6 |
| Compact binary | 1 | 1.8 | 1.7 | 1.7 |

Table 18: Size of the benchmark file after applying different compression methods.

- The three-momenta of decayed hadrons (status code 2 ) can be reconstructed from the sum of the momenta of the decay products.
- The mass of a stable particle can be deduced from the particle ID.
- The position of a vertex can be deduced from the previous vertex position and the life-time and momentum direction of the connecting particle.
- Each particle in a HepMC event has a unique bar code, which is an otherwise arbitrary integer. No loss of information would result from renumbering the particles, simply inferring their bar code from the order in which they appear in the event.

Precision Clearly, having 8 byte floating point numbers is not very relevant for many of the numbers in an event file. When comparing with experimental data, there is no point in having much larger precision than what is achievable in the experiment, and it makes sense to match the the information in the HepMC file to the precision of the actually measured variables in the experiments.
A possible example is to store masses and transverse momenta as integers in units of 0.1 MeV , azimuthal angles as integers in units of $0.00002 \times \pi$, pseudorapidities as integers in units of 0.00001 and vertex positions as integers in units of 0.001 mm .

### 22.3 Benchmark Results

We have investigated several of the options listed in the previous section, and the resulting file sizes when applied to the benchmark file is presented in table 18 . Firstly we see the size reduction using the standard format and simply reducing the number of particles, keeping only those with status code 2 and 1 or only 1 . Next we present the same results, but using a compact format which keeps the structure of the HepMC ASCII file but applies all optimizations discussed above. Finally, for reference, we present an aggressively compacted Binary format which uses the following optimizations for each particle: stores 1 float for transverse and 1 float for longitudinal momentum, a 3-byte integer for phi, and 1 byte for PDG IDs (rare PDG IDs are written out with 4 full bytes). This format loses the HepMC structure of the event and in some sense this represents the target size, below which it is difficult to go.
It is clear that one does not gain much by using a binary format provided one uses the optimizations presented above together with bzip2 compression algorithm.

### 22.4 Outlook

Given the results above, the work to include a more efficient file format for the HepMC has begun. The suggestion is to keep the current structure of the file format, but to add options to exclude all particles except those with status code 1 (or 2). Furthermore options for the representation and precision of momenta and vertex positions will be included as well as options for excluding (simply replacing with a single exclamation mark for easy parsing) information which can be reconstructed. The new format will be included in a forthcoming HepMC version during 2012.

In this report we have not looked carefully at the time it takes to read the different formats. With the default HepMC format this can be many times larger than the time taken for typical particle-level analyses, while for minimal binary formats it is of the same order. We defer detailed study of this question to future work.

Abstract: We present a detailed phenomenological study of direct photon production in association with a heavy-quark jet in $p A$ collisions at the Relativistic Heavy Ion Collider (RHIC) and at the Large Hadron Collider (LHC) at next-to-leading order in QCD. The dominant contribution to the cross-section comes from the gluon-heavy-quark $(g Q)$ initiated subprocess, making $\gamma+Q$ production a process very sensitive to both the gluon and the heavy-quark parton distribution functions (PDFs). Additionally, the RHIC and LHC experiments are probing complementary kinematic regions in the momentum fraction $x_{2}$ carried by the target partons. Thus, the nuclear production ratio $R_{p A}^{\gamma+Q}$ can provide strong constraints, over a broad $x$-range, on the poorly determined nuclear parton distribution functions which are extremely important for the interpretation of results in heavy-ion collisions.

## 1 Introduction

Parton distribution functions (PDFs) are an essential component of any prediction involving colliding hadrons. The PDFs are non-perturbative objects which have to be determined from experimental input and link theoretical perturbative QCD (pQCD) predictions to observable phenomena at hadron colliders. In view of their importance, the proton PDFs have been a focus of long and dedicated global analyses performed by various groups; see e.g. refs. [1-8] for some of the most recent studies. Over the last decade, global analyses of PDFs in nuclei - or nuclear PDFs (nPDFs) - have been performed by several groups: nCTEQ [9-11], nDS [12], EKS98 [13], EPS08/EPS09 [14, 15], and HKM/HKN [16-18] (for a recent review, see ref. [19]). In a manner analogous to the proton PDFs, the nPDFs are needed in order to predict observables in proton-nucleus $(p A)$ and nucleus-nucleus $(A A)$ collisions. However, as compared to the proton case, the nuclear parton distribution functions are far less well constrained. Data that can be used in a global analysis are available for fewer hard processes and also cover a smaller kinematic range. In particular, the nuclear gluon distribution is only very weakly constrained, leading to a significant uncertainty in the theoretical predictions of hard processes in $A A$ collisions.

For this reason it is crucial to use a variety of hard processes in $p A$ collisions, both at RHIC and at LHC, in order to better constrain nuclear parton densities. The inclusive production of jets, lepton pairs or vector bosons are natural candidates since they are already used in global analyses of proton PDFs. ${ }^{1}$ In addition, other processes which could constrain the gluon nPDF have been discussed in the literature and have yet to be employed. For instance, the production of isolated direct photons [21] as well as inclusive hadrons [22] at RHIC and LHC can provide useful constraints on the nuclear gluon distribution, ${ }^{2}$ even though in the latter channel the fragmentation process complicates its extraction. Another natural candidate for measuring the gluon nPDF is heavy-quark [23] or heavy-quarkonium [24] production. Quarkonium production is however still not fully under control theoretically (see e.g. [25] for a review), hence it is not obvious whether a meaningful extraction of the nuclear gluon PDF will eventually be possible in this channel, yet indirect constraints might be obtained [26].

In this paper, we investigate the production of a direct photon in association with a heavy-quark jet in $p A$ collisions in order to constrain parton densities in nuclei. ${ }^{3}$ As we will show, this process is dominated by the heavy-quark-gluon $(Q g)$ initial state at both RHIC and the LHC making the nuclear production ratio in $p A$ over $p p$ collisions,

$$
\begin{equation*}
R_{p A}^{\gamma Q}=\frac{\sigma(p A \rightarrow \gamma Q \mathrm{X})}{A \sigma(p p \rightarrow \gamma Q \mathrm{X})}, \tag{1.1}
\end{equation*}
$$

a useful observable in order to determine the gluon and heavy-quark nPDFs in complementary $x$-ranges from RHIC to LHC. One of the advantages of such a ratio is that many of the experimental and theoretical uncertainties cancel. Nevertheless, for a solid interpretation of the ratios it is also necessary to compare the theory directly with the (differential) measured cross-sections. For this reason we present cross-sections and $p_{T}$-distributions computed at next-to-leading order (NLO) of QCD using acceptance and isolation cuts appropriate for the PHENIX and ALICE experiments at RHIC and LHC, respectively. Using the available luminosity values we also provide simple estimates for the expected event numbers.

The paper is organized as follows. In section 2 we briefly describe the NLO calculation used in the present paper (more details can be found in [28, 29]). In section 3, we discuss the different nPDF sets used in our analysis, focusing especially on the gluon and the heavyquark sectors. In sections 4 and 5 , results in $p A$ collisions at RHIC and LHC, respectively, are presented. In each case, we start with a discussion of the acceptance and isolation cuts, then turn to the (differential) cross-sections and event numbers, followed by a discussion of the nuclear production ratios. Finally, we summarize our main results in section 6 .

[^243]
## 2 Direct photon production in association with a heavy-quark jet

Single direct photons have long been considered an excellent probe of the structure of the proton due to their point-like electromagnetic coupling to quarks and due to the fact that they escape confinement [30,31]. Their study can naturally be extended to high-energy nuclear collisions where one can use direct photons to investigate the structure of nuclei as well [21].

However, it might also be relevant to study more exclusive final states, such as the double inclusive production of a direct photon in association with a heavy-quark (charm, bottom) jet ${ }^{4}$ in order to get additional constraints on parton distribution functions. The lower counting rates expected for this observable are compensated by various advantages:

- As shown below, the cross-section for direct photon plus heavy-quark production in $p p$ and $p A$ collisions is largely dominated by the gluon-heavy-quark $(g Q)$ channel. This offers in principle a direct access to the gluon and heavy-quark distributions in a proton and in nuclei;
- A two-particle final-state allows for the independent determination of the parton momentum fractions $x_{1}$ (projectile) and $x_{2}$ (target), using leading order kinematics and in the absence of fragmentation processes;
- Since the valence up quark distribution (to which single photons mostly couple) is smaller in neutrons - and therefore in nuclei - as compared to that in a proton, the nuclear production ratio $R_{p A}^{\gamma}$ of single photon production at large $x_{T}=2 p_{T} / \sqrt{s}$ is different than 1 independently of any nPDF effects [32]. In the $\gamma+Q$ production channel the photon couples mostly to the heavy-quark, which, by isospin symmetry, has the same distribution in a proton or neutron, i.e. $Q^{p}=Q^{n}$, leading to a nuclear production ratio $R_{p A}^{\gamma Q}$ free of any "isospin" effects and thus properly normalized to 1 in the absence of nPDF corrections.

At leading-order accuracy, $\mathcal{O}\left(\alpha \alpha_{s}\right)$, at the hard-scattering level the production of a direct photon with a heavy-quark jet only arises from the $g Q \rightarrow \gamma Q$ Compton scattering process, making this observable highly sensitive to both the gluon and heavy-quark PDFs. This is at variance with the single photon channel for which the Compton scattering ( $g q \rightarrow$ $\gamma q)$ as well as annihilation process $(q \bar{q} \rightarrow \gamma g)$ channels compete. ${ }^{5}$ At NLO the number of contributing subprocesses increases to seven, listed in table 1. As can be seen, all subprocesses apart from $q \bar{q} \rightarrow \gamma Q \bar{Q}$ are $g$ and/or $Q$ initiated. Which of these subprocesses dominate is highly dependent on the collider type ( $p \bar{p} v s . p p / p A$ ) and the collider center-of-mass energy. For example, $g$ and $Q$ initiated subprocesses will be more dominant at $p p$ and $p A$ colliders, whereas at the Tevatron ( $p \bar{p}$ collisions) the $q \bar{q} \rightarrow \gamma Q \bar{Q}$ dominates at high $p_{T}$ because of the valence-valence $q \bar{q}$ scattering in these collisions.

[^244]| $g g \rightarrow \gamma Q \bar{Q}$ | $g Q \rightarrow \gamma g Q$ |
| :---: | :---: |
| $Q q \rightarrow \gamma q Q$ | $Q \bar{q} \rightarrow \gamma \bar{q} Q$ |
| $Q \bar{Q} \rightarrow \gamma Q \bar{Q}$ | $Q Q \rightarrow \gamma Q Q$ |
| $q \bar{q} \rightarrow \gamma Q \bar{Q}$ |  |

Table 1. List of all $2 \rightarrow 3$ NLO hard-scattering subprocesses.

When one considers higher order subprocesses, such as $q Q \rightarrow q Q \gamma$, the produced photon may be emitted collinearly with the final state $q$ giving rise to a collinear singularity. This singular contribution is absorbed in fragmentation functions (FFs) $D_{\gamma / q}\left(z, \mu^{2}\right)$, which satisfy a set of inhomogeneous DGLAP equations, the solutions of which are of order $\mathcal{O}\left(\alpha / \alpha_{s}\right)$. As a consequence, another class of contributions of order $\mathcal{O}\left(\alpha \alpha_{s}\right)$ consists of $2 \rightarrow 2$ QCD subprocesses with at least one heavy-quark in the final state and another parton fragmenting into a collinear photon. These so-called fragmentation contributions need to be taken into account at each order in the perturbative expansion. As in the LO direct channel, we also include the $\mathcal{O}\left(\alpha \alpha_{s}^{2}\right)$ fragmentation contributions, which are needed for a complete NLO calculation. It should however be mentioned that isolation requirements - used experimentally in order to minimize background coming from hadron decays - greatly decrease these fragmentation contributions.

The present calculations have been carried out using the strong coupling constant corresponding to the chosen PDF set: $\alpha_{s}^{\overline{\mathrm{MS}}, 5}\left(M_{Z}\right)=0.118$ in next-to-leading order for both nCTEQ and EPS09, and $\alpha_{s}^{\overline{\mathrm{MS}}, 5}\left(M_{Z}\right)=0.1165$ for HKN. The renormalization, factorization and fragmentation scales have been set to $\mu_{R}=\mu_{F}=\mu_{f}=p_{T \gamma}$ and we have used $m_{c}=$ 1.3 GeV and $m_{b}=4.5 \mathrm{GeV}$ for the charm and bottom quark masses. We utilize the photon fragmentation functions of L. Bourhis, M. Fontannaz and J.P. Guillet [33]. For further details on the theoretical calculations, the reader may refer to [28, 29].

## 3 Nuclear parton distribution functions

In order to obtain results in hadronic collisions, the partonic cross-sections have to be convoluted with PDFs for protons and nuclei. For the latter we show results using the most recent nCTEQ [9, 10], EPS09 [15], and HKN07 [18] nuclear PDF sets. ${ }^{6}$ Each set of nuclear PDFs is connected to a set of proton PDFs to which it reduces in the limit $A \rightarrow 1$ where $A$ is the atomic mass number of the nucleus. ${ }^{7}$ Therefore we use the various ${ }^{n}$ PDFs together with their corresponding proton PDFs in the calculations. Since our goal is to probe gluon and heavy-quark nPDFs, let us now discuss these specific distributions in greater detail.

[^245]

Figure 1. Nuclear modifications $R_{g}^{A}=g^{p / A}(x, Q) / g^{p}(x, Q)$. Left: for gold at $Q=15 \mathrm{GeV}$. Right: for lead at $Q=50 \mathrm{GeV}$. Shown are results for nCTEQ decut3 (solid, black line), EPS09 (dashed, blue line) + error band, HKN07 (dash-dotted, red line) + error band. The boxes exemplify the $x$-regions probed at RHIC $\left(\sqrt{s_{\mathrm{NN}}}=200 \mathrm{GeV}\right)$ and the LHC $\left(\sqrt{s_{\mathrm{NN}}}=8.8 \mathrm{TeV}\right)$, respectively.

### 3.1 Gluon sector

As already mentioned, the nuclear gluon distribution is only very weakly constrained in the $x$-range $0.02 \lesssim x \lesssim 0.2$ from the $Q^{2}$-dependence of structure function ratios in deepinelastic scattering (DIS) [37], $F_{2}^{S n}\left(x, Q^{2}\right) / F_{2}^{C}\left(x, Q^{2}\right)$, measured by the NMC collaboration [38]. ${ }^{8}$

In order to compare the various nPDF sets, we plot in figure 1 the gluon distribution ratio $R_{g}^{A}(x, Q)=g^{p / A}(x, Q) / g^{p}(x, Q)$ as a function of $x$ for a gold nucleus at $Q=15 \mathrm{GeV}$ (left) and for a lead nucleus at $Q=50 \mathrm{GeV}$ (right). The chosen hard scales $Q=15,50 \mathrm{GeV}$ are typical for prompt photon production at RHIC and the LHC, respectively, and the boxes highlight the $x$-regions probed by these colliders.

As can be seen, the nuclear gluon distribution is very poorly constrained, ${ }^{9}$ especially in the regions $x<0.02$ and $x>0.1$. The uncertainty bands of the HKN07 and EPS09 gluon distributions do not overlap for a wide range of momentum fractions with $x>0.02$. Also the rather narrow and overlapping bands at small $x<0.02$ do not reflect any constraints by data, but instead are theoretical assumptions imposed on the small- $x$ behavior of the gluon distributions. The nCTEQ gluon has again quite a different $x$-shape which is considerably larger (smaller) in the $x$-region probed by RHIC (the LHC) as compared to HKN07 and EPS09.

At present, the nCTEQ nPDFs do not come with an error band. In order to assess the uncertainty of the nuclear gluon PDF we have performed a series of global fits to $\ell A$ DIS and Drell-Yan data in the same framework as described in ref. [10]. However, each time we have varied assumptions on the functional form of the gluon distribution. ${ }^{10}$ More precisely, the coefficient $c_{1}=c_{1,0}+c_{1,1}\left(1-A^{-c_{1,2}}\right)$ influencing the small $x$ behavior of the

[^246]| Name | (initial) fit parameter | $c_{1,1}$ | $c_{1,2}$ |
| :---: | :---: | :---: | :---: |
| decut3 | free | -0.29 | -0.09 |
| decut3g1 | fixed | 0.2 | 50.0 |
| decut3g2 | fixed | -0.1 | -0.15 |
| decut3g3 | fixed | 0.2 | -0.15 |
| decut3g4 | free | 0.2 | -0.15 |
| decut3g5 | fixed | 0.2 | -0.25 |
| decut3g7 | fixed | 0.2 | -0.23 |
| decut3g8 | fixed | 0.35 | -0.15 |
| decut3g9 | fixed - free proton | 0.0 | - |

Table 2. Start values for the parameter $c_{1}=c_{1,0}+c_{1,1}\left(1-A^{-c_{1,2}}\right)$ governing the small $x$ behavior of the gluon distribution at the initial scale $Q_{0}=1.3 \mathrm{GeV}$. The parameter $c_{1,0}$ corresponds to the gluon in the proton and has been kept fixed. With one exception, decut3g4, the parameters $c_{1,1}$ and $c_{1,2}$ have been kept fixed as well. For further details on the functional form the reader may refer to ref. [10].

Figure 2. Left: nPDF ratio $R_{g}^{P b}$ at $Q_{0}=1.3 \mathrm{GeV}$ predicted within the different nCTEQ sets - fits from top to bottom: decut3g9, decut3g5, decut3g7, decut3g8, decut3g3, decut3g4, decut3g2, decut3g1, decut3. Right: nCTEQ gluon nPDFs for different $\mathrm{A}(1,2,4,9,12,27$, $56,108,207)$ vs x at $Q_{0}=1.3 \mathrm{GeV}$ - from left to right, and top to bottom: decut3, decut3g1, decut3g2, decut3g3, decut3g4, decut3g5, decut3g7, decut3g8, decut3g9.
gluon distribution, see eq. (1) in [10], has been varied as summarized in table 2. Each of these fits is equally acceptable with an excellent $\chi^{2} /$ dof in the range of $\chi^{2} /$ dof $=0.88-0.9$.

In order to give an idea about the gluon nPDF uncertainty, we plot in figure 2 (left) a collection of ratios $R_{g}^{P b}$ for a lead nucleus as a function of the momentum fraction $x$ at the initial scale $Q_{0}=1.3 \mathrm{GeV}$, while in figure 2 (right) the actual gluon nPDFs are plotted versus $x$ for a range of $A$ values. Results are shown for several of the fits of the decut3g series. The ensemble of these curves together with the HKN07 and EPS09 uncertainty bands provides a much more realistic estimate of the uncertainty of the nuclear gluon distribution which is clearly underestimated by just one individual error band. This is due to the fact that for a specific fit, assumptions on the functional form of the nPDFs have

Figure 3. Nuclear modifications to deuteron, $R_{g}^{d}=g^{p / d}(x, Q) / g^{p}(x, Q)$ at $Q=15 \mathrm{GeV}$, nCTEQ (solid black line), EPS09 (dashed blue line), HKN (dash-dotted red line) + error band
been made so that the error bands based on the Hessian matrix for a given minimum only reflect the uncertainty relative to this set of assumptions.

In order to explore the allowed range of nCTEQ predictions for the nuclear production ratios to be discussed in section 4 and 5 we choose the three sets decut3 (solid black line), decut3g9 (dotted red line), and decut3g3 (dash-dotted green line). The original fit decut3 [10] exhibits a very strong shadowing at small $x$; conversely, the decut3g9 fit closely follows the distribution of the gluon in a (free) proton and the decut 3 g 3 gluon lies between the two extremes. In most cases, however, we focus on the original fit decut3 to which we refer by default as $n C T E Q$, if the fit name is not specified. Together, with the HKN07 and EPS09 predictions this will cover to a good degree the range of possibilities for the nuclear production ratios.

At RHIC, the incoming projectile is not a proton but a deuteron nucleus $(A=2)$, whose PDFs may be different from that of a proton. In figure 3 the expected nuclear modifications of the deuteron nucleus are shown. The EPS09 nPDFs do not include nuclear corrections to the deuteron PDFs, while the HKN and nCTEQ sets do. Those corrections are not large, at most $5 \%$, with nCTEQ having them more pronounced.

### 3.2 Heavy-quark sector

Let us now turn to the heavy-quark distribution. In the standard approach used in almost all global analyses of PDFs, the heavy-quark distributions are generated radiatively, according to DGLAP evolution equations [39-41], starting with a perturbatively calculable boundary condition [42, 43] at a scale of the order of the heavy-quark mass. In other words, there are no free fit parameters associated to the heavy-quark distribution and it is entirely related to the gluon distribution function at the scale of the boundary condition. As a consequence, the nuclear modifications to the radiatively generated heavy-quark PDF are very similar to those of the gluon distribution ${ }^{11}$ and quite different from the nuclear corrections in the valence-quark sector. This feature is illustrated in figure 4 (left) where

[^247]

Figure 4. Left: nPDF ratios $R_{g}^{P b}=g^{p / P b}(x, Q) / g^{p}(x, Q)$ (top), $R_{c}^{P b}=c^{p / P b}(x, Q) / c^{p}(x, Q)$ (middle), $R_{u_{v}}^{P b}=u_{v}^{p / P b}(x, Q) / u_{v}^{p}(x, Q)$ (bottom) at $Q=50 \mathrm{GeV}$ within nCTEQ (solid black line), EPS09 (dashed blue line), and HKN07 (dash-dotted red line). The shaded regions correspond to the $x$-values probed at RHIC $\left(x \sim 10^{-1}\right)$ and the LHC $\left(x \sim 10^{-2}\right)$. Right: double ratios $R_{c}^{P b} / R_{g}^{P b}$ and $R_{c}^{P b} / R_{u_{v}}^{P b}$ using the same nPDF sets.
we show the nuclear modifications for the gluon (upper panel), charm (middle panel) and the valence up-quark (bottom panel), in a lead nucleus, for three different sets of nuclear PDFs at the scale $Q=50 \mathrm{GeV}$ as in figure 1 (right). The shaded regions in figure 4 (left) correspond to the typical $x$-values probed at RHIC $\left(x \sim 10^{-1}\right)$ and the LHC $\left(x \sim 10^{-2}\right)$. The close similarity between the charm and the gluon nPDFs can be better seen in figure 4 (right) where the double ratios, $R_{c}^{P b} / R_{g}^{P b}$ and $R_{c}^{P b} / R_{u_{v}}^{P b}\left(u_{v} \equiv u-\bar{u}\right.$ being the valence distribution), are plotted. Remarkably, the nuclear effects in the gluon and the charm PDFs are different by at most $20 \%$ at large $x\left(R_{c} / R_{g} \lesssim 1.2\right)$, whereas the difference can be as large as $80 \%\left(R_{c} / R_{u_{v}} \simeq 1.8\right)$ when comparing the valence up-quark and the charm nPDF ratios. Therefore, in the standard approach, the LO direct contribution $(g Q \rightarrow \gamma Q)$ only depends on the gluon distribution, either directly or via the dynamically generated heavy-quark distribution, making this process an ideal probe of the poorly known gluon nPDF.

Conversely, light-cone models predict a nonperturbative (intrinsic) heavy-quark component in the proton wave-function [44, 45] (see [46] for an overview of different models). Recently, there have been studies investigating a possible intrinsic charm (IC) content in the context of a global analysis of proton PDFs [1, 47]. In the nuclear case, there are no global PDF studies of IC (or IB) available. This is again mainly due to the lack of nuclear data sensitive to the heavy-quark components in nuclei. For this reason, we only consider the standard radiative charm approach in the present paper. Measurements of $\gamma+Q$ production in $p A$ collisions at backward (forward) rapidities are sensitive to the BHPS-IC in nuclei (the proton) complicating the analysis. A similar statement is true for RHIC, where due to the lower center-of-mass energy the results depend on the amount of intrinsic charm. Therefore, once the nuclear gluon distribution has been better determined from other processes these cases may be useful in the future to constrain the nuclear IC.

|  | $p_{T}$ | Rapidity | $\phi$ | Isolation Cuts |

Table 3. Experimental cuts used for the theoretical predictions at RHIC.

Figure 5. Differential cross-section for $\gamma+c$ (left) and $\gamma+b$ (right) production in $d$-Au collisions at a center-of-mass energy of $\sqrt{s_{\mathrm{NN}}}=200 \mathrm{GeV}$ : NLO (solid black line + band), LO (dashed blue line).

## 4 Phenomenology at RHIC

In this section we present the theoretical predictions for the associated production of a photon and a heavy-quark jet in $d$-Au collisions at RHIC at $\sqrt{s_{\mathrm{NN}}}=200 \mathrm{GeV}$.

### 4.1 Cuts

The experimental cuts used for the theoretical predictions are listed in table 3. The photon rapidity and isolation requirements are appropriate for the PHENIX detector [48]. When $p_{T, \gamma}=p_{T, Q}$ the NLO cross-section is known to become infrared sensitive. ${ }^{12}$ Therefore, in order to acquire an infrared safe cross-section, the minimum transverse momentum of the photon is kept slightly above that of the heavy-quark [49, 50] which ensures a proper cancellation between real and virtual contributions. Also note that the $p_{T}^{\min }$ cuts in the $\gamma+b$ channel $\left(p_{T, Q}^{\min }=14 \mathrm{GeV}\right.$ and $\left.p_{T, \gamma}^{\min }=17 \mathrm{GeV}\right)$ were taken to be higher than those in $\gamma+c$ events in order to keep terms of $\mathcal{O}\left(m_{Q} / p_{T}\right)$ small.

### 4.2 Spectra and expected rates

The $p_{T_{\gamma}}$ spectra are shown for $\gamma+c$ production in figure 5 (left) and $\gamma+b$ production in figure 5 (right) where the band represents the scale uncertainty obtained by varying

[^248]

Figure 6. Subprocess contributions to the differential cross-section at RHIC: NLO (solid black line), LO $+g g \rightarrow Q \bar{Q} \gamma$ (dashed blue line), $g Q \rightarrow g Q \gamma$ (dash-dotted purple line), $q \bar{q} \rightarrow Q \bar{Q} \gamma$ (dotted red line), $q(\bar{q}) Q(\bar{Q}) \rightarrow q(\bar{q}) Q(\bar{Q}) \gamma, Q Q \rightarrow Q Q \gamma$ (dash-dot-dotted magenta line).
the renormalization, factorization and fragmentation scales by a factor of two around the central scale choice, i.e., $\mu_{R}=\mu_{F}=\mu_{f}=\xi p_{T \gamma}$ with $\xi=1 / 2,2$.

The total integrated cross-section for $\gamma+c$ events is $\sigma_{\gamma+c}^{d A u}=37036 \mathrm{pb}$. Using the projected weekly luminosity for $d-A u$ collisions at RHIC-II, $\mathcal{L}^{\text {week }}=62 \mathrm{nb}^{-1}$ [51], and assuming 12 weeks of ion runs per year, the yearly luminosity is $\mathcal{L}^{y e a r}=744 \mathrm{nb}^{-1}$. Thus, an estimate of the number of events expected in one year is $N_{\gamma+c}^{d A u}=\mathcal{L}^{y e a r} \times \sigma_{\gamma+c}^{d A u} \simeq 2.8 \times 10^{4}$ in $d$-Au collisions, without taking into account effects of the experimental acceptances and efficiencies. At $p_{T_{\gamma}} \simeq 20 \mathrm{GeV}\left(\mathrm{d} \sigma / \mathrm{d} p_{T_{\gamma}} \simeq 45 \mathrm{pb} / \mathrm{GeV}\right)$, the number of events would still be large, $\mathcal{O}\left(10^{2}\right)$ per GeV -bin. This indicates that the number of $\gamma+\mathrm{c}$ events in a year produced at RHIC-II will be substantial. The rates expected in the $\gamma+b$ channel at RHIC are naturally much more modest. Using the total integrated cross-section $\sigma_{\gamma+b}^{d A u}=32 \mathrm{pb}$, the number of events to be expected in a year is $N_{\gamma+b}^{d A u}=24$. Therefore we shall mostly focus the discussion on the $\gamma+c$ channel in the following.

In figure 6 the individual subprocess contributions to the $\gamma+c$ NLO production crosssection are presented. As can be seen, the dominant subprocesses are the LO Compton scattering $g Q \rightarrow \gamma Q$, as well as the higher-order $g Q \rightarrow \gamma g Q$ and $g g \rightarrow \gamma Q \bar{Q}$ channels. Thus almost all the PDF dependence in the NLO $\gamma+c$ cross-section comes from the gluon and heavy-quark PDFs and not from the light-quark PDFs. The relative increase of the contributions by the annihilation subprocess, $q \bar{q} \rightarrow Q \bar{Q} \gamma$, and the light quark-heavy quark subprocess $q Q \rightarrow q Q \gamma$ at higher $x\left(p_{T \gamma} \sim 15 \mathrm{GeV}\right)$ is due to the slower decrease of the valence quark PDF at high $x$ as compared to the rest of the PDFs.

### 4.3 Nuclear production ratios

Let us now discuss the nuclear modifications of $\gamma+c$ production in $d$-Au collisions. The nuclear production ratio,

$$
\begin{equation*}
R_{d A u}^{\gamma+c}=\frac{1}{2 \times 197} \frac{d \sigma / d p_{T \gamma}(d \mathrm{Au} \rightarrow \gamma+c+X)}{d \sigma / d p_{T \gamma}(p p \rightarrow \gamma+c+X)}, \tag{4.1}
\end{equation*}
$$

Figure 7. Left: nuclear production ratio of the $\gamma+c$ cross-section at RHIC using nCTEQ (solid black line), nCTEQ without nuclear corrections in the deuteron (dotted magenta line), EPS09 (dashed blue line) + error band, HKN (dash-dotted red line) + error band. Right: nuclear modification of the gluon in gold, $R_{g}^{A u}\left(x, Q=x \sqrt{S} / 2 \sim p_{T}\right)$, for the $x$-region probed at RHIC. This figure corresponds to the enlargement of the box region in the left panel of figure 1.

Figure 8. Nuclear production ratio of the $\gamma+c$ cross-section at RHIC using the three nCTEQ fits discussed in section 3 . Also shown is the scale dependence of $R_{d A u}^{\gamma+c}$.
is plotted in figure 7 (left) as a function of $p_{T \gamma}$ using the three nPDF sets discussed in section 3, namely nCTEQ (solid black line), EPS09 (dashed blue line + error band) and HKN (dash-dotted red line + error band). There is some overlap between $R_{\text {HKN }}^{\gamma+c}$ and $R_{\text {EPS } 09}^{\gamma+c}$ at not too large $p_{T} \lesssim 15 \mathrm{GeV}$, whereas the difference between $R_{\mathrm{nCTEQ}}^{\gamma+c}$ on the one hand and $R_{\text {HKN }}^{\gamma+c}$ and $R_{\text {EPS09 }}^{\gamma+c}$ on the other hand is larger for all transverse momenta. The $R_{\text {nCTEQ }}^{\gamma+c}$ ratio is further increased by the anti-shadowing corrections in the deuteron projectile, as can be seen in figure 7 (left) where the nCTEQ predictions are performed with (solid line) and without (dashed) corrections in the deuteron (see also figure 3). Due to the rather low center-of-mass energy (as compared to the Tevatron/LHC) the collisions at central rapidity at RHIC probe relatively high values of momentum fractions carried by the partons in the nuclear target, $x_{2}=\mathcal{O}\left(2 p_{T} / \sqrt{s}\right)=\mathcal{O}\left(10^{-1}\right)$. In figure 7 (right) we show the nuclear modifications of the gluon distribution in a gold nucleus, $R_{g}^{A u}\left(x, Q=x \sqrt{S} / 2 \sim p_{T}\right)$, for the typical $x$-region probed at RHIC. Note that, this figure corresponds to the enlargement

|  | $p_{T}$ | Rapidity | $\phi$ | Isolation Cuts |
| :---: | :---: | :---: | :---: | :---: |
| Photon (PHOS) | $p_{T, \gamma}^{\min }=20 \mathrm{GeV}$ | $\left\|y_{\gamma}\right\|<0.12$ | $220^{\circ}<\phi<320^{\circ}$ | $R=0.2, p_{T}^{\mathrm{th}}=2 \mathrm{GeV}$ |
| Photon (EMCal) | $p_{T, \gamma}^{\min }=20 \mathrm{GeV}$ | $\left\|y_{\gamma}\right\|<0.7$ | $80^{\circ}<\phi<180^{\circ}$ | $R=0.2, p_{T}^{\mathrm{th}}=2 \mathrm{GeV}$ |
| Heavy Jet | $p_{T, Q}^{\min }=15 \mathrm{GeV}$ | $\left\|y_{Q}\right\|<0.7$ | - | - |

Table 4. Experimental cuts for the ALICE detector.
of the box-region in the left panel of figure 1. As can be seen the nuclear production ratios of $\gamma+c$ events shown in figure 7 (left) closely correspond to the different nuclear modifications of the gluon distribution depicted on the right side of figure 7. Clearly, measurements of this process with appropriately small error bars will be able to distinguish between these three different nuclear corrections to the cross-section and therefore be able to constrain the gluon nuclear PDF.

In figure 8 we present the dependence of the nuclear modifications on the three nCTEQ fits (decut3, decut3g9, decut3g3) discussed in section 3. It is clear that these different fits cover quite a spread of nuclear modifications, ranging from ones which are quite pronounced (decut3) to almost none (decut3g9). We stress again, that neither of these predictions is preferred over the other since the nuclear gluon distribution is so poorly known. Finally, we also show in figure 8 the scale uncertainty which is entirely negligible compared to the PDF uncertainty.

In the next section we present the phenomenology of $\gamma+Q$ production at the LHC where smaller values of $x_{2}$ are probed due to the higher center-of-mass energy.

## 5 Phenomenology at LHC

In this section, calculations are carried out for $p-\mathrm{Pb}$ collisions at the LHC nominal energy, $\sqrt{s_{\mathrm{NN}}}=8.8 \mathrm{TeV}$, different from the $p p$ collision energy $(\sqrt{s}=14 \mathrm{TeV})$.

### 5.1 Cuts

The cuts used in the present calculation are shown in table 4 and are appropriate for the ALICE detector ${ }^{13}$ [52-56]. Note that the rapidity shown in table 4 is given in the laboratory frame, which in $p A$ collisions is shifted by $\Delta y=-0.47$ with respect to the center-ofmass frame [57, 58]. In ALICE, photons can be identified in the EMCal electromagnetic calorimeter, or in the PHOS spectrometer with a somewhat more limited acceptance.

### 5.2 Spectra and expected rates

The differential NLO cross-section is plotted as a function of the photon transverse momentum in the $\gamma+c(\gamma+b)$ channel in figure 9 left (right) for both PHOS (lower band) and EMCal (upper band); the dotted curves indicate the theoretical scale uncertainty.

[^249]|  | $\sigma_{\gamma+Q}^{p P b}$ | $N_{\gamma+Q}^{p P b}$ |
| :---: | :---: | :---: |
| $\gamma+c$ PHOS | 22700 pb | 2270 |
| $\gamma+b$ PHOS | 3300 pb | 330 |
| $\gamma+c$ EMCal | 119000 pb | 11900 |
| $\gamma+b$ EMCal | 22700 pb | 2270 |

Table 5. Total integrated cross-section and number of events per year for $\gamma+Q$ production in $p-\mathrm{Pb}$ collisions at the LHC for PHOS and EMCal acceptances.

Figure 9. NLO differential cross-section for $\gamma+c$ (left) and $\gamma+b$ (right) production in $p-\mathrm{Pb}$ collisions at a center-of-mass energy of $\sqrt{s_{\mathrm{NN}}}=8.8 \mathrm{TeV}$ in PHOS (lower band) and EMCal (upper band) acceptances.

In order to estimate the number of events produced, we use the instantaneous luminosity $\mathcal{L}^{\text {inst }}=10^{-7} \mathrm{pb}^{-1} s^{-1}[58]$ which corresponds to a yearly integrated luminosity of $\mathcal{L}^{\text {year }}=10^{-1} \mathrm{pb}^{-1}$ assuming one month $\left(\Delta t=10^{6} s\right)$ of running in the heavy-ion mode at the LHC. In table 5 the total integrated cross-section for $\gamma+Q$ for both PHOS and EMCal along with the respective anticipated number of events (before experimental efficiencies), $N_{\gamma+Q}^{p P b}=\sigma_{\gamma+Q}^{p P b} \times \mathcal{L}^{\text {year }}$ are given. As expected the $\gamma+b$ and $\gamma+c$ cross-sections at EMCal are increased substantially by the larger acceptance of that detector. The number of expected $\gamma+b$ events is large, at variance with what is expected at RHIC (see section 4.2).

The individual subprocess contributions to the cross-section are depicted in figure 10 . As one can see the Compton $(g Q \rightarrow \gamma Q)$ as well as the $g Q \rightarrow \gamma g Q$ and $g g \rightarrow \gamma Q \bar{Q}$ are the dominant subprocesses, demonstrating the sensitivity of this process to the gluon and charm nPDFs. Here the contribution by the annihilation subprocess proves much smaller than at RHIC. This is caused by the less pronounced difference in the light anti-quark and heavy quark PDFs at small $x$ as compared to large $x$. So that now $q \bar{q} \rightarrow \gamma Q \bar{Q}$ can no longer compete with the light quark-heavy quark (antiquark) piece of the cross-section $(q Q \rightarrow q Q \gamma, q \bar{Q} \rightarrow q \bar{Q} \gamma, \bar{q} Q \rightarrow \bar{q} Q \gamma, \bar{q} \bar{Q} \rightarrow \bar{q} \bar{Q} \gamma)$.

Figure 10. Subprocess contributions to the differential cross-section shown in figure 9 (left), NLO (solid black line), LO $+g g \rightarrow Q \bar{Q} \gamma$ (dashed blue line), $g Q \rightarrow g Q \gamma$ (dash-dotted purple line), $q \bar{q} \rightarrow Q \bar{Q} \gamma$ (dotted red line), $q Q \rightarrow q Q \gamma ; Q Q \rightarrow Q Q \gamma$ (dash-dot-dotted magenta line).

Figure 11. Left: nuclear production ratio of $\gamma+c$ cross-section at LHC within ALICE PHOS acceptances, using nCTEQ decut3 (solid black line), nCTEQ decut3g3 (dotted black line), nCTEQ decut3g9 (dash-dot-dashed black line), EPS09 (dashed blue line) + error band, HKN07 (dash-dotted red line) + error band. Right: $R_{g}^{P b}\left(x, Q=x \sqrt{S} / 2 \sim p_{T}\right)$ ratio as a function of $x$, in the $x$ region probed at the LHC. This figure corresponds to the enlargement of the box region in the right panel of figure 1 .

### 5.3 Nuclear production ratios

The nuclear production ratio $R_{p P b}^{\gamma+c}=\frac{1}{208} \frac{d \sigma / d p_{T \gamma}(p \mathrm{~Pb} \rightarrow \gamma+c+X)}{d \sigma / d p_{T \gamma}(p p \rightarrow \gamma+c+X)}$ is shown in figure 11 (left) using the nCTEQ decut3 (solid black line), nCTEQ decut3g3 (dotted black line), nCTEQ decut3g9 (dash-dot-dashed black line), EPS09 (dashed blue line), and HKN07 (dashdotted red line) nuclear PDFs. For the latter two cases the bands represent the nPDF uncertainties calculated as described in section 3. Remarkably, there is almost no overlap between the EPS09 and the HKN predictions, therefore an appropriate measurement of this process will be able to distinguish between the two nPDF sets. The nCTEQ nuclear modification, using the decut3 fit, is considerably different from the two other sets at lower values of $p_{T}$. On the other hand, for the decut3g9 set, the nuclear modification factor is close to unity in the $x$-range as shown in figure 11 (right), giving rise to the nuclear pro-
duction ratio for this nCTEQ set which lies inside the EPS09 uncertainty band, figure 11 (left). We stress again that both, decut3 and decut3g9, are perfectly acceptable fits to the $\ell A$ DIS + DY data with different assumptions on the small $x$ behavior. We further show the ratio for decut3g3, as a representative lying between the two extremes. Inspecting figure 2, it is clear that the rest of the predictions from the decut3g series would fill the gap between the decut3 curve and the decut3g9 curve. Taken together, this gives a more realistic impression of the true PDF uncertainty of the nuclear production ratio. Therefore, measurements in this region will provide useful constraints on the nuclear gluon distribution.

Some further comments are in order: (i) In this paper we have demonstrated that the ratio of the $\gamma+c$ cross-section in $p A$ over $p p$ collisions at central rapidities will be very useful to constrain the nuclear gluon distribution. At forward rapidities, even smaller $x_{2}$ values could be probed in the nuclear targets where the uncertainties are largest. At backward rapidities, large $x_{2}$ is probed, hence the cross-section in this rapidity region will be sensitive to any existent intrinsic charm contribution in the nucleus. Such a measurement could be performed with the CMS and ATLAS detectors which cover a wider range in rapidity. We postpone such a study to a future publication, since currently there are no available IC nuclear PDFs; (ii) At the LHC $\gamma+b$ events will also be produced with sufficient statistics. Experimentally this channel might be preferable due to the much better $b$-tagging efficiencies. Furthermore, uncertainties related to possible intrinsic charm contributions should be much reduced in the bottom case. However, as for $\gamma+c$ production, the nuclear production ratios follow closely the gluon ratio and, therefore, we do not show a separate figure here.

## 6 Conclusions

We have performed a detailed phenomenological study of direct photon production in association with a heavy-quark jet in $p A$ collisions at RHIC and at the LHC, at next-to-leading order in QCD. The dominant contribution to this process is given by the $g Q \rightarrow \gamma Q[+g]$ subprocess. This offers a sensitive mechanism to constrain the heavy-quark and gluon distributions in nuclei, whose precise knowledge is necessary in order to predict the rates of hard processes in heavy-ion collisions where quark-gluon plasma is expected to be formed.

We have performed the calculation of $\gamma+Q$ production spectra at RHIC and at the LHC within the acceptances of various detectors (PHENIX and ALICE-PHOS/ALICE-EMCal) and have presented the corresponding counting rates. At the LHC the $\gamma+c$ and $\gamma+b$ production rate is important, while at RHIC only $\gamma+c$ events will be copiously produced.

Our results for RHIC (see figure 7) exhibit a strong sensitivity to the nuclear gluon distribution permitting to constrain it at $x \sim 0.1-0.2$. Similarly to RHIC the ratio at the LHC (see figure 11) is very sensitive to the gluon distribution probing a smaller $x \sim 10^{-2}$, i.e. in a complementary range to RHIC . These results have been obtained in the "standard approach" of radiatively generated charm distribution. A future study will focus on the possibility to constrain the intrinsic charm contribution to the nucleus as well as the proton.

## Acknowledgments

We are much indebted to J. Faivre and C. Furget and G. Conesa for many helpful discussions on the ALICE experiment in the initial stage of the project. We are grateful to R. Granier de Cassagnac and H. Woehri for help with the experimental cuts for the CMS detector. We also would like to thank Z. Conesa del Valle for useful remarks. The work of T. Stavreva was supported by a research grant of the University of Grenoble. The work of F. Arleo and I. Schienbein was supported by a CNRS research grant "PEPS Physique Théorique aux Interfaces". This work was partially supported by the U.S. Department of Energy under contract DE-FG02-04ER41299, and the Lightner-Sams Foundation.

(Received 25 October 2010; published 22 December 2010)

#### Abstract

We report a parton distribution function analysis of a complete set of hadron scattering data, in which a color-octet fermion (such as a gluino of supersymmetry) is incorporated as an extra parton constituent along with the usual standard model constituents. The data set includes the most up-to-date results from deep inelastic scattering and from jet production in hadron collisions. Another feature is the inclusion in the fit of data from determinations of the strong coupling $\alpha_{s}(Q)$ at large and small values of the hard scale $Q$. Our motivation is to determine the extent to which the global parton distribution function analysis may provide constraints on the new fermion, as a function of its mass and $\alpha_{s}\left(M_{Z}\right)$, independent of assumptions such as the mechanism of gluino decays. Based on this analysis, we find that gluino masses as low as 30 to 50 GeV may be compatible with the current hadronic data. Gluino masses below $15 \mathrm{GeV}(25 \mathrm{GeV})$ are excluded if $\alpha_{s}\left(M_{Z}\right)$ varies freely (is equal to 0.118 ). At the outset, stronger constraints had been anticipated from jet production cross sections, but experimental systematic uncertainties, particularly in normalization, reduce the discriminating power of these data.

## I. INTRODUCTION

Heavy color-octet particles are postulated in theories of beyond-the-standard-model (BSM) phenomena, including supersymmetry (SUSY) [1], universal extra dimensions [2], Randall-Sundrum [3], and Little Higgs models [4]. Direct searches for such states are usually guided by aspects of the production and decay dynamics in the particular BSM approach. Analyses of search data have so far produced various bounds on the masses of the states, often conditioned by model-dependent assumptions [5-15]. Different constraints, such as the SUSY gluino mass bounds $m_{\tilde{g}}>$ 26.9 GeV [16] and 51 GeV [17] at $95 \%$ confidence level (C.L.), are based on the analysis of LEP event shapes in soft-collinear effective theory and other quantum chromodynamics (QCD) resummation formalisms. Constraints such as these may depend on theoretical modeling of nonperturbative hadronization and the matching of hard scattering and resummed contributions, similar to the determination of $\alpha_{s}\left(M_{Z}\right)$ from LEP data in QCD [18-22]. In a previous publication [23], we examine the possibility that a global analysis of hadron data, within the framework of parton distribution function (PDF) determinations, can be used to derive constraints on the existence and masses of color-octet fermions, independently of other information on such states. Global analysis has discriminating power for several reasons: one is that new colored states modify the evolution with hard scale $Q$ of the strong coupling strength $\alpha_{s}(Q)$. Second, in perturbative QCD , the coupling of a color-octet fermion to quarks and gluons alters the set of evolution equations that governs the behavior of all parton distribution functions, thus affecting many hadron scattering cross sections. Moreover, production of the color-octet
states will affect relevant observables, such as jet rates, whose cross sections are included in the global fits.

The specific case of a gluino from supersymmetry is included as an extra degree of freedom in our earlier work [23]. We refer to the PDFs obtained in that publication as "SUSY PDFs," although our analysis is applicable to a broader class of standard model (SM) extensions. In Ref. [23], a lower bound on the gluino mass $m_{\tilde{g}}$ is obtained in terms of an assumed value of $\alpha_{s}\left(M_{Z}\right)$ at $Z$ boson mass $M_{Z}$. For the then standard model world-average value of $\alpha_{s}\left(M_{Z}\right)=0.118$, gluinos lighter than 12 GeV were shown to be disfavored, whereas the lower bound was relaxed to less than 10 GeV (less than 2 GeV ) when $\alpha_{s}\left(M_{Z}\right)$ was increased above 0.120 ( 0.127 ).

In this paper, we use new hadron scattering data incorporated in the next-to-leading order (NLO) CT10 generalpurpose PDF analysis [24], along with a new approach for incorporating the variation of $\alpha_{s}(Q)$ into PDF determinations [25], to obtain improved bounds on the mass of a relatively light gluino. The essential new elements are these:
(i) New Tevatron jet data [26-28] and combined DIS data [29] from HERA. In a global QCD analysis, the presence of light gluinos is revealed primarily by modifications of $\alpha_{s}\left(M_{Z}\right)$, the gluon PDFs, and the charm and bottom quark PDFs, generated radiatively above the respective heavy-quark thresholds. We include the latest hadronic scattering data sensitive to such modifications. The most stringent constraints on the gluon PDF are imposed by electron-proton deep inelastic scattering (DIS) data at $x<0.1$ and single-inclusive jet production data from the Tevatron $p \bar{p}$ collider at $x \gtrsim 0.1$. The study reported
here incorporates up-to-date information from the combined H1 Collaboration and ZEUS Collaboration data on deep inelastic scattering at HERA-1 [29], as well as single-inclusive jet data from the Tevatron Run-II analyses [26-28]. Hard scattering contributions of massive gluinos, with full dependence on the gluino's mass, are included in the jet production cross sections we use, the only process we examine where these contributions are large enough to be relevant at NLO accuracy.
(ii) Floating $\alpha_{s}\left(M_{Z}\right)$. Our fits are performed by treating $\alpha_{s}\left(M_{Z}\right)$ at the mass $M_{Z}$ of the $Z$ boson as a variable parameter of the standard model. We constrain $\alpha_{s}\left(M_{Z}\right)$ by requiring that the fitted $\alpha_{s}(Q)$ agree with its direct determinations at low-energy scales $(Q<10 \mathrm{GeV})$ and at $Q=M_{Z}$, within the quoted uncertainties of these measurements. Virtual gluino contributions result in a slower evolution of the QCD coupling strength $\alpha_{s}(Q)$ at scales $Q$ above the gluino mass threshold. By including data that constrain $\alpha_{s}$ at low and high $Q$ scales, we effectively probe for deviations from pure QCD. We find, in particular, that the value of $\alpha_{s}\left(M_{Z}\right)=0.123 \pm$ 0.004 derived in some analyses of LEP event shapes [20] can be accommodated if gluinos have mass of about 50 GeV .
The remainder of this paper is organized as follows. In Sec. II, we describe the role of new color-octet fermions in a global QCD analysis. The incorporation of data on $\alpha_{s}(Q)$ within the global fits is discussed in Sec. III, where we also present the values of $\alpha_{s}(Q)$ at high and low $Q$ used in our fits. Our simultaneous global fit to hadronic scattering data and $\alpha_{s}(Q)$ is described in Sec. IV, where we also examine the effects of an additional gluino degree of freedom on the PDFs. We present figures that show the relative magnitudes of the PDFs and the variation of their momentum fractions with gluino mass and hard scale.

Section V contains the results of our detailed comparison with data. We present figures that show the variation of the values of $\chi^{2}$ in the global analyses, as a function of gluino mass, for both floating and fixed $\alpha_{s}\left(M_{Z}\right)$. Section V also includes the comparison of our calculated cross sections with jet data from the Tevatron collider and a discussion of the systematic uncertainties that limit the constraining power of these data. The sensitivity of jet cross sections at the LHC to the presence of gluinos is examined in Sec. VI. Our conclusions are presented in Sec. VII. The appendices contain an analytic expression for the evolution of the strong coupling $\alpha_{s}(Q)$ in terms of the SM and SUSY degrees of freedom, expressions for the contributions of massive gluinos to the jet production cross sections, and parton-parton luminosity functions for various combinations of SM partons and gluinos.

Based on our analysis, we conclude that gluino masses as low as 30 to 50 GeV may be compatible with the current
hadronic data, depending on the value of $\alpha_{s}\left(M_{Z}\right)$. For a floating $\alpha_{s}\left(M_{Z}\right)$, gluinos lighter than 15 GeV are excluded. For an assumed fixed value $\alpha_{s}\left(M_{Z}\right)=0.118$, the worldaverage value used in many phenomenological analyses, gluinos lighter than 25 GeV , are disfavored.

We acknowledge that a gluino as light as $\sim 50 \mathrm{GeV}$ is not typical in phenomenological models of SUSY breaking, nor of the results of experimental direct search analyses based on specific models of SUSY breaking and assumptions about mass relationships among SUSY states [15]. As long as the SUSY neutralino $\tilde{\chi}^{0}$ is lighter than the gluino, the typical decay process for a light gluino is $\tilde{g} \rightarrow$ $q \bar{q} \tilde{\chi}^{0}$, where $q$ stands for a SM quark. Missing energy would signal the presence of a neutralino. However, for a small mass splitting $m_{\tilde{g}}-m_{\tilde{\chi}^{0}}$, the gluino's decay into missing energy and soft quark jets would be undetected. The analysis reported here is complementary to other approaches for bounding the gluino mass, and it is in some respects more general in that we make no assumptions about the gluino decay.

Precise determination of $\alpha_{s}\left(M_{Z}\right)$ and proton PDFs are essential ingredients for obtaining reliable predictions from perturbative QCD calculations. Such calculations are key for the general physics program and for new physics searches at the CERN Large Hadron Collider (LHC) and Fermilab Tevatron collider. As we show here, these ingredients themselves may be affected by non-SM contributions, at all values of the momentum fraction $x$, as a result of the global interconnections in PDF analyses. The determination of the QCD coupling $\alpha_{s}$ and of the gluon PDF from the Tevatron or LHC single-inclusive jet data, such as in recent Tevatron Run-2 measurements [26-28,30], may be sensitive to scattering of color-octet fermions in the ways discussed in Sec. VI. As a result of our work, we determine new sets of PDFs that include a relatively light gluino as a hadron constituent.

## II. COLOR-OCTET FERMIONS IN A GLOBAL QCD ANALYSIS

Under well-defined conditions, a relatively light strongly-interacting fundamental particle may be treated as a constituent of the colliding hadrons. It will share the momentum of the parent hadron with the standard model quark, antiquark, and gluon partners. The experimental consequences of this picture become evident when the parent hadron is probed at a sufficiently large hard scale. For example, the charm quark $c$ and bottom quark $b$ are treated appropriately as partonic constituents of hadrons when the characteristic energy scale $Q$ exceeds the mass of the heavy quark $m_{q}$. Likewise, when $Q$ greatly exceeds the mass of a new strongly-interacting particle, this object must also be incorporated as a hadronic constituent. We refer to Ref. [23] for an exposition of the PDF analysis in which a gluino is included as an additional partonic degree of freedom.

FIG. 1. LO scattering diagrams in inclusive jet production with gluinos in the initial or final state. The double lines stand for the squark exchange contributions that we neglect in our approximation.

As in Ref. [23], we take the gluino as the only colored non-SM degree of freedom that needs to be considered. In some models of SUSY breaking, such as split supersymmetry [31,32], the squarks are much heavier than the gluinos, and therefore could be omitted from our PDF analysis. Moreover, as illustrated in Eq. (A3) of Appendix A, color-octet spin- $1 / 2$ fermions have a greater impact on the evolution of the strong coupling $\alpha_{s}$ than color triplet scalars, such as squarks. ${ }^{1}$

The presence of a light gluino $\tilde{g}$ modifies the PDF global analysis in three ways.
(1) The gluino changes the evolution of the strong coupling strength $\alpha_{s}(Q)$, as the scale $Q$ is varied. This influence is implemented in our results, and we provide details on the running of $\alpha_{s}(Q)$ in Appendix A. The constraints on the gluino mass from our global analysis depend significantly on the value of the strong coupling strength $\alpha_{s}\left(M_{Z}\right)$.
(2) The gluino provides an additional partonic degree of freedom that shares in the nucleon's momentum. It alters the coupled set of Dokshitzer-Gribov-Lipatov-Altarelli-Parisi equations that govern the evolution of the parton distributions,

$$
\begin{align*}
Q^{2} \frac{d}{d Q^{2}}\left(\begin{array}{c}
\Sigma(x, Q) \\
g(x, Q) \\
\tilde{g}(x, Q)
\end{array}\right) & =\frac{\alpha_{s}(Q)}{2 \pi} \times \int_{x}^{1} \frac{d y}{y}\left(\begin{array}{ccc}
P_{\Sigma \Sigma}^{\mathrm{NLO}}(x / y) & P_{\Sigma g}^{\mathrm{NLO}}(x / y) & P_{\Sigma \tilde{g}}^{\mathrm{LO}}(x / y) \\
P_{g \Sigma}^{\mathrm{NLO}}(x / y) & P_{g g}^{\mathrm{NL}}(x / y) & P_{g \tilde{\mathrm{~L}}}^{\mathrm{L}}(x / y) \\
P_{\tilde{g} \Sigma}^{\mathrm{LO}}(x / y) & P_{\tilde{g} g}^{\mathrm{LO}}(x / y) & P_{\tilde{g} \tilde{g}}^{\mathrm{L}}(x / y)
\end{array}\right)\left(\begin{array}{c}
\Sigma(y, Q) \\
g(y, Q) \\
\tilde{g}(y, Q)
\end{array}\right) ; \\
\Sigma(x, Q) & =\sum_{i=u, d, s, \ldots}\left(q_{i}(x, Q)+\bar{q}_{i}(x, Q)\right) . \tag{1}
\end{align*}
$$

Here $\Sigma(x, Q), g(x, Q)$, and $\tilde{g}(x, Q)$ are the singlet quark, gluon, and gluino distributions, respectively; $q_{i}(x, Q)$ and $\bar{q}_{i}(x, Q)$ are the quark and antiquark distributions for a flavor $i$. The previous analysis [23] shows that the gluino's contribution is small in the momentum fraction range $x>10^{-5}, \tilde{g}(x, Q) \ll$ $g(x, Q)$, and $\tilde{g}(x, Q) \ll q(x, Q)$. NLO variations in the relevant SUSY cross sections are small and comparable in size to variations associated with next-to-next-to-leading order (NNLO) SM contributions. Therefore, the leading-order (LO) approximation for the splitting functions and hard scattering amplitudes of SUSY terms is numerically adequate, when combined with NLO expressions for SM contributions.
(3) At energies above its mass threshold, a color-octet fermion contributes to hard scattering processes as

[^250]an incident parton and/or as a produced particle. However, as argued in Ref. [23], in the absence of light squarks, gluino hard scattering contributions to DIS and Drell-Yan process are of next-to-next-toleading order and negligible in the current study. At the same time, the hard scattering gluino terms contribute at the LO in single-inclusive jet production, so that it is essential that we include the gluino in the corresponding hard scattering matrix elements of jet cross sections.
The $2 \rightarrow 2$ hard scattering contributions with two gluinos in the initial or final states are illustrated in Fig. 1. We assume that the masses of the squarks are large enough that diagrams containing a squark propagator are negligible. The remaining SUSY diagrams can be evaluated in the the S-ACOT factorization scheme $[34,35]$, in order to simplify treatment of the gluino mass dependence. In this scheme, gluino mass terms are retained in diagrams with two final-state gluinos in the subprocesses $g g \rightarrow \tilde{g} \tilde{g}$ and $q \bar{q} \rightarrow \tilde{g} \tilde{g}$. Explicit scattering amplitudes in these
channels are documented in Eqs. (B2) and (B3) of Appendix B. Massless amplitudes are used for the remaining $2 \rightarrow 2$ hard scattering subprocesses, in which one or two gluinos are present in the initial state, and whose contributions are proportional to the gluino PDF $\tilde{g}(x, Q)$. This arrangement captures the full gluino mass dependence, while including the mass terms only in the essential scattering amplitudes.

## III. QCD COUPLING STRENGTH AS A FITTING PARAMETER

Since the range of $m_{\tilde{g}}$ values allowed by the global fits depends strongly on the assumed value of $\alpha_{s}\left(M_{Z}\right)$, we do a simultaneous fit to hadronic data and to data on $\alpha_{s}(Q)$ in this work. A judicious choice is required therefore of the set of data on $\alpha_{s}(Q)$.

Our approach is to fit the global set of data using $\alpha_{s}(Q)$ as a floating parameter, constraining it with additional data on $\alpha_{s}(Q)$ measurements at $Q<10 \mathrm{GeV}$ (i.e., in the range where gluino contributions are excluded by the previous analysis), and at $Q=M_{Z}$ (in $e^{+} e^{-}$hadroproduction at LEP). This approach is similar to the floating $\alpha_{s}\left(M_{Z}\right)$ fit in Ref. [25]. However, we constrain $\alpha_{s}(Q)$ at two distinct $Q$ values, to probe for deviations of its running from the SM prediction.

## A. Low-energy constraints

The QCD coupling constraint at low $Q=5 \mathrm{GeV}$,

$$
\begin{equation*}
\alpha_{s}(Q=5 \mathrm{GeV})=0.213 \pm 0.002 \tag{2}
\end{equation*}
$$

is obtained as a weighted average of three precise determinations of $\alpha_{s}$ at comparable energies:

$$
\begin{gather*}
\alpha_{s}(Q=5 \mathrm{GeV})=0.219 \pm 0.006 \text { from } \tau \text { decays }  \tag{3}\\
\alpha_{s}(Q=5 \mathrm{GeV})=0.214 \pm 0.003  \tag{4}\\
\text { from heavy quarkonia, } \\
\alpha_{s}(Q=5 \mathrm{GeV})=0.209 \pm 0.004 \text { from lattice } \mathrm{QCD} \tag{5}
\end{gather*}
$$

These values are reconstructed by QCD evolution to the common scale $Q=5 \mathrm{GeV}$ of the published $\alpha_{s}$ values provided at different energy scales,

$$
\begin{gather*}
\left(\alpha_{s}\right)_{\tau}=0.330 \pm 0.014 \quad \text { at } m_{\tau}=1.77 \mathrm{GeV}  \tag{6}\\
\left(\alpha_{s}\right)_{Q \bar{Q}}=0.1923 \pm 0.0024 \text { at } M_{Q \bar{Q}}=7.5 \mathrm{GeV}  \tag{7}\\
\left(\alpha_{s}\right)_{\text {lattice }}=0.1170 \pm 0.0012 \text { at } M_{Z}=91.18 \mathrm{GeV} \tag{8}
\end{gather*}
$$

The value of $\left(\alpha_{s}\right)_{\tau}$ is determined from measurements of $\tau$ decays [36], $\left(\alpha_{s}\right)_{Q \bar{Q}}$ comes from heavy-quarkonium decays [37], and $\left(\alpha_{s}\right)_{\text {lattice }}$ is obtained from lattice computations [37].

The $\tau$ decay and heavy-quarkonium determinations of $\alpha_{s}$ can be reasonably assumed to be independent of gluino effects. Even if very light gluinos $(\approx 10 \mathrm{GeV})$ were present, the value of $\alpha_{s}$ in these measurements would not be affected. The lattice QCD value $\left(\alpha_{s}\right)_{\text {lattice }}$ is also determined at $Q<10 \mathrm{GeV}$ from the energy levels of heavy quarkonia [37], and then evolved by the authors to $Q=M_{Z}$ assuming the $\mathrm{SM} \beta$ function. We reconstruct the "directly measured" lattice QCD value at $Q=5 \mathrm{GeV}$ (independent of the gluino effects) by backward SM evolution. We then combine the lattice QCD value with the other two low- $Q$ measurements, evolved to the same scale using the $\operatorname{SM} \beta$ function, to obtain a composite data input to the fit.

## B. $Z$ pole constraints

If $m_{\tilde{g}}<M_{Z}$, the value of $\alpha_{s}\left(M_{Z}\right)$ extracted from the LEP $e^{+} e^{-}$hadroproduction data could differ from the value obtained from SM fits. On the other hand, various determinations of $\alpha_{s}\left(M_{Z}\right)$ from $Z$ boson width and hadronic event shapes [18-22,38] show no obvious need for BSM contributions. Thus, if gluinos are lighter than $Z$ bosons, their contributions to the LEP observables are of the order of theoretical uncertainties from other sources. Notably related to assumptions about nonperturbative hadronization in LEP observables, these uncertainties remain substantial and produce central values of $\alpha_{s}\left(M_{Z}\right)$ ranging from 0.1135 [21,22] to 0.1224 [20]. To deal with this issue of choice, one solution is to include available values of $\alpha_{s}\left(M_{Z}\right)$ derived from the $Z$ width and/or event shape measurements, assuming that gluino contributions for these measurements are comparable with the current experimental plus theoretical uncertainties.

FIG. 2 (color online). Running of the strong coupling as a function of the scale $Q$. The red solid line represents the SM evolution, while the dashed lines are plotted for $m_{\tilde{g}}=50,25,10$, 5 GeV . The points with the error bands represent the low- $Q$ and high- $Q$ constraints, given in Eqs. (2) and (9), respectively.

Absent a gluino lighter than the $Z$ boson (i.e., if only SM particles contribute at $Q<M_{Z}$ ), NLO evolution of the composite low- $Q$ value in Eq. (2) to the $Z$ pole results in $\alpha_{s}\left(M_{Z}\right)$ close to 0.118 . Global analysis of hadronic scattering alone also leads to a preferred value $\alpha_{s}\left(M_{Z}\right)=$ $0.118 \pm 0.005$ at $90 \%$ C.L., cf. recent CTEQ fits [25].

If the gluino is lighter than $M_{Z}$, the resulting evolved value at $Q=M_{Z}$ is higher. For example, the evolved $\alpha_{s}\left(M_{Z}\right)$ is 0.126 or 0.121 , if $m_{\tilde{g}}$ is 20 or 50 GeV . This variation is illustrated in Fig. 2, showing the dependence of $\alpha_{s}(Q)$ on the scale $Q$ in the absence of light gluinos (solid line) and with gluinos of mass $m_{\tilde{g}}=50,25,10$, and 5 GeV . In the figure, we show the low- $Q$ constraint (the left data point), as well as one of available constraints at the $Z$ pole, $\alpha_{s}\left(M_{Z}\right)=0.123 \pm 0.004$ [20]. As seen in the figure, a light gluino with a mass of $m_{\tilde{g}}=10 \mathrm{GeV}$ cannot simultaneously accommodate the low- $Q$ and high- $Q$ constraints. On the other hand, gluinos with mass about 50 GeV are compatible with both constraints, and are even preferred if the high- $Q$ constraint on $\alpha_{s}$ is larger than 0.118 .

To illustrate typical possibilities, we therefore present two kinds of fits in this paper: one in which a fixed value of $\alpha_{s}\left(M_{Z}\right)=0.118$ is assumed, and the other in which $\alpha_{s}\left(M_{Z}\right)$ varies and is constrained by an assumed high- $Q$ data point,

$$
\begin{equation*}
\alpha_{s}\left(M_{Z}\right)=0.123 \pm 0.004 \tag{9}
\end{equation*}
$$

compatible with [20].

## C. Log-likelihood function for coupling strength constraints

With the additional constraints on the running coupling, the total log-likelihood function $\chi_{\text {tot }}^{2}$ is

$$
\begin{equation*}
\chi_{\mathrm{tot}}^{2}=\chi_{\text {h.s. }}^{2}+\chi_{\alpha_{s}}^{2}, \tag{10}
\end{equation*}
$$

where $\chi_{\text {h.s. }}^{2}$ is the $\chi^{2}$ contribution of the hadron scattering (h.s.) experiments, i.e., DIS, vector boson production, and jet production; $\chi_{\alpha_{s}}^{2}$ is the contribution from the direct constraints on $\alpha_{s}$ :

$$
\begin{equation*}
\chi_{\alpha_{s}}^{2}=\lambda \sum_{i=1}^{N_{\alpha_{s}}}\left(\frac{\left.\alpha_{s}^{(i)}\right|_{\exp }-\left.\alpha_{s}^{(i)}\right|_{\mathrm{th}}}{\left.\delta \alpha_{s}^{(i)}\right|_{\exp }}\right)^{2} \tag{11}
\end{equation*}
$$

In this equation, $N_{\alpha_{s}}$ is the number of data points constraining $\alpha_{s} ; N_{\alpha_{s}}=2$ in our case. $\left.\alpha_{s}^{(i)}\right|_{\text {exp }}$ and $\left.\delta \alpha_{s}^{(i)}\right|_{\text {exp }}$ are the central value and error of the experimental measurements in Eqs. (2) and (9); $\left.\alpha_{s}^{(i)}\right|_{\text {th }}$ are the respective two-loop theoretical values. We assume that an increase in $\chi^{2}$ by 100 units above the best-fit value corresponds to approximately $90 \%$ C.L. error, in accordance with the convention of the previous CTEQ6 analysis [39] and 2004 gluino study [23]. To match this convention, the $\alpha_{s}$ contribution $\chi_{\alpha_{s}}^{2}$ is included with a factor $\lambda=37.7$, so that a deviation of $\left.\alpha_{s}^{(i)}\right|_{\text {th }}$ by $\left.1.6 \delta \alpha_{s}^{(i)}\right|_{\exp }$ ( $90 \%$ C.L.) corresponds to $\Delta \chi_{\alpha_{s}}^{2} \approx 100$.

## IV. GLOBAL FITS

In this section we describe our simultaneous global fit to hadronic scattering data and $\alpha_{s}(Q)$, and we examine the effects of an additional gluino degree of freedom on the PDFs.

Our SUSY fits include the same set of data as the latest CT10 fit of parton distributions [24]. A total of 2753 data points from 35 experiments is included. Besides the data studied in the previous CTEQ6.6 analysis [40], the new analysis includes the combined DIS data from HERA-1 [29] and single-inclusive jet data from the Tevatron Run-2 analyses [26-28]. The new data provide important constraints on the gluon PDF, the parton density that is most affected by the gluinos. The charm and bottom PDFs are also affected, since they are generated by DGLAP evolution from the gluon PDF above the initial scale $Q_{0}=m_{c}=$ 1.3 GeV .

The ratios of the best-fit gluon and charm PDFs in the SUSY sets to their counterparts in the standard model CT10 set, $f_{\text {SUSY }}(x, Q) / f_{\text {CT10 }}(x, Q)$, are shown as dashed curves in Figs. 3 and 4, at $Q=2$ and 85 GeV , for two values of the gluino mass, $m_{\tilde{g}}=20$ and 50 GeV . The normalized CT10 uncertainty bands are shown also, defined as

$$
\begin{equation*}
\frac{f_{\mathrm{CT} 10}(x, Q) \pm \delta_{ \pm} f_{\mathrm{CT} 10}(x, Q)}{f_{\mathrm{CT} 10}(x, Q)} \tag{12}
\end{equation*}
$$

in terms of asymmetric PDF uncertainties $\delta_{ \pm} f_{\mathrm{CT} 10}(x, Q)$ [24,41]. Figure 3 pertains to fits with a floating $\alpha_{s}\left(M_{Z}\right)$, whereas Fig. 4 is based on a fixed $\alpha_{s}\left(M_{Z}\right)=0.118$.

If $\alpha_{s}\left(M_{Z}\right)$ varies (Fig. 3), modifications in the gluon distribution are moderate at most. Some differences with the CT10 predictions are observed at large $x$, notably in the range $x>0.01$ in $g(x, Q)$ at $Q=85 \mathrm{GeV}$ and in $c(x, Q)$ at $Q=2 \mathrm{GeV}$. The difference is larger for a lighter gluino with $m_{\tilde{g}}=20 \mathrm{GeV}$. Other PDFs exhibit smaller differences, all contained in the standard model uncertainty band.

For a fixed $\alpha_{s}\left(M_{Z}\right)=0.118$ (Fig. 4), the differences with CT10 are substantial. At $Q=2 \mathrm{GeV}$, the SUSY PDFs lie outside of CT10 error bands for $x$ as low as $10^{-3}$. At $Q=85 \mathrm{GeV}$, the difference persists at $x>$ $0.01-0.05$. Large differences between the SUSY and CT10 PDF's in the case of a fixed strong coupling are attributed to sizable deviations from SM running of $\alpha_{s}$ and compensating adjustments in $g(x, Q)$ observed for relatively light gluinos; cf. Figs. 12b and 5 in Ref. [23].

The effect of the gluino on the standard model quark and gluon PDFs can be significant, even if $m_{\tilde{g}}$ is large compared to $m_{c}$ and $m_{b} .{ }^{2}$ Because the gluino is an active

[^251]

FIG. 3 (color online). Ratios of $g(x, Q)$ (upper row) and $c(x, Q)$ (lower row) distributions in SUSY fits with floating $\alpha_{s}\left(M_{Z}\right)$ and the CT10 fit at $Q=2 \mathrm{GeV}$ (left) and $Q=85 \mathrm{GeV}$ (right), for the gluino mass $m_{\tilde{g}}$ of 20 and 50 GeV .
constituent of the proton, it carries a finite momentum fraction, taken from the other non-SUSY partons, primarily the gluon. This feature is evident in Table I where we display the partonic momentum fractions for gluino masses $m_{\tilde{g}}=\{20,50,100\} \mathrm{GeV}$.

Gluinos draw most of their momentum fraction from the gluon, since the primary coupling is via the process $g \rightarrow$ $\tilde{g} \tilde{g}$. The influence on the quarks is a second-order effect transmitted through the gluon. At $Q=100 \mathrm{GeV}$, the momentum fraction of the lighter gluinos $\left(m_{\tilde{g}} \sim 20 \mathrm{GeV}\right)$ is comparable to that of the strange quark, even though the gluino mass is an order of magnitude larger. For $m_{\tilde{g}} \sim$ 50 GeV , the momentum fraction of the gluino is comparable to that of the bottom quark. The magnified impact of the gluino on the QCD evolution, compared to the usual quark flavors, can be understood from a comparison of the $g \rightarrow \tilde{g}$ splitting kernel,

$$
\begin{equation*}
P_{g \rightarrow \tilde{g}}(x)=3\left[(1-x)^{2}+x^{2}\right] \tag{13}
\end{equation*}
$$

with the usual gluon-quark splitting function

$$
\begin{equation*}
P_{g \rightarrow q}(x)=\frac{1}{2}\left[(1-x)^{2}+x^{2}\right] . \tag{14}
\end{equation*}
$$

The effect of the gluino as a hadronic constituent in the QCD evolution is thus equivalent to that of 6 quark flavors, $P_{g \rightarrow \tilde{g}}=6 P_{g \rightarrow q}$.

As an illustration of the relative magnitude of the gluino PDF, Fig. 5 displays PDFs for various parton flavors as a function of $x$ for our $m_{\tilde{g}}=50 \mathrm{GeV}$ PDF set and a hard scale of $Q=100 \mathrm{GeV}$. At $x>0.001$, the gluino PDF is about equal to the bottom quark PDF, the smallest of the quark PDFs. For smaller $x$, it grows in magnitude and catches up with the other quark PDFs at $x=10^{-5}$, as a consequence of its faster DGLAP evolution. Parton-parton luminosities dependent on the gluino PDF, useful for computations of cross sections, are plotted in Appendix C.

## V. COMPARISON OF THEORY AND DATA

In this section, we show the results of our global fits, the constraints we obtain on the mass of a gluino, and the impact of a gluino degree of freedom on the analysis of jet data.

FIG. 4 (color online). Same as Fig. 3, but for a fixed $\alpha_{s}\left(M_{Z}\right)=0.118$.

The figures in the previous section show that the SM +SUSY PDFs disagree with CT10 PDFs if gluinos are lighter than 20 GeV , indicating that the SM+SUSY PDFs for these gluino masses cannot describe the global hadronic data well. Gluinos with somewhat larger masses can be accommodated, or may be slightly preferred to the pure SM case, depending on the value of $\alpha_{s}\left(M_{Z}\right)$. These points are illustrated in a different way by the summary of values of $\chi^{2}$ in Table II, for $m_{\tilde{g}}=10,20$, and 50 GeV , as well as for the standard model case (equivalent to $m_{\tilde{g}}=\infty$ ). The

TABLE I. Momentum fraction $F_{i}=\int_{0}^{1} d x x f_{i}(x, Q)$ for each partonic flavor $i$ at scale $Q=100 \mathrm{GeV}$. Momentum fractions for $\{\bar{s}, \bar{c}, \bar{b}\}$ are not shown and must be included to satisfy the sum rule.

| Momentum fractions for $Q=100 \mathrm{GeV}$ in percent |  |  |  |  |  |  |  |  |  |

table shows the log-likelihood values $\chi_{\text {h.s. }}^{2}$ and $\chi_{\text {tot }}^{2}$, without and with the imposition of $\alpha_{s}$ constraints, as defined in Eqs. (10) and (11); as well as $\chi^{2}$ per number of data points for HERA-1 DIS [29] and Tevatron Run-1 and Run-2 single-inclusive jet cross sections [26-28,42,43]. In the fit with a floating $\alpha_{s}$, the best-fit $\alpha_{s}\left(M_{Z}\right)$ is also shown. A comparison of the upper and lower halves of the table shows that the relation between $\chi^{2}$ and $m_{\tilde{g}}$ depends on whether $\alpha_{s}\left(M_{Z}\right)$ is fixed or floating.

Fixed $\alpha_{s}\left(M_{Z}\right)$. In a fit with a fixed $\alpha_{s}\left(M_{Z}\right)$, only constraints from the hadronic data, associated with the term $\chi_{\text {h.s. }}^{2}$ (and not with the total $\chi_{\text {tot }}^{2}$ ) play a meaningful role. The upper half of Table II shows $\chi^{2}$ values from a fit with fixed $\alpha_{s}\left(M_{Z}\right)=0.118$. $^{3}$ In this case, the gluino's effect of slowing the evolution of $\alpha_{s}(Q)$ from $Q=M_{Z}$ to $Q=5 \mathrm{GeV}$ runs into strong disagreement with the low- $Q$

[^252]

FIG. 5 (color online). PDFs for various flavors at $Q=$ 100 GeV , for $m_{\tilde{g}}=50 \mathrm{GeV}$.
constraint; $\chi_{\text {tot }}^{2}$ grows quickly as $m_{\tilde{g}}$ decreases, corresponding to a difference of many standard deviations between the measured and predicted $\alpha_{s}$ values at $Q=5 \mathrm{GeV}$. More importantly, the hadronic data by themselves disfavor very light gluinos, with $m_{\tilde{g}}=25 \mathrm{GeV}$ or less excluded according to the criterion $\Delta \chi^{2} \equiv \chi_{\text {SUSY }}^{2}\left(m_{\tilde{g}}\right)-\chi_{\text {CT10 }}^{2}<100$ applied to $\chi_{\text {h.s. }}^{2}$.

Floating $\alpha_{s}\left(M_{Z}\right)$. The values in the lower half of Table II are for SM+SUSY fits with a variable $\alpha_{s}\left(M_{Z}\right)$. In this case, the constraints from both the hadronic scattering and direct measurements of $\alpha_{s}\left(M_{Z}\right)$ are relevant. The most meaningful log-likelihood term is $\chi_{\text {tot }}^{2}=\chi_{\text {h.s. }}^{2}+\chi_{\alpha_{s}}^{2}$. If $\alpha_{s}\left(M_{Z}\right)$ varies, the hadronic scattering data on their own, including the HERA-1 and Tevatron jet data sets, are compatible with practically any gluino mass. The contribution to $\chi^{2}$ from the hadron scattering experiments, $\chi_{\text {h.s. }}^{2}$, stays approximately the same as in the SM case, or improves slightly, as gluinos with masses of 10,20 , and 50 GeV are introduced.

This agreement with the hadronic scattering data, hardly affected by the gluino mass, results from compensation between modifications in the shape of the gluon PDF and an increase in the preferred $\alpha_{s}\left(M_{Z}\right)$, which grows from 0.118 in the SM case to 0.132 for $m_{\tilde{g}}=10 \mathrm{GeV}$. In contrast, the total likelihood function for the fit to the hadronic scattering data and $\alpha_{s}$ values, introduced as $\chi_{\text {tot }}^{2}$ in Eq. (10), varies considerably as a function of the gluino mass. Our assumed high- $Q$ constraint of $\alpha_{s}\left(M_{Z}\right)=0.123 \pm 0.004$ is slightly higher than $\alpha_{s}\left(M_{Z}\right)=0.118$ obtained by the SM evolution from $\alpha_{s}(Q=5 \mathrm{GeV})=0.213 \pm 0.002$ in Eq. (2). This enhanced value of $\alpha_{s}\left(M_{Z}\right)$ would favor a slower QCD evolution above the gluino mass threshold at about 50 GeV , cf. Figure 2. Consequently, $\chi_{\text {tot }}^{2}$ is smaller at $m_{\tilde{g}}=50 \mathrm{GeV}$ than in the SM case, with the difference dependent on the choice of the high- $Q$ value of $\alpha_{s}\left(M_{Z}\right)$. Specifically, we observe that $\chi_{\text {SUSY }}^{2}\left(m_{\tilde{g}}\right)-\chi_{\mathrm{CT} 10}^{2}$ can be as small as -50 , if we take $\alpha_{s}\left(M_{Z}\right)=0.123 \pm 0.004$, but this difference decreases if a smaller $\alpha_{s}\left(M_{Z}\right)$ is used for the high $-Q$ constraint. For lower gluino masses of 10 or $20 \mathrm{GeV}, \alpha_{s}\left(M_{Z}\right)$ increases and eventually is incompatible with the direct constraints.

## A. $\Delta \boldsymbol{\chi}^{\mathbf{2}}$ as a function of gluino mass

The behavior of $\Delta \chi^{2}$ in the whole range of gluino masses is illustrated by Fig. 6 for a fixed $\alpha_{s}\left(M_{Z}\right)=$ 0.118 , and by Fig. 7 for a floating $\alpha_{s}\left(M_{Z}\right)$. The quantitative likelihood of a given mass $m_{\tilde{g}}$ is specified by $\Delta \chi^{2}=$ $\chi^{2}\left(m_{\tilde{g}}\right)-\chi_{\mathrm{CT} 10}^{2}$, the difference from the $\chi^{2}$ value obtained in the CT10 SM fit. Values of $\Delta \chi^{2}$ in excess of 100 units disfavor an assumed $m_{\tilde{g}}$ at about $90 \%$ C.L. (Refs. [23,39]), while a negative $\Delta \chi^{2}$ indicates a preference for this $m_{\tilde{g}}$. Variations in $\Delta \chi^{2}$ with a magnitude below 100 units can result from a variety of sources and are generally viewed as not significant enough to warrant strong conclusions.

In Fig. 6, two curves are shown for $\Delta \chi_{\text {h.s. }}^{2}$, the difference between the log-likelihoods in the fits performed in the

FIG. 6 (color online). Values of $\Delta \chi_{\text {h.s. }}^{2}$ vs $m_{\tilde{g}}$ are shown for a fixed value of $\alpha_{s}\left(M_{Z}\right)=0.118$ for the 2004 study (blue dashed line) and our new one (red solid line).

SM+SUSY and SM scenarios for $\alpha_{s}\left(M_{Z}\right)=0.118$. Here $\Delta \chi_{\mathrm{h} . \mathrm{s} .}^{2}$ is computed from the hadronic scattering contribution only, $\chi_{\text {h.s. }}^{2}$. The blue (dashed) curve represents the 2004 analysis [23]. The red (solid) curve is obtained in the present study, resulting in a tighter lower bound on $m_{\tilde{g}}$. The left branch of the 2010 curve intercepts the $\Delta \chi_{\text {h.s. }}^{2}=$ 100 line at $m_{\tilde{g}} \approx 25 \mathrm{GeV}$. The 2004 curve allows for 15 GeV gluinos and has a broader valley with respect to the 2010 one. This figure shows the improvements in the constraints from the present study, reflecting the inclusion of the latest precise data and technical advances in the the CTEQ analysis since the 2004 publication, including treatment of correlated systematic uncertainties and normalization uncertainties.

Figure 7 illustrates the fits with a variable $\alpha_{s}\left(M_{Z}\right)$. Two curves are shown for $\Delta \chi_{\mathrm{tot}}^{2}$, the difference between the loglikelihoods in the fits performed in the SM+SUSY and SM

FIG. 7 (color online). Values of $\Delta \chi_{\text {tot }}^{2}$ vs $m_{\tilde{g}}$ are shown for varying values of $\alpha_{s}\left(M_{Z}\right)$ for the 2004 study (blue dashed) and our new one (red solid).
scenarios in 2004 (blue dashed line) and 2010 (red solid line). Best-fit values of $\alpha_{s}\left(M_{Z}\right)$ for some gluino masses are indicated by numerical labels near each curve. In this figure, $\Delta \chi_{\mathrm{tot}}^{2}$ is computed from the total function $\chi_{\mathrm{tot}}^{2}$. It includes the direct constraints on $\alpha_{s}(Q)$ in the current study and does not include the $\alpha_{s}$ constraint in the 2004 fit.

The figure emphasizes our earlier observation that the direct $\alpha_{s}$ constraints improve the constraining power of the global analysis. At $m_{\tilde{g}} \rightarrow \infty$, the fit converges to the pure QCD value and $\alpha_{s}\left(M_{Z}\right) \approx 0.119$. According to the $\Delta \chi^{2} \leq$ 100 test, gluinos lighter than 15 GeV are disfavored for all $\alpha_{s}\left(M_{Z}\right)$. Gluinos in the mass range 15 to 50 GeV are allowed if $\alpha_{s}\left(M_{Z}\right)$ takes a value in the range 0.121 to 0.131 . Gluinos heavier than 50 GeV are allowed for practically any $\alpha_{s}\left(M_{Z}\right)$ value. By contrast, the 2004 curve exhibits only a shallow minimum around 5 to 6 GeV , and it is relatively flat as compared to the 2010 curve. The 2004 curve does not establish pronounced lower bounds on $m_{\tilde{g}}$, for a free $\alpha_{s}\left(M_{Z}\right)$.

The 2010 curve in Fig. 7 exhibits an intriguing minimum for a gluino of about 50 GeV , corresponding to $\alpha_{s}\left(M_{Z}\right)$ of 0.121 . Other that noting it, we choose not to base conclusions on this minimum for two reasons. First, from the point of view of the fit itself, given its initial inputs, we adhere to statement that only values of $\left|\Delta \chi^{2}\right|$ in excess of 100 units are considered significant. Second, the depth of this minimum is a reflection of the value of the input constraint $\alpha_{s}\left(M_{Z}\right)=0.123 \pm 0.004$. The dip grows deeper (becomes more shallow) if a larger (smaller) value of the direct constraint is taken at $M_{Z}$. For example, gluinos with mass 50 GeV would be disfavored if the direct constraint $\alpha_{s}\left(M_{Z}\right)<0.118$ were taken, compatible with some existing analyses of LEP data in pure QCD [21,22]. Stronger conclusions on $m_{\tilde{g}}$ await an independent reduction in the uncertainties on $\alpha_{s}\left(M_{Z}\right)$.

## B. Comparison with Tevatron jet cross sections

Table II indicates that the hadronic scattering data, including the combined HERA-1 and Tevatron jet cross sections, may still allow contributions from fairly light gluinos. This observation is somewhat counterintuitive with regard to the precise Tevatron jet cross sections, which could be expected to be sensitive to non-SM contributions in the strong interaction sector. SUSY degrees of freedom introduce new subprocesses in the jet cross sections, such as $g g \rightarrow \tilde{g} \tilde{g}$ and $q \bar{q} \rightarrow \tilde{g} \tilde{g}$. The change in $\alpha_{s}(Q)$ and the alteration of the gluon and quark PDFs also influence the jet rate. However, jet cross section measurements are affected by systematic effects that dominate over statistical uncertainties, notably by the uncertainty on jet energy scale and jet energy resolution. Correlated systematic shifts in the Tevatron jet data must be taken into account when comparisons are made to theory predictions [44]. In our study, systematic uncertainties in the jet data limit the strength of our conclusions.

These observations are illustrated by plots of the CDF Run-2 and D0 Run-2 data vs theory in Figs. 8 and 9. Our results are computed with a floating $\alpha_{s}$. As reference values, we use SM cross sections computed with the CT10 PDFs. Differences from the SM cross section are presented as

$$
\begin{equation*}
\left(\sigma_{i}-\sigma_{\mathrm{CT} 10}\right) / \sigma_{\mathrm{CT} 10} \tag{15}
\end{equation*}
$$

where $\sigma_{i}$ are the SM+SUSY cross sections computed for gluino masses of 10,20 , and 50 GeV . The values of the jet transverse momentum $p_{T}$ are displayed along the horizontal axis. Two bins in the rapidity variable $y$ are shown for each experiment; the behavior in the rest of the bins is similar.

The lower (red) error bars represent the unshifted data. The upper (blue) error bars show the data that are shifted by their systematic uncertainty so as to maximize the agreement with theory for $m_{\tilde{g}}=10 \mathrm{GeV}$. Without the correlated shifts, the data would disfavor the light gluinos with a mass of 10 GeV . The perspective changes significantly if systematic shifts are allowed: the line representing

CDF Run-2 jet production, $\sqrt{ } \mathrm{s}=1.96 \mathrm{TeV}$

FIG. 8 (color online). Comparison of theoretical predictions for single-inclusive jet cross sections with data from CDF Run-2 for two bins in jet rapidity $y$.

FIG. 9 (color online). Same as Fig. 8, for two bins in jet rapidity $y$ in the D0 Run- 2 jet cross section measurement.
$m_{\tilde{g}}=10 \mathrm{GeV}$ now lies completely inside the error bars. Similarly, if $m_{\tilde{g}}$ is equal to 20 or 50 GeV , the effective shifts of the data change to achieve acceptable agreement with the theory curve for this mass. ${ }^{4}$

The systematic uncertainties make it difficult to disfavor the light gluinos solely on the basis of the Tevatron Run-2 jet data. The figures show that the gluino contributions affect the whole $p_{T}$ range, as a result of the momentum sum rule and other connections between the PDFs of different flavors and at different $(x, Q)$ values. Modifications in the jet cross sections due to "new physics" associated with the gluinos cannot be isolated to a specific $p_{T}$ interval, contrary to the assumptions made in some experimental studies of jet cross sections [30].

## VI. CROSS SECTIONS AT THE LHC

The possible existence of color-octet fermions with masses in the range 30 to 100 GeV , allowed by hadronic

[^253]data according to our analysis, raises the prospects for their detection in the extended range of transverse momenta at the LHC. As explained in early sections of this paper, these new fermions modify QCD inputs, primarily the QCD coupling $\alpha_{s}\left(M_{Z}\right)$ and the gluon and sea-quark PDFs. Precise studies of cross sections at LHC energies thus have the potential to reveal differences from pure SM QCD, such as the presence of color-octet fermions, provided the LHC measurements are supplemented by a robust program to reduce uncertainties in $\alpha_{s}, \mathrm{PDFs}$, and other SM parameters, which may otherwise reduce sensitivity of the LHC observables to the gluino contributions.

LHC 7 TeV . Fit with a fixed $\alpha_{s}\left(\mathrm{M}_{\mathrm{Z}}\right)=0.118$

LHC 7 TeV . Fit with a fixed $\alpha_{s}\left(\mathrm{M}_{\mathrm{Z}}\right)=0.118$

FIG. 10 (color online). Ratios of single-inclusive jet cross sections at $\sqrt{s}=7 \mathrm{TeV}$, obtained from the central PDF set of CT10, CT10.00, and the SM+SUSY PDFs for gluino masses $m_{\tilde{g}}=20 \mathrm{GeV}$ (dashed line) and 50 GeV (dot-dashed line). The asymmetric PDF uncertainty of the CT10 set is also shown as a filled band. The SM+SUSY PDFs are obtained under the assumption of $\alpha_{s}\left(M_{Z}\right)=0.118$ for both sets.

Compare, for example, single-inclusive jet cross sections at the LHC energies $\sqrt{s}=7$ and $\sqrt{s}=14 \mathrm{TeV}$, computed at NLO with the Ellis-Kunszt-Soper code named EKS $[45,46]$ in the pure SM case and in the presence of light gluinos. The CT10 asymmetric PDF error bands on the cross sections, normalized to the predictions based on the central CT10.00 PDF set, are also shown in Figs. 10-13 as a function of the jet's transverse momentum $p_{T}$, in several bins of the jet rapidity $y$. Ratios of the expectations based on the SM+SUSY PDFs for $m_{\tilde{g}}=20$ and 50 GeV to their counterparts based on the CT10.00 set are shown as the dashed and dot-dashed lines, respectively.

In Figs. 10 and 11, these ratios are computed with $\alpha_{s}\left(M_{Z}\right)=0.118$ assumed in all PDFs and cross sections. In this case, the SM+SUSY curves lie outside the respective CT10 PDF uncertainty bands for some $p_{T}$, suggesting that the SM and SM+SUSY scenarios can be distinguished, if sufficient experimental accuracy is achieved. On the other

LHC 14 TeV . Fit with a fixed $\alpha_{\mathrm{s}}\left(\mathrm{M}_{\mathrm{Z}}\right)=0.118$

FIG. 11 (color online). Same as Fig. 10 , for $\sqrt{s}=14 \mathrm{TeV}$.
hand, if $\alpha_{s}\left(M_{Z}\right)$ takes the values of 0.126 and 0.121 that are preferred in the SM+SUSY fits with $m_{\tilde{g}}=20$ and 50 GeV , respectively, then the $\mathrm{SM}+\mathrm{SUSY}$ curves lie within the CT10 PDF error bands, as shown in Figs. 12 and 13. In this case, discrimination of the SM and the SM+SUSY cases is more challenging, as reduction of the experimental uncertainty below the current PDF uncertainty would be necessary.

For the inclusive jet cross sections to provide a good discrimination between the SM and SM+SUSY scenarios, the uncertainties on both $\alpha_{s}$ and PDFs must be reduced below the current values. NNLO contributions to SM processes and NLO gluino contributions must also be implemented in both the PDFs and jet cross sections.

A different approach to detecting the presence of new colored states could be based on the expectation that QCD

FIG. 12 (color online). Same as Fig. 10, but with $\alpha_{s}\left(M_{Z}\right)=$ 0.126 in the SM+SUSY calculation with $m_{\tilde{g}}=20 \mathrm{GeV}$, and $\alpha_{s}\left(M_{Z}\right)=0.121$ in the SM+SUSY calculation with $m_{\tilde{g}}=$ 50 GeV .

LHC 14 TeV . Fit with a floating $\alpha_{\mathrm{s}}\left(\mathrm{M}_{\mathrm{Z}}\right)$

FIG. 13 (color online). Same as Fig. 12, for $\sqrt{s}=14 \mathrm{TeV}$.
radiation off a heavy colored object differs from that from massless partons that dominate the inclusive cross sections. It may be possible to identify jets containing gluinos by studying distributions in the jet mass or other jet shapes. The distribution in the jet mass produced by conventional QCD radiation decreases smoothly as the jet mass increases. Decays of gluinos would result in jets whose mass distributions peak at $m_{\tilde{g}}$, and gluino jet contributions could be identifiable above the continuous SM background in the distributions in the jet mass or related observables, using methods being developed [47-50].

## VII. SUMMARY AND DISCUSSION

In this paper, we explore modifications in QCD scattering cross sections introduced by color-octet Majorana fermions in supersymmetry (gluinos) and other popular
extensions of the standard model. Their influence must be included in the evolution of the strong coupling strength and the parton distribution functions, especially if these fermions have mass below 100 GeV (possible in the absence of model-specific assumptions). In addition to modifying the evolution of $\alpha_{s}(Q)$ and the PDFs of the SM quarks and gluons, a relatively light gluino also introduces new production channels such as $g g \rightarrow \tilde{g} \tilde{g}$ in the inclusive jet production case. In this context, hadronic scattering data included in global PDF analyses can provide modelindependent constraints on the color-octet particles.

We examine the values of $\chi^{2}$ obtained from our global fits as a function of the gluino mass $m_{\tilde{g}}$. By analyzing a combination of the latest HERA and Tevatron data on hadronic scattering, and world measurements of the QCD coupling at $Q<10 \mathrm{GeV}$ and $Q=M_{Z}$, we conclude that gluinos must be heavier than 25 GeV at $90 \%$ C.L., if $\alpha_{s}\left(M_{Z}\right)=0.118$, and heavier than 15 GeV if $\alpha_{s}\left(M_{Z}\right)$ is arbitrary. These constraints supersede the 2004 study based on the CTEQ6 data set, in which we found a lower limit on the gluino mass of $m_{\tilde{g}}>12 \mathrm{GeV}$ for $\alpha_{s}\left(M_{Z}\right)=0.118$, and no limit if $\alpha_{s}\left(M_{Z}\right)$ is arbitrary [23]. These new bounds are comparable to the gluino mass bounds $m_{\tilde{g}}>26.9$ and 51 GeV obtained from the analysis of event shapes in $e^{+} e^{-}$hadroproduction at LEP $[16,17]$. Our constraints on $m_{\tilde{g}}$ are obtained from the analysis of inclusive QCD observables and are not affected by theoretical uncertainties of the kind that arise in the determination of $\alpha_{s}\left(M_{Z}\right)$ from the LEP data [18-22] and LEP event shapes.

The changes in $\alpha_{s}\left(M_{Z}\right)$ and in the PDFs of standard model partons must be taken into consideration when QCD tests are made with LHC data. The high energy of the LHC and the extended range in jet transverse momentum offers hope that BSM deviations from pure QCD will show up in inclusive jet cross sections. As discussed in our comparisons with Tevatron jet data, it will be critical to control experimental uncertainties on the jet energy scale and jet energy resolution. Gluino contributions and adjustments in the SM parameters tend to offset one another. The power of precise measurements of the LHC single-inclusive jet cross sections will be enhanced provided that $\alpha_{s}\left(M_{Z}\right)$ and the PDFs for gluons and quarks are constrained more tightly than now by measurements in other channels.

For the purpose of studying jet properties in detail, we provide routines to interface with the SM+gluino PDFs. These are linked from the CTEQ webpage at cteq.org. We also note that the MADGRAPH/MADEVENT programs [51] provide a mechanism to incorporate SUSY PDFs in the initial state; information for using this interface is also provided on the webpage.

## ACKNOWLEDGMENTS

We thank Tom Rizzo for discussions regarding searches for new physics and bounds on gluino masses, and Mike Whalley and Andy Buckley for extending the LHAPDF
library $[55,56]$ to incorporate PDFs with light gluinos. The authors also thank CTEQ members for helpful discussions. E. L. ## APPENDIX A: MODIFICATION OF THE STRONG COUPLING

The running of $\alpha_{s}(Q)$ must be matched to the individual PDF set with the appropriate mass thresholds. The expansion of the evolution equation for $\alpha_{s}(Q)$,

$$
\begin{align*}
Q \frac{\partial}{\partial Q} \alpha_{s}(Q) & =-\frac{\alpha_{s}^{2}}{2 \pi} \sum_{n=0}^{\infty} \beta_{n}\left(\frac{\alpha_{s}}{4 \pi}\right)^{n} \\
& =-\left[\beta_{0} \frac{\alpha_{s}^{2}}{2 \pi}+\beta_{1} \frac{\alpha_{s}^{3}}{2^{3} \pi^{2}}+\ldots\right] \tag{A1}
\end{align*}
$$

can be solved perturbatively. It takes the form [52]

$$
\begin{align*}
\alpha_{s}(Q)= & \frac{4 \pi}{\beta_{0} \ln \left(\frac{Q^{2}}{\Lambda^{2}}\right)}\left[1-\frac{\beta_{1}}{\beta_{0}^{2}} \frac{\ln \left[\ln \left(Q^{2} / \Lambda^{2}\right)\right]}{\ln \left(Q^{2} / \Lambda^{2}\right)}\right. \\
& \left.+\frac{\beta_{1}^{2}}{\beta_{0}^{4} \ln ^{2}\left(Q^{2} / \Lambda^{2}\right)}+\cdots\right] . \tag{A2}
\end{align*}
$$

The beta functions, $\beta_{0}$ and $\beta_{1}$ depend on the number of active fermions and bosons. When supersymmetric particles are included [53], the first two coefficients in Eq. (A2) are

$$
\beta_{0}=11-\frac{2}{3} n_{f}-2 n_{\tilde{g}}-\frac{1}{6} n_{\tilde{f}},
$$

and

$$
\begin{equation*}
\beta_{1}=102-\frac{38}{3} n_{f}-48 n_{\tilde{g}}-\frac{11}{3} n_{\tilde{f}}+\frac{13}{3} n_{\tilde{g}} n_{\tilde{f}}, \tag{A3}
\end{equation*}
$$

where $n_{f}$ is the number of quark flavors, $n_{\tilde{g}}$ is the number of gluinos, and $n_{\tilde{f}}$ is the number of squark flavors. As the evolution proceeds across mass thresholds, these numbers and, consequently $\alpha_{s}$, must be adjusted.

## APPENDIX B: GLUINO CONTRIBUTIONS TO THE SINGLE-INCLUSIVE JET CROSS SECTION

The leading-order cross section for inclusive (di)jet production, $H_{1} H_{2} \rightarrow j\left(p_{3}\right) j\left(p_{4}\right) X$, expressed in terms of the transverse momentum $p_{T}$ and rapidities $y_{3}, y_{4}$ of the jets, is

$$
\begin{align*}
\frac{d \sigma}{d p_{T} d y_{3} d y_{4}}= & \frac{2 \pi \alpha_{s}^{2} p_{T}}{\hat{s}^{2}} \sum_{i, j} x_{1} x_{2} f_{H_{1} \rightarrow i}\left(x_{1}, \mu_{F}^{2}\right) \\
& \times f_{H_{2} \rightarrow j}\left(x_{2}, \mu_{F}^{2}\right) \sum_{\text {spin }}\left|\mathcal{M}_{p_{1} p_{2} \rightarrow p_{3} p_{4}}\right|^{2} \tag{B1}
\end{align*}
$$

where $x_{1}=m_{T} / \sqrt{s}\left(e^{y_{3}}+e^{y_{4}}\right)$, and $x_{2}=m_{T} / \sqrt{s}\left(e^{-y_{3}}+\right.$ $\left.e^{-y_{4}}\right)$ are the parton momentum fractions, $m_{T}^{2}=p_{T}^{2}+m_{\tilde{g}}^{2}$ is the gluino's transverse mass, and $\sqrt{s}$ is the collider center-of-mass energy. In our analysis, scattering amplitudes for subprocesses with gluino pair production, $g g \rightarrow$ $\tilde{g} \tilde{g}$ and $q \bar{q} \longrightarrow \tilde{g} \tilde{g}$, are included with full dependence on gluino mass $m_{\tilde{g}}$. Scattering amplitudes for the other LO subprocesses (with at least one initial-state gluino) are evaluated in the $m_{\tilde{g}}=0$ approximation, in accord with the S-ACOT factorization scheme [34,35].

SUSY contributions with full mass dependence can be found in the literature (e.g., in $[37,54]$ ), but they are presented here in a consistent notation for completeness. In terms of the usual parton-level Mandelstam variables, $\hat{s}=\left(p_{1}+p_{2}\right)^{2}, \hat{t}=\left(p_{1}-p_{3}\right)^{2}$, and $\hat{u}=\left(p_{1}-p_{4}\right)^{2}$, the square of the amplitude for $q \bar{q} \rightarrow \tilde{g} \tilde{g}$ is

$$
\begin{align*}
\left|\mathcal{M}_{q \bar{q} \rightarrow \tilde{g} \tilde{g}}\right|^{2}= & \frac{8}{9}\left[\frac{\hat{s} m_{\tilde{g}}^{2}}{3\left(m_{\tilde{q}}^{2}-\hat{t}\right)\left(m_{\tilde{q}}^{2}-\hat{u}\right)}+\frac{4\left(m_{\tilde{g}}^{2}-\hat{t}\right)^{2}}{3\left(m_{\tilde{q}}^{2}-\hat{t}\right)^{2}}\right. \\
& -\frac{3\left(\hat{s} m_{\tilde{g}}^{2}+\left(m_{\tilde{g}}^{2}-\hat{t}\right)^{2}\right)}{\hat{s}\left(m_{\tilde{q}}^{2}-\hat{t}\right)}+\frac{4\left(m_{\tilde{g}}^{2}-\hat{u}\right)^{2}}{3\left(m_{\tilde{q}}^{2}-\hat{u}\right)^{2}} \\
& -\frac{3\left(\hat{s} m_{\tilde{g}}^{2}+\left(m_{\tilde{g}}^{2}-\hat{u}\right)^{2}\right)}{\hat{s}\left(m_{\tilde{q}}^{2}-\hat{u}\right)} \\
& \left.+\frac{3\left(2 \hat{s} m_{\tilde{g}}^{2}+\left(m_{\tilde{g}}^{2}-\hat{t}\right)^{2}+\left(m_{\tilde{g}}^{2}-\hat{u}\right)^{2}\right)}{\hat{s}^{2}}\right] . \tag{B2}
\end{align*}
$$

Here $m_{\tilde{q}}$ is the mass of the squark, and the prefactor $8 / 9$ is a color factor. We report the expression with all the fermion mass dependence, but in our computations we have taken the limit $m_{\tilde{q}} \rightarrow \infty$.

The square of the amplitude for $g g \rightarrow \tilde{g} \tilde{g}$ is

FIG. 14 (color online). Parton-parton luminosity $\tau d \mathcal{L}_{i j}(\tau, Q) / d \tau$ vs $\sqrt{\tau}$ for $m_{\tilde{g}}=50 \mathrm{GeV}$ at $Q=100$ and 300 GeV .

$$
\begin{align*}

& +\frac{9 m_{\tilde{g}}^{2}}{\hat{s}}-\frac{27 \hat{t}^{2} m_{\tilde{g}}^{2}}{4 \hat{s}^{2}\left(\hat{u}-m_{\tilde{g}}^{2}\right)}+\frac{45 \hat{t} m_{\tilde{g}}^{2}}{2 \hat{s}\left(\hat{u}-m_{\tilde{g}}^{2}\right)}+\frac{9 \hat{t}^{2}}{4 \hat{s}^{2}}+\frac{9 \hat{u}^{2}}{4 \hat{s}^{2}}+\frac{9 \hat{t} \hat{u}}{2 \hat{s}^{2}}+\frac{9 \hat{u}^{3}}{4 \hat{s}^{2}\left(\hat{t}-m_{\tilde{g}}^{2}\right)}+\frac{9 \hat{t}^{3}}{4 \hat{s}^{2}\left(\hat{u}-m_{\tilde{g})}^{2}\right.} . \tag{B3}
\end{align*}
$$

## APPENDIX C: PARTON LUMINOSITIES

Parton-parton luminosity functions portray the relative size of various partonic contributions. The parton luminosity is defined as a convolution integral of the PDFs $f_{i}(\xi, Q)$ for two incoming partons $(i, j=\tilde{g}, g, u, d, s, \ldots)$ :

$$
\frac{d \mathcal{L}_{i j}(\tau, Q)}{d \tau}=f_{i} \otimes f_{j}=\int_{\tau}^{1} \frac{d \xi}{\xi} f_{i}(\xi, Q) f_{j}\left(\frac{\tau}{\xi}, Q\right)
$$

where $\tau=\hat{s} / s$. Here $\hat{s}$ is the square of the center-of-mass energy in the incident parton-parton system. In terms of this luminosity, the production cross section for a specific reaction is

$$
\begin{equation*}
\sigma(s)=\sum_{i, j} \int_{\tau_{0}}^{1} d \tau \hat{\sigma}_{i j}(\tau) \frac{d \mathcal{L}_{i j}(\tau, Q)}{d \tau} \tag{C1}
\end{equation*}
$$

The sum is over the initial-state parton flavors $i$ and $j$, and $\hat{\sigma}_{i j}(\tau)$ is the partonic cross section for the subprocess initiated by partons $i, j$.

The luminosities for some flavor combinations are shown in Fig. 14 for $m_{\tilde{g}}=50 \mathrm{GeV}$. At $Q=100 \mathrm{GeV}$ all gluino luminosities are smaller than the SM luminosities,
but they grow in magnitude as $Q$ increases. The gluongluino luminosity is roughly the same as the gluon-bottom quark luminosity, as would be expected from the momentum fractions presented in Table I. At $Q=300 \mathrm{GeV}$ the $\tilde{g} \otimes g$ contribution is comparable to that of the ordinary quarks. The $\tilde{g} \otimes g$ combination is smaller than $s \otimes g$ throughout the $x$ range for $Q=100 \mathrm{GeV}$. At $Q=$ 300 GeV , the evolution of the gluino is enhanced, and $\tilde{g} \otimes g$ exceeds various SM pairings for $x>0.1$.

#### Abstract

We summarize several projects carried out by the CTEQ global analysis of parton distribution functions (PDFs) of the proton during 2010. We discuss a recently released CT10 family of PDFs with a fixed and variable QCD coupling strength; implementation of combined HERA and Tevatron lepton asymmetry data sets; theoretical issues associated with the analysis of $W$ charge asymmetry in PDF fits; PDFs for leading-order shower programs; and constraints on new color-octet fermions from the hadronic data.

## CTEQ PDFs in 2010

Parton distribution functions (PDFs) are essential nonperturbative functions of quantum chromodynamics (QCD). They describe the internal structure of the proton in high-energy scattering at the Fermilab Tevatron collider, CERN Large Hadron Collider, and in other experiments. Modern PDFs continuously evolve to include emerging theoretical developments and latest data from hadronic experiments, and to provide reliable estimates of uncertainties associated with various experimental and theoretical inputs. In this paper, we review the recent progress in the determination of the PDFs by CTEQ collaboration [1, 2, 3, 4], which is one of three groups involved in the global analysis of hadronic data, besides the MSTW [5] and NNPDF [6] groups.

## Implementation of new data sets

Since the release of the previous general-purpose CTEQ6.6 PDF set [7] in 2008, new data sets have been published in every category of processes included in the global QCD analysis: deep inelastic scattering (DIS), vector boson production, and inclusive jet production. These data sets include a combination of DIS cross sections by the H1 and ZEUS collaborations in HERA-1 [8], as well as measurements of $W$ lepton asymmetry $[9,10,11], Z$ rapidity distributions $[12,13]$, and single-inclusive jet cross sections $[14,15]$ by CDF and D $\emptyset$ collaborations at the Tevatron. All these new data are included in our latest global analysis, designated as CT10 [3].

The new analysis produced two families of general-purpose PDF sets, denoted as CT10 and CT10W, which differ in their treatment of the Tevatron $W$ lepton asymmetry data sets affecting the ratio of $d$ and $u$ quark PDFs at $x>0.1$, as discussed below, but are very similar in all other aspects. In addition, we examined the dependence of the PDFs on the QCD coupling $\alpha_{s}\left(M_{Z}\right)$ and provided special CT10AS PDF sets with a varied $\alpha_{s}\left(M_{Z}\right)$ in the range 0.113-0.123 to evaluate the combined PDF- $\alpha_{s}$ uncertainty in practical applications. The CT10 PDFs are obtained at next-toleading order in $\alpha_{s}$, using the general-mass treatment of charm and bottom quark contributions to hadronic observables. To support calculations for heavy-quark production in the fixed-flavornumber factorization scheme, we also provide additional PDF sets CT10(W). 3 F and CT10(W). 4 F , obtained from the best-fit CT10.00 and CT10W PDF sets by QCD evolution with three and four active quark flavors. All the PDF sets discussed in this paper (CT10, CT10W, CT10AS, CT10XF, and CT09MC) are available as a part of the LHAPDF library [16] and from our website [17].

## Constraints from combined DIS data by HERA-1

The CT10/CT10W fits include a combined set of HERA-1 cross sections on neutral-current and charged-current DIS [8], which replaces 11 separate HERA-1 data sets used in CTEQ6.6 and earlier fits. In the combined set, systematic factors that are in common to both experiments were presented as a table of 114 correlated systematic errors, whose effect is shared by each data point in all scattering channels. As a result of the cross calibration of detection parameters between the H1 and ZEUS experiments, the combined data set has a reduced total systematic uncertainty. Consequently, the PDF uncertainties at $x<10^{-3}$, in the region where the HERA data provide tightest constraints on the gluon and heavy-quark PDFs, are also reduced.

The impact of the combined HERA-1 set on the PDFs is illustrated by Fig. 1, showing relative differences between the CT10 PDF set, fitted to the combined HERA-1 data, and a counterpart fit, fitted to the separate HERA-1 data sets. In the left subfigure, comparing the best-fit PDFs in the two fits, one observes reduction in the gluon and charm PDFs at $x<0.05$, accompanied by a few-percent increase in the $u$ and $d$ quark PDFs in the same $x$ region. The strange quark PDF shows a larger suppression (up to $25 \%$ at $x=10^{-5}$ ), which, however, is small compared to the large

Figure 1: Left: ratios of CT10 central PDFs fitted to the combined HERA-1 data set and to the separate HERA-1 data sets, at scale $\mu=2 \mathrm{GeV}$. Right: bands of the PDF uncertainty (relative to the the central PDF set) for the gluon PDF in (red) CT10 with the combined HERA-1 data, (blue) CT10 with the separate HERA data. $g(x), Q=2 \mathrm{GeV}$.

PDF uncertainty associated with this flavor. Fig. 1 (right) shows the asymmetric fractional PDF uncertainty, computed as in [18], and normalized to the best-fit gluon PDF of each fit. The impact of the HERA-1 data on the uncertainties of the gluon and charm PDFs is visible in the small- $x$ region, starting from $x=10^{-3}$ and going down to $x=10^{-5}$, where the error bands contract upon the combination of the HERA data sets. In the large $x$ region, the error bands for the combined and separate HERA data sets are almost coincident.

## Agreement with the HERA data at small and large $x$

The overall agreement of the CT10 fit with the combined HERA-1 data is slightly worse than with the separate HERA-1 data sets, as a consequence of some increase in $\chi^{2} /$ d.o.f. for the neutralcurrent DIS data at $x<0.001$ and $x>0.1$. While the origin of this increase is uncertain, the pattern of point-to-point contributions to $\chi^{2}$ from the data is consistent with random fluctuations that turn out to be larger than normally expected. No systematic discrepancies between the HERA-1 DIS data and theoretical cross sections are observed, suggesting that the NLO QCD theory based on CT10 PDFs is generally consistent with the HERA experiments in the region $Q>2 \mathrm{GeV}$ included in the CT10 fit.

In looking for potential systematic deviations of this kind, we examined the agreement with the data as a function of either $x$ and $Q$, or the "geometric scaling" variable $A_{g s}=Q^{2} x^{0.3}$ proposed by NNPDF authors in Refs. [19, 20]. At $A_{g s} \rightarrow 0$, DGLAP factorization that is required to introduce the PDFs can be invalidated by higher-twist terms or saturation; the question is whether such effects may bias the determination of the PDFs at $A_{g s} \gtrsim 0.1$, in the kinematical region commonly included in the global fits.

Indeed, the NNPDF study finds that the PDFs fitted to the HERA data above some cutoff value $\left(A_{g s}>A_{c u t}\right)$, disagree at the $2 \sigma$ level with the HERA data in the "causally connected" region below the cutoff, $0.5<A_{g s}<A_{c u t}$. The NNPDF analysis is realized in the zero-mass approximation and includes DIS data in the less safe region $\sqrt{2} \mathrm{GeV}<Q<2 \mathrm{GeV}$. We repeated the $A_{\text {cut }}$ fits proposed by NNPDF as closely as possible, in the general-mass factorization scheme, and in the region of $Q>2 \mathrm{GeV}$ where our data are customarily selected to suppress higher-order

Figure 2: Comparison of CDF Run-2 lepton asymmetry data [9] with LO, NLO, and resummed predictions from ResBos [35].

and higher-twist terms. While the outcomes of our $A_{\text {cut }}$ fits bear some similarity to those by NNPDF, the discrepancies between our best-fit NLO predictions and the data below $A_{\text {cut }}$ are less significant than those quoted by NNPDF and are characterized by a large PDF uncertainty. Thus, our fits do not corroborate the existence of stable deviations of the NLO DGLAP factorization from the data, if the lower $Q$ bound is chosen to be above 2 GeV . See further discussion in the appendix of Ref. [3].

## Tevatron Run-2 W lepton asymmetry data

The puzzle of Run-2 W asymmetry. Recently, the Fermilab DØ Collaboration [10, 11] published measurements of $W$ charge asymmetry $A_{\ell}\left(y_{\ell}\right)$ in electron $(\ell=e)$ and muon $(\ell=\mu)$ decay channels, presented as a function of the rapidity of the charged decay lepton. NLO predictions based on CTEQ6.1 and CTEQ6.6 sets disagree with these data at surprisingly large $\chi^{2} / N p t$ of about 5 . The values of $\chi^{2} / N p t$ can be even higher (as high as 20 ) for some other recent (N)NLO PDF sets [11, 22]. Such level of disagreement may appear surprising, given that the Tevatron $W$ asymmetry probes the ratio of $d$ and $u$ quark PDFs [21] in the region $x>0.1$, where they are known quite well from the other experiments.

Sensitivity to the $d / u$ slope. The discrepancy involving $A_{\ell}$ can be understood in part by noticing that the $A_{\ell}$ measurement is very sensitive to the average $x$ derivative (slope) of the ratio of the up and down quark PDFs, $d\left(x, M_{W}\right) / u\left(x, M_{W}\right)$, computed between the typical $x$ values $x_{1,2}=M_{W} e^{ \pm y_{W}} / \sqrt{s}$ accessible at a given boson rapidity $y_{W}[21,23]$. Small variations of the $d / u$ slopes in distinct PDF sets can change the behavior of $A_{\ell}$ by large amounts [24].

Impact of soft gluon resummation. Another factor at play are soft parton emissions with small transverse momenta, which affect the precise $A_{\ell}$ data because of constraints imposed on the transverse momentum $p_{T \ell}$ of the decay charged lepton. The $A_{\ell}$ data require $p_{T \ell}$ to be above 20-25 GeV in order to suppress charged leptons from background processes that do not involve a $W$ boson decay. In addition, the Run- $2 A_{\ell}$ data are organized into bins of $p_{T \ell}$, e.g., $25-35 \mathrm{GeV}$ and $35-45$ GeV in order to better probe the $x$ dependence of $d(x, Q) / u(x, Q)$ [9]. While such binning amplifies the sensitivity of the $A_{\ell}$ data to the PDFs, it also makes it dependent on the shape of the $p_{T \ell}$ distribution near the Jacobian peak at $p_{T \ell} \approx M_{W} / 2 \approx 40 \mathrm{GeV}$ or, equivalently, to the transverse momentum $\left(Q_{T}\right)$ distribution of $W$ bosons at $Q_{T}<20 \mathrm{GeV}$, where large logarithms $\ln \left(Q_{T} / Q\right)$ dominate the cross section. A calculation that evaluates these logarithms to all orders in $\alpha_{s}[25,26$, $27]$, in addition to including the leading NNLO corrections [29, 28], results in somewhat different

Figure 3: Comparison of the CT10W and CTEQ6.6 predictions with the DØ Run-II data for the electron charge asymmetry $A_{e}\left(y_{e}\right)$ for an integrated luminosity of $0.75 \mathrm{fb}^{-1}$ [10]

Figure 4: The $d / u$ ratio for CT10 (left) and CT10W (right) versus that for CTEQ6.6, at scale $\mu=85 \mathrm{GeV}$.

predictions for $A_{\ell}$ than (N)NLO calculations without resummation, like those implemented in the other available codes $[30,32,33,34]$.

In CT10 fits, the QCD radiative contributions to $A_{\ell}\left(y_{\ell}\right)$ are implemented to the next-to-next-to-leading accuracy in $Q_{T}$ logarithms and NLO accuracy in the QCD coupling strength using the program ResBos that realizes the approach of Refs. [25, 26, 27]. The resummed differential distributions for $d \sigma / d Q_{T}$ and $d \sigma / d p_{T \ell}$ both agree well with the data, in contrast to the fixed-order results. We thus expect that the resummed predictions for $A_{\ell}$ implemented in the CT10 fit are more reliable as well.

The magnitude of differences between the NLO and resummed predictions is illustrated by Fig. 2, comparing the CDF Run-2 $A_{\ell}\left(y_{\ell}\right)$ data [9] with LO, NLO, and resummed NNLL-NLO predictions from ResBos. The NLO and resummed curves are clearly distinct in the bin $25<p_{T \ell}<$ 35 GeV , shown in the left panel, and some differences are also seen in the bin $35<p_{T \ell}<45 \mathrm{GeV}$, shown in the right panel. The shape of the NLO prediction in this comparison is not unique and depends on the phase space slicing parameter $Q_{T}^{\text {sep }}$ that defines the size of the lowest $Q_{T}$ bin where the real and virtual NLO singularities are canceled [26]. In the current comparison, $Q_{T}^{s e p}=3 G e V$, but other values of $Q_{T}^{s e p}$ are equally possible and would lead to NLO predictions lying closer to, or further from, the shown resummed curve. Such variations due to $Q_{T}^{s e p}$ or factorization scale indicate that resummation effects are important and should be included in precise fits to $A_{\ell} .{ }^{1}$

Numerical predictions of the CT10W analysis. When included in the CTEQ global analysis, the CDF measurements of $A_{\ell}$ in Tevatron Run-1 [37] and Run-2 [9] agree well with the other data sets constraining the $d / u$ ratio, provided by deep inelastic scattering on proton and

[^254]deuteron targets by the NMC [38] and BCDMS [39, 40] collaborations. However, the most precise Run-2 lepton $A_{\ell}$ data by the $\mathrm{D} \emptyset$ Collaboration $[10,11]$ run into disagreement with the NMC and BCDMS deuteron DIS data, and in addition, exhibit some tension among themselves. Because of these disagreements, two separate fits are produced: CT10, which does not contain the DØ $W$ electron asymmetry sets, and CT10W, in which they are included using weight factors larger than 1 to ensure an acceptable fit. We obtain $\chi^{2} / N p t=91 / 45=2$ in the CT10W fit to the Run- 2 $A_{\ell}$, which is a significant improvement compared to $200 / 45=4.4$ obtained in CT10. Comparison of NNLL-NLO predictions based on CT10W PDFs with the electron charge asymmetry data is presented in Fig. 3.

In the CT10W analysis, the inclusion of the Run- $2 A_{\ell}$ data increases the slope of $d(x) / u(x)$ at $x$ between 0.1 and 0.5 and reduces its uncertainty, as compared to CTEQ6.6 and CT10. This is illustrated by Fig. 4, which shows uncertainty bands for the $d / u$ ratio in CTEQ6.6, CT10, CT10W PDFs vs. the momentum fraction $x$ at scale $Q=85 \mathrm{GeV}$.

Fig. 5 shows the ratios $r_{W Z}=\sigma\left(p p \rightarrow W^{ \pm} X\right) / \sigma\left(p p \rightarrow Z^{0} X\right)$ and $r_{W^{+} W^{-}}=\sigma(p p \rightarrow$ $\left.W^{+} X\right) / \sigma\left(p p \rightarrow W^{-} X\right)$ of the rapidity distributions in $W^{ \pm}$and $Z$ boson production at the LHC, obtained using CTEQ6.6, CT10 and CT10W PDFs and divided by the predictions based on the CTEQ6.6M set. Here, the reduction of the uncertainty bands in the ratio of $W^{+}$to $W^{-}$cross sections predicted based on the CT10W PDFs, as compared to CT10, is again evident.

Comparison with other fits. The MSTW'08 [5] and NNPDF2.0 [36] groups have also explored the impact of the $\mathrm{D} \emptyset$ Run- $2 A_{\ell}$ data. While their conclusions are broadly compatible with ours, the details vary. For example, in the CT10W fit, we find that all three $p_{T \ell}$ bins of the electron $A_{\ell}$ data and the second $p_{T \ell}$ bin of the fit can be combined with the other data sets, despite the remaining disagreement with the deuteron DIS experiments. NNPDF, on the other hand, finds that all bins of the muon $A_{\ell}$ are compatible with the deuteron DIS and all other experiments, but incompatible with the second and third $p_{T \ell}$ bins of the electron $A_{\ell}$. NNPDF compute their NLO $A_{\ell}$ predictions using the DYNNLO code [34], which can deviate from the resummed NNLL + NLO predictions by ResBos used by CTEQ, as discussed above.

The resolution of the Run- $2 A_{\ell}$ puzzle thus seems to require consistent implementation of perturbative QCD calculations both in experimental analyses and PDF fits, including small- $Q_{T}$ resummed contributions, when constraints on the lepton $p_{T \ell}$ are imposed. For greater precision it may be preferable to perform the small- $Q_{T}$ resummation for every component of the angular distribution of the decay lepton [41], in addition to the resummation for two dominant angular components that is currently implemented in ResBos. Resummation of the full dependence on the polar and azimuthal angles $\theta$ and $\phi$ of the lepton in the vector boson rest frame may be important especially in situations in which the experimental coverage is not uniform in all directions, or when there are gaps in the coverage. Normally the angular coverage varies with rapidity, notably at large rapidity, and this variation may well affect the lepton asymmetry, with different consequences in different experiments.

Figure 5: CT10, CT10W, and CTEQ6.6 PDF uncertainty bands for the ratios $\left(d \sigma\left(W^{ \pm}\right) / d y\right) /(d \sigma(Z) / d y)$ (upper two subfigures) and $\left(d \sigma\left(W^{+}\right) / d y\right) /\left(d \sigma\left(W^{-}\right) / d y\right)$ (lower two subfigures), at the LHC energies 7 and 14 TeV .

## CT10 predictions for collider observables

Fig. 6 compares the NLO total cross sections, obtained using CT10 and CT10W PDFs, to those obtained using CTEQ6.6 PDFs, for some selected processes at the Tevatron Run-2 and the LHC at $\sqrt{s}=7 \mathrm{TeV}$. For most of the cross sections, CT10 and CT10W sets provide similar predictions and uncertainties, which are also in good agreement with those from CTEQ6.6 (i.e., well within the PDF uncertainty band). At the LHC, the PDF uncertainties in CT10 and CT10W predictions for some processes are larger than those in the counterpart CTEQ6.6 predictions, reflecting the changes in the framework of the fit discussed in the next paragraph. At the Tevatron, the CT10(W) PDF uncertainties tend to be about the same as those for CTEQ6.6, with a notable exception of $t \bar{t}$ production cross sections, which have a smaller PDF uncertainty with the CT10W set, because of stricter constraints on the up- and down-quark PDFs at the relevant $x$ values.

## New PDF parametrizations; advancements in statistical analysis

The CT10 global analysis implements several new features which were not available in the previous studies. The systematic uncertainty associated with the overall normalization factor in each of the data sets is handled in the same manner that all other systematic error parameters are handled. The best-fit values of the normalizations are found algebraically, and their variations are included in the final estimate of the PDF uncertainties. More flexible parametrizations are assumed for the gluon, $d$-quark, and strange quark PDFs at the initial scale 1.3 GeV , to reduce biases in predictions in kinematical regions where the constraints from the data are weak. Finally, a new statistical procedure is introduced to guarantee the agreement of the fits at $90 \%$ C.L. with all included experiments, for any PDF eigenvector set produced by the error analysis. This is realized by adding an extra contribution to the total $\chi^{2}$, which guarantees the quality of fit to each individual data set and halts the displacement along any eigenvector early, if necessary, to prevent one or more individual data sets from being badly described. The old procedure to enforce the $90 \%$ C.L. agreement with all experiments in the CTEQ6 family of fits, by artificially increasing statistical weights of $\chi^{2}$ contributions from those experiments that may be fitted poorly by some PDF eigenvector sets, is phased out by this more efficient method. As a result of these changes, the CT10/CT10W PDF uncertainty may be smaller or larger than the CTEQ6.6 uncertainty, depending on whether the improved constraints from the data outweigh the increased uncertainty due to the relaxed PDF parametrizations and variations of normalizations during the determination of PDF eigenvector sets.

## Dijet invariant mass distributions

Fig. 7 compares NLO predictions based on CTEQ6.6, CT10, and CT10W PDFs with the data on the dijet invariant mass distribution $d \sigma / d M_{j j}$ reported recently by the $\mathrm{D} \emptyset$ Collaboration [42]. These data are not included in the CT10 fit, but they are sensitive to the same scattering subprocesses, and include the same events, as the single-inclusive jet data constraining the gluon PDF in the CT10 fit. The cross sections are normalized to the theory prediction based on the central CT10 PDF set. The statistical and systematic errors of the D $\varnothing$ data are added in quadrature. The renormalization and factorization scales in the theoretical predictions are set equal to a half of the average $p_{T}$ of the jets, $\left\langle p_{T}\right\rangle / 2$, consistent with the scale used in the single-jet cross sections when determining the gluon PDFs. With this choice of the scale, all three PDF sets agree with most of the data points within the PDF uncertainty. There appears to be a systematic excess of theory over the data, but its magnitude strongly depends on the assumed factorization scale. For example, it can be much worse if a different scale is taken, such as $\mu=\left\langle p_{T}\right\rangle$ assumed in Fig.

Figure 6: Ratios of NLO total cross sections obtained using CT10 and CT10W to those using CTEQ6.6M PDFs, in various scattering processes at the Tevatron Run-II and LHC.

Figure 7: Comparison of DØ Run-II data for dijet invariant mass distributions [42] with NLO theoretical predictions and their PDF uncertainties for CTEQ6.6 (black), CT10 (red) and CT10W (blue) PDFs. The cross sections are normalized to theoretical predictions based on the best-fit CT10 set, designated as CT10.00.

2 of the D $\emptyset$ paper [42]. We conclude that the CT10 PDFs are reasonably compatible with the $\mathrm{D} \emptyset$ dijet data within the present theoretical uncertainties, although an overall systematic shift, of order of the systematic shifts observed in the CT09 study of the single-inclusive jet distributions [1], would further improve the agreement, once the full correlated systematic errors of the dijet data become available.

## Uncertainty due to $\alpha_{s}$ in CTEQ6.6 and CT10 PDF analyses

Many calculations for collider processes (e.g., production of $t \bar{t}$ pairs and Standard Model Higgs bosons) require to evaluate two leading theoretical uncertainties, due to the choice of the PDF parametrization at the initial scale, and the value of the strong coupling constant $\alpha_{s}\left(M_{Z}\right)$ assumed in the hard cross sections and the PDFs. These uncertainties can be comparable in size, and their interplay, or correlation, may be important. In Ref. [2], we examine the $\alpha_{s}$ dependence of CTEQ6.6 PDFs [7] and show how the PDF- $\alpha_{s}$ correlations are adequately captured by a simple calculation, without resorting to more elaborate methods proposed in other studies [43].

At the beginning of the PDF fit, one decides which data determine the $\alpha_{s}\left(M_{Z}\right)$ value and its uncertainty. CTEQ best-fit PDFs and their parametrization uncertainties are usually determined for a constant value of $\alpha_{s}\left(M_{Z}\right)$ that is close to its latest world-average central value; e.g., $\alpha_{s}\left(M_{Z}\right)=$ $0.118 \pm 0.002$ assumed in Ref. [2]. This input value of $\alpha_{s}\left(M_{Z}\right)$ can be viewed as an additional data point that summarizes world constraints on $\alpha_{s}$, mostly determined by precise experiments that are not included in the global fit (notably, LEP event shapes and $\tau$ and quarkonium decays). In Ref. [2], we explore a more general procedure, in which the world-average data point on $\alpha_{s}\left(M_{Z}\right)$ is included in the fit in addition to the usual hadronic scattering data. A theoretical parameter for $\alpha_{s}\left(M_{Z}\right)$ is varied in this fit; its output value and uncertainty are determined by all input data. We find that the output value of $\alpha_{s}\left(M_{Z}\right)=0.118 \pm 0.0019$ obtained in this way essentially coincides with its input value $\alpha_{s}\left(M_{Z}\right)=0.118 \pm 0.002$. If the input value is not included, the output uncertainty on $\alpha_{s}$ is increased significantly, to $\alpha_{s}\left(M_{Z}\right)=0.118 \pm 0.005$. This indicates that the hadronic scattering data included in the fit imposes significantly weaker constraints on $\alpha_{s}$ than the other experiments contributing to the world-average value.

The Hessian PDF eigenvector sets returned by such floating- $\alpha_{s}$ fit can be used to estimate the correlation between the PDF parameters and $\alpha_{s}\left(M_{Z}\right)$. However, each of these eigenvector sets is inconveniently associated with its own value of $\alpha_{s}\left(M_{Z}\right)$. Instead, one can apply a simpler procedure, in which all eigenvector sets except two are determined for the best-fit value of $\alpha_{s}\left(M_{Z}\right)$. These eigenvector sets provide the usual PDF uncertainty for a fixed $\alpha_{s}\left(M_{Z}\right)$. Separately, the uncertainty in the PDFs induced by the uncertainty in $\alpha_{s}\left(M_{Z}\right)$ is assessed, by producing two alternative PDF fits for the $\alpha_{s}\left(M_{Z}\right)$ values at the lower and upper ends of the $\alpha_{s}$ uncertainty interval (i.e., $\alpha_{s}\left(M_{Z}\right)=0.116$ and 0.120$)$. These PDF and $\alpha_{s}$ uncertainties are then added in quadrature to obtain the total uncertainty.

This procedure is valid both formally and numerically. It is based on a theorem that is applicable within the quadratic approximation for the log-likelihood function $\chi^{2}$ in the vicinity of the best fit. The proof of the theorem, as well as a numerical demonstration of the equivalence of the addition in quadrature to the full estimation of the $\mathrm{PDF}+\alpha_{s}$ uncertainty based on the Hessian method, are given in Ref. [2]. The series of best-fit PDFs for $\alpha_{s}\left(M_{Z}\right)$ values in the interval 0.113-0.123, needed to evaluate the combined $\mathrm{PDF}+\alpha_{s}$ uncertainty in any application, are made available both for CTEQ6.6 and CT10 PDFs.

Figure 8: Left: Ratio of $g(x, Q)$ in SUSY fits with a fixed $\alpha_{s}\left(M_{Z}\right)=0.118$ and CT10 fit. Right: $\Delta \chi^{2}$ in 2004 and 2010 SUSY fits vs. gluino mass.

## Constraints on new physics from a global PDF analysis

Besides providing the PDFs and their uncertainties, the global QCD analysis can establish bounds on masses of hypothetical particles beyond the standard model (BSM), for example, relatively light color-octet Majorana fermions that contribute to strong interaction processes with the same coupling strength as the gluons. Gluinos of a supersymmetric (SUSY) origin serve as an example of such fermions; but other models can introduce them as well. Constraints on the "gluinos" are often imposed in the context of a specific BSM model for their production and decay, which helps to rule out "gluinos" with masses up to a few hundred GeV. But, if no model-specific assumptions are imposed, much lighter gluinos are allowed: as light as $\approx 12-15 \mathrm{GeV}$ according to the 2004 global fit based on the CTEQ6 set data [44], or $6-51 \mathrm{GeV}$ according to the NLO/resummation analyses of $e^{+} e^{-}$hadroproduction at LEP [45, 46, 47]. Note that the limit based on the global fit is not affected by (potentially important) theoretical uncertainties in the LEP analyses, associated with nonperturbative and matching effects in the resummation techniques that they employ.

In Ref. [48], we improve the earlier limits [44] on relatively light gluinos based on an extended CT10 fit with added gluino scattering contributions. In this study, an independent PDF describing gluinos, and one-loop splitting functions describing interactions of gluinos with quarks and gluons, are introduced in the DGLAP equation. Two-loop gluino contributions are included in the renormalization group equation for the running of $\alpha_{s}$. Cross sections for single-inclusive jet production are modified to include hard matrix elements for $2 \rightarrow 2$ processes involving gluinos, with full dependence on the gluino mass evaluated in the general-mass factorization scheme. These modifications capture the essential dependence on gluinos in inclusive processes studied in the CT10 fits. Generally, the gluino contributions to inclusive observables are small, so that they can be evaluated at the one-loop level to achieve the same accuracy as the SM contributions evaluated at two loops. Squarks and other BSM particles are assumed to be heavier than a few hundred GeV and not included.

Constraints on the gluino mass $m_{\tilde{g}}$ depend strongly on the value of $\alpha_{s}\left(M_{Z}\right)$ [44]. To reproduce the existing limits on $\alpha_{s}(Q)$, we introduce two data points at $Q=5 \mathrm{GeV}$ and $M_{Z}$, representing a combination of measurements at low $Q$ and $Q \approx M_{Z}$, respectively. The low- $Q$ bound on $\alpha_{s}$ has been obtained by combining measurements of $\alpha_{s}\left(M_{Z}\right)$ in $\tau$ and quarkonium decays. These low- $Q$
measurements are not affected by gluinos heavier than 10 GeV . Gluino contributions to the high- $Q$ data point are of the same order as the experimental uncertainties.

With the $\alpha_{s}$ data and latest hadronic data included, the 2010 SUSY PDF fits reduce the allowed range of gluino masses, as compared to the 2004 fits [44]. For example, Fig. 8 illustrates SUSY fits with a constant QCD coupling strength, $\alpha_{s}\left(M_{Z}\right)=0.118$, for gluino masses $m_{\tilde{g}}$ shown in the figure. The left subfigure compares the gluon PDF obtained in SUSY fits with $m_{\tilde{g}}=20$ and 50 GeV (solid lines) to the CT10 error band (corresponding to $m_{\tilde{g}}=\infty$ ). It is clear that too light gluinos distort the shape of the CT10 gluon PDF to an unacceptable level. The right subfigure shows the differences $\Delta \chi^{2}=\chi^{2}\left(\alpha_{s}, m_{\tilde{g}}\right)-\chi_{C T 10}^{2}$. One can see that $\Delta \chi^{2}>100$ for $m_{\tilde{g}}<25 \mathrm{GeV}$, suggesting that gluinos lighter than 25 GeV are excluded at about $90 \%$ C.L., for $\alpha_{s}\left(M_{Z}\right)=0.118$. This improves the 2004 constraint [44], $m_{\tilde{g}}>12 \mathrm{GeV}$ for $\alpha_{s}\left(M_{Z}\right)=0.118$, by a factor of two. Similarly, the 2004 limit on $m_{\tilde{g}}$ for a free $\alpha_{s}$, which allowed $m_{\tilde{g}}=1 \mathrm{GeV}$ for $\alpha_{s}\left(M_{Z}\right)=0.135$, is increased to $m_{\tilde{g}}>13 \mathrm{GeV}$ for any $\alpha_{s}$ in the 2010 fit.

Gluinos with mass about 50 GeV remain allowed both by the global fits and LEP data analysis. Such light gluinos may alter cross sections for jet production and other LHC processes [48]. We provide tables of PDFs with contributions of gluinos in this mass range to explore phenomenological implications.

## W+ rapidity distribution

## SM Higgs boson rapidity distribution

## PDFs for leading-order showering programs

Monte Carlo event generators, especially, the most mature leading-order generators, play a critical role in all stages of modern particle physics. Neither conventional LO PDFs, nor NLO PDFs produce satisfactory results when implemented in the showering programs. In Ref. [4], we modified the usual leading-order global analysis to find optimized PDFs for leading-order Monte-Carlo (LO-MC) simulations at the LHC. Besides the usual constraints from the existing hard-scattering experimental data, the joint input of this analysis incorporates pseudodata points for cross sections of $W, Z, t \bar{t}$, SM Higgs, and $g g \rightarrow b b^{\prime}$ production at the LHC, as predicted by NLO QCD theory. The PDFs resulting from this analysis are not strictly at the leading order: they include some information about key LHC processes evaluated at NLO. Event generators, including "LO event generators", have some elements of higher-order contributions and, in this sense, are not at the stated order in the QCD coupling. We can use their flexibility to find the LO-MC PDFs that better reproduce the benchmark NLO cross sections, when combined with LO matrix elements in a fixed-order calculation or a LO event generator.

To examine the available possibilities, we provide three representative LO-MC PDF sets, designated as CT09MCS, CT09MC1, and CT09MC2. These PDFs realize different strategies for bringing the LO predictions closer to NLO. Their differences stem from varying assumptions about the running of $\alpha_{s}$ (evaluated at one or two loops), factorization scales in the LHC pseudodata cross sections (fixed or fitted), and the momentum sum rule imposed on the PDFs (exact or relaxed by $10-15 \%$ [49]). An example of the LO-MC PDFs in action is shown in Fig.9, which compares cross sections for $W^{+}$boson and Standard Model Higgs boson rapidity distributions at the LHC, obtained with LO matrix elements and CT09MC2 and MRST2007lomod PDFs [49], and at NLO with CTEQ6.6. In the $W^{+}$production case (upper left subfigure), the CT09MC2 calculation closely reproduces both the normalization and shape of the NLO cross section at all three LHC energies, while the MRST2007lomod prediction differs from NLO in normalization at $\sqrt{s}=7 \mathrm{TeV}$, and both in normalization and shape at 10 and 14 TeV . For Higgs production (upper right subfigure), both CT09MC2 and MRST2007lomod predictions provide almost identical distributions, which are smaller than the NLO prediction by a nearly constant normalization factor. This difference with NLO reflects especially large virtual corrections present in Higgs production cross sections, which cannot be completely compensated by an increase in the LO gluon density. However, since the average normalization factors $K$ for each pseudodata process are also known from the fit (and published in our paper), end users can multiply the LO-MC cross sections for Higgs production and other pseudodata processes by these K-factors to better approximate the NLO cross sections (cf. the lower left subfigure). If an LHC process is not included as the pseudodata, comparison of LO predictions based on several LO-MC sets may still provide a reasonable estimate of the NLO cross section, as illustrated by the cross section for SM Higgs boson production via vector boson fusion in the lower right subfigure.

In summary, the CT10 and CT10W sets are based on the most up-to-date information about the PDFs available from global hadronic experiments. There are 26 free parameters in both new PDF sets; thus, there are 26 eigenvector directions and a total of 52 error PDFs for both CT10 and CT10W. The CT10 and CT10W PDF error sets, along with the accompanying $\alpha_{s}$ error sets, allow for a complete calculation of the combined $\mathrm{PDF}+\alpha_{s}$ uncertainties for any observable.

(Received 2 August 2009; published 24 February 2010)

#### Abstract

We discuss the correlated systematic theoretical uncertainties that may be ascribed to the next-toleading order QCD theory used to predict the one-jet inclusive cross section in hadron collisions. We estimate the magnitude of these errors as functions of the jet transverse momentum and rapidity. The total theoretical error is decomposed into a set of functions of transverse momentum and rapidity that give a model for statistically independent contributions to the error. This representation can be used to include the systematic theoretical errors in fits to the experimental data.

## I. INTRODUCTION

Predictions of the standard model are typically made with the aid of next-to-leading order (NLO) perturbative calculations (or sometimes with NNLO calculations). Evidently, these predictions are not exactly equal to what one should measure if the standard model is correct. If we have an NLO calculation, we leave out NNLO and $\mathrm{N}^{3} \mathrm{LO}$ contributions, etc. We also leave out contributions that are suppressed by a power of the large momentum scale of the problem. Of course, we do not know exactly how big these contributions are: if we could calculate them, we would include them in the prediction. Nevertheless, we can estimate the size of the corrections. They then constitute "theory errors" in the prediction, which are quite similar to experimental systematic errors in the measurement.

In this paper we distinguish between errors associated with higher order contributions and power suppressed contributions to the cross section, which we call theory errors, and errors associated with our imperfect knowledge of the parton distribution functions needed for the prediction. Estimated theory errors are needed in two contexts. First, if an experiment does not agree with the theoretical prediction within the experimental statistical and systematic errors, then we need to see if there is agreement within the combined experimental and theory errors and the errors from the parton distributions used in the prediction. In the case that the disagreement is outside of the combined errors, then we have a signal for new physics.

The second context in which we need estimated theory errors is in the determination of parton distribution functions from experimental measurements. The theory errors give a contribution to the errors that we associate with the parton distribution functions that emerge from a fit to the data. Evidently, if we do not include theory errors, the resulting errors in the parton distribution functions will be too small. Additionally, if for one kind of process the

[^255]theory errors are large while for another kind of process the theory errors are small, then we will give the large-error process too much weight in the fit.

In this paper, we provide an estimate of the theory error for the one-jet inclusive cross section $d^{2} \sigma / d P_{T} d y$ in hadron-hadron collisions, where $P_{T}$ is the transverse momentum or "transverse energy" of the jet, and $y$ is the rapidity of the jet. There is good data for this process from the CDF and D0 experiments at Fermilab, including careful estimates of the experimental systematic errors. Estimates of the theory errors are needed to accompany the estimates of the experimental systematic errors.

We warn that there is no unique method to estimate theory errors. Thus our task is to provide a method that is defensible if not necessarily optimal. We seek to provide an estimate in a form that includes the correlations from one $\left\{P_{T}, y\right\}$ point to another.

## II. GENERAL SETUP

We treat theory errors in a fashion that is similar to that used for correlated systematic errors in the experimental results. We use next-to-leading order quantum chromodynamics (QCD) theory to make predictions for the one-jet inclusive cross section ${ }^{1}$

$$
\frac{d \sigma}{d P_{T} d y}=\int d x_{1} \int d x_{2} f_{a / A}\left(x_{1}, \mu\right) f_{b / B}\left(x_{2}, \mu\right) \frac{d \hat{\sigma}_{a b \rightarrow \mathrm{jet}}}{d P_{T} d y}
$$

In the calculation, one uses Monte Carlo integration so that there is a random statistical error for each point $\left\{P_{T}, y\right\}$. We do not include these statistical errors in the analysis here since they are typically quite small (say $2 \%$ ) and one can reduce them by running the program for a longer time. If we wished to include the errors from fluctuations in the Monte Carlo integrations, that task would be straightfor-

[^256]

FIG. 1 (color online). illustration of (a) uncorrelated and (b) correlated theoretical errors. In (a), the total error is about $10 \%$ for all $P_{T}$, but the error at any $P_{T}$ is not correlated with the error at nearby points. In (b), there are just three functions $f_{J}\left(P_{T}\right)$ giving, again, about a $10 \%$ total error at any one $P_{T}$. Because the $f_{J}\left(P_{T}\right)$ are smooth functions, the theoretical error at a given $P_{T}$ will be smoothly related to the error at other $P_{T}$ values.
ward because the statistical nature of these fluctuations is known.

We will start our investigation by studying jet production corresponding to the Tevatron Run 2, with $\sqrt{s}=$ 1960 GeV , as a function of $P_{T}$ and $y$. We will display the results for $y=\{0,1,2\}$ as functions of $P_{T}$; we also present formulas for the $P_{T}$ and $y$ dependence, from which estimated errors for the specific kinematic ranges used by CDF and D0 can be inferred.

We need estimated errors that can be used in a statistical analysis. However, we do not have at hand a statistical ensemble of worlds in which terms beyond those included in the NLO theory vary. Thus we make estimates that we hope are reasonable but that can and should be subject to debate.

We formulate the treatment of theory errors as follows. We let

$$
\begin{equation*}
\frac{d \sigma}{d P_{T} d y}=\left[\frac{d \sigma}{d P_{T} d y}\right]_{\mathrm{NLO}}\left\{1+\sum_{J} \lambda_{J} f_{J}\left(P_{T}, y\right)\right\} . \tag{1}
\end{equation*}
$$

Here the functions $f_{J}\left(P_{T}, y\right)$ are definite functions, while the $\lambda_{J}$ are unknown parameters. Thus $\lambda_{J} f_{J}\left(P_{T}, y\right)$ represents an unknown theoretical contribution that might modify the NLO theory. We treat the $\lambda_{J}$ as Gaussian random variables with variance 1 . That is, the size of the uncertainty with label $J$ is represented by how $\operatorname{big} f_{J}\left(P_{T}, y\right)$ is. If one thinks of this as representing an imaginary ensemble of worlds in which theory calculations come out differently, then these worlds all have the same $f_{J}$ but the $\lambda_{J}$ vary.

We will propose to use just a few functions $f_{J}$. We offer the following defense of this strategy. Consider a simplified case of a cross section that is a function of just one variable, $P_{T}$. If we were to believe that the uncertainty in the prediction of this cross section is of order, say, $10 \%$, but we have no idea of what the shape of the true cross section is within a $10 \%$ band about the prediction, then we would choose many functions $f_{J}\left(P_{T}\right)$, each of size 0.10 , but with
each being nonzero only in a very tiny range of $P_{T}$. This approach is illustrated in Fig. 1(a); such a view seems to us unreasonable.

Experience with various perturbative and nonperturbative contributions teaches that they are smooth functions of the relevant variables, $P_{T}$ in this case. This arguably more reasonable scenario is illustrated in Fig. 1(b). As illustrated by the three curves, ${ }^{2}$ one contribution beyond NLO could be flat, amounting to a constant " K factor," another might be a smoothly increasing function of $P_{T}$, while yet another might be positive at high and low $P_{T}$ and negative in between. However, we judge it unlikely that a currently uncalculated contribution would have multiple maxima between low and high $P_{T}$.

Thus we seek a few functions $f_{J}\left(P_{T}, y\right)$ that have some dependence on $\left\{P_{T}, y\right\}$ and represent, as best we can determine, our understanding of the character of uncalculated contributions. In the following sections, we analyze several sources of theory errors and associate them with functions $f_{J}\left(P_{T}, y\right)$.

## III. PERTURBATIVE UNCERTAINTY

The main source of uncertainty at large jet transverse momentum, at least in our estimation, is the fact that we have calculated only at NLO, leaving contributions from higher orders of perturbation uncalculated. We estimate this uncertainty using the dependence of the computed cross section on the renormalization and factorization scales. We present this estimate in this section. In the

[^257]following section, we check this estimate using an independent method involving threshold effects.

## A. Error estimate from scale dependence

The first ingredient in our estimation of theory errors is based on the traditional method in which one evaluates the dependence of the computed NLO cross section on two scales: the renormalization scale $\mu_{\mathrm{R}}$ and the factorization scale $\mu_{\mathrm{F}}$. One often makes a standard choice for these scales: $\mu_{\mathrm{R}}=\mu_{\mathrm{F}}=P_{T} / 2$. We will take this choice as our central value and define

$$
\begin{equation*}
x_{1}=\log _{2}\left(\frac{\mu_{\mathrm{R}}}{P_{T} / 2}\right), \quad x_{2}=\log _{2}\left(\frac{\mu_{\mathrm{F}}}{P_{T} / 2}\right) \tag{2}
\end{equation*}
$$

We compute the cross section near $x_{1}=x_{2}=0$, that is near the scale choice $\mu_{\mathrm{R}}=\mu_{\mathrm{F}}=P_{T} / 2$. Then $\left\{x_{1}, x_{2}\right\}$ measures (logarithmically) the distance from this central value. We then fit the cross section to a quadratic polynomial $P(\vec{x})$ in $\vec{x}$-space,

$$
\begin{equation*}
\left[\frac{d \sigma\left(x_{1}, x_{2}\right)}{d P_{T}}\right]_{\mathrm{NLO}} \approx\left[\frac{d \sigma(0,0)}{d P_{T}}\right]_{\mathrm{NLO}}[1+P(\vec{x})] \tag{3}
\end{equation*}
$$

where

$$
\begin{equation*}
P(\vec{x})=\sum_{J} x_{J} A_{J}+\sum_{J, K} x_{J} M_{J K} x_{K}, \tag{4}
\end{equation*}
$$

with $\vec{x}=\left(x_{1}, x_{2}\right)$ and $J, K=\{1,2\}$.
We know that if we had an NNLO calculation, the dependence of the cross section on $\vec{x}$ would be canceled to order $\alpha_{s}^{2}$. Thus the coefficients $A_{J}$ and $M_{J K}$ carry information about the perturbative coefficients beyond NLO. For this reason, we use the coefficients $A_{J}$ and $M_{J K}$ to provide an estimate of the error induced by truncating the perturbative expansion at one-loop order. We define a simple recipe for this purpose. We define an estimated error ${ }^{3} \mathcal{E}_{\text {scale }}$ as the root-mean-square average of $P(\vec{x})$ over a circle with a certain radius $|\vec{x}|$,

$$
\begin{equation*}
\mathcal{E}_{\text {scale }}^{2}=\frac{1}{2 \pi} \int_{0}^{2 \pi} d \theta P(|\vec{x}| \cos \theta,|\vec{x}| \sin \theta)^{2} \tag{5}
\end{equation*}
$$

We need to select a value of $|\vec{x}|$, and we make the choice

$$
\begin{equation*}
|\vec{x}|=2 \tag{6}
\end{equation*}
$$

In the most common method of estimating errors from scale variation, we would vary $\left(2 \mu_{\mathrm{R}} / P_{T}, 2 \mu_{\mathrm{F}} / P_{T}\right)$ between $(1,1)$ and $(2,2)$ and between $(1,1)$ and $(1 / 2,1 / 2)$. This amounts to changing $\vec{x}$ from 0 to a vector of length $|\vec{x}|=\sqrt{2}$ in a particular direction that corresponds to something close to the direction of strongest variation. The choice $|\vec{x}|=2$ is somewhat larger than this standard choice. For instance, $|\vec{x}|=2$ in the direction $\vec{x} \propto(1,1)$

[^258]corresponds to
\[

$$
\begin{equation*}
\left(\frac{\mu_{\mathrm{R}}}{P_{T} / 2}, \frac{\mu_{\mathrm{F}}}{P_{T} / 2}\right)=\left(2^{\sqrt{2}}, 2^{\sqrt{2}}\right) \approx(2.7,2.7) \tag{7}
\end{equation*}
$$

\]

We average over the directions of $\vec{x}$ instead of taking a particular direction. For this reason, the value of Eq. (6) gives results that are similar to the method that is often used. While varying the $\mu$-scales along the $(1,1)$ direction will often work, our averaging technique provides a general method that seems sensible even when the one of the directions of slowest variation happens to align with the $(1,1)$ direction.

A straightforward calculation shows that, with the definition (5),

$$
\begin{equation*}
\mathcal{E}_{\text {scale }}^{2}=\frac{|\vec{x}|^{2}}{2} \vec{A}^{2}+\frac{|\vec{x}|^{4}}{8}\left[(\operatorname{Tr} M)^{2}+2 \operatorname{Tr} M^{2}\right] \tag{8}
\end{equation*}
$$

We determine the coefficients $A_{J}$ and $M_{J K}$ by calculating the one-jet inclusive cross section for a given value of $P_{T}$ and rapidity. We use nine points in $\vec{x}$-space, obtained by setting each $\left\{\mu_{\mathrm{R}}, \mu_{\mathrm{F}}\right\}$ scale to $\left\{\frac{1}{4} P_{T}, \frac{1}{2} P_{T}, P_{T}\right\}$ and fit the results to the form given in Eqs. (3) and (4).

## B. Contour plots

We illustrate this procedure for estimating the theoretical error from this source in Fig. 2, where we display contour plots of $1+P(\vec{x})$ corresponding to the jet cross section at the Tevatron with $P_{T}=100 \mathrm{GeV}$ for $y=0$ and for $y=2$. For both values of $y$, we find a saddle point in the vicinity of $\left\{x_{1}, x_{2}\right\}=\{0,0\}$ which corresponds to $\left\{\mu_{\mathrm{R}}, \mu_{\mathrm{F}}\right\}=\left\{P_{T} / 2, P_{T} / 2\right\}$. This location of the saddle point is a general feature that holds throughout much of the kinematic range; it motivates the choice $\left\{\mu_{R}, \mu_{\mathrm{F}}\right\}=$ $\left\{P_{T} / 2, P_{T} / 2\right\}$ as our central values.

The estimated scale dependence error, $\mathcal{E}_{\text {scale }}$, is then obtained by averaging the deviation of the cross section at a given radius in $\vec{x}$-space. As discussed above, we choose a radius of $|\vec{x}|=2$, as indicated by the circle in Fig. 2. The slope of the $\left\{x_{1}, x_{2}\right\}$ surface is steeper for the $y=2$ case as compared with the $y=0$ case. Consequently, we find a larger $\mathcal{E}_{\text {scale }}$ for $y=2(\sim 18 \%)$ as compared to $y=0(\sim$ $9 \%$ ).

## C. Comment on the range of scale choices

In the above analysis, we estimate the theoretical uncertainty by varying the $\mu$ scales by a factor about a central value. This is a conventional choice, but is it reasonable? To examine this question, one can look at cases in which NNLO calculations exist. Here, we choose one typical case as an example. In Fig. 3, we show the NNLO cross section for Higgs production at the Large Hadron Collider (LHC) as a function of the $P_{T}^{\text {veto }}$ parameter as calculated by Ref. [2]. Here, the renormalization and factorization scales are varied by a factor of $2,\left\{\mu_{\mathrm{R}}, \mu_{\mathrm{F}}\right\} \in\left[M_{\mathrm{h}} / 2,2 M_{\mathrm{h}}\right]$.

FIG. 2 (color online). Contour plot of the jet cross section in the $\left\{x_{1}, x_{2}\right\}$ plane for the Tevatron $(\sqrt{s}=1960 \mathrm{GeV})$ with $P_{T}=$ 100 GeV and (a) central rapidity $y=0$ and (b) forward rapidity $y=2$. We plot the ratio of the cross section compared to the central value at $\left\{x_{1}, x_{2}\right\}=\{0,0\}$. Contour lines are drawn at intervals of 0.10. The (red) circle is at radius $|x|=2$.

Consider, for example, $P_{T}^{\text {veto }}$ near 80 GeV . To simplify our argument, let us suppose that the exact QCD result is known and that it lies in the middle of the NNLO error band. We then ask whether the estimated NLO error band was reasonable, now that we know the exact answer. To do a real statistical analysis, we should have at hand many NLO calculations of separate and independent quantities, each with its error estimate. For each such quantity, a NNLO calculation that we can regard as nearly "exact" should be available. We would then plot the distribution of the differences between the NLO central value and the true answer in units of the NLO $1 \sigma$ error estimate. If the error estimates are reliable, this distribution should be a Gaussian distribution with width 1 . We cannot do that with just one datum. However, we can say that if the

PHYSICAL REVIEW D 81, 035018 (2010)

FIG. 3 (color online). The cross section for Higgs production at the LHC for LO, NLO, and NNLO calculations as taken from Ref. [2]. The computed cross section vetos jets $\left(P_{T}^{\text {jet }}>P_{T}^{\text {veto }}\right)$ in the central region $|\eta|<2.5$.

NLO estimate is reasonable then the central NNLO value in the one case that we have should be roughly $1 \sigma$ away from the NLO central value. If it is $3 \sigma$ away, then it seems likely that the NLO error was underestimated. If it is $0.1 \sigma$ away, then seems likely that the NLO error was overestimated. In the case at hand, the difference is about $1 \sigma$, so we have some evidence that the error was correctly estimated.

## D. Scale dependence total uncertainty

Implementing the procedure outlined above, we find the theoretical systematic error estimated from scale dependence, $\mathcal{E}_{\text {scale }}$; this is displayed in Fig. 4. The (blue) points are $\mathcal{E}_{\text {scale }}$ computed as described above from the NLO cross section [1] and the (red) curve is a smooth fit to these points.

We see that $\mathcal{E}_{\text {scale }}\left(P_{T}, y\right)$, is a slowly rising function of $P_{T}$. For the rapidity $y=0$ at the Tevatron $(\sqrt{s}=$ 1960 GeV ), we find that $\mathcal{E}_{\text {scale }}\left(P_{T}, y\right)$ varies from $9 \%$ to $11 \%$. For $y=1$, the uncertainty ranges from $9 \%$ to $20 \%$, and for $y=2$ the uncertainty increases even more, ranging from $12 \%$ to $25 \%$ over a more limited $P_{T}$ range.

## E. Scale dependence correlated uncertainty

As described in Sec. II, we decompose the total scale dependence uncertainty, $\mathcal{E}_{\text {scale }}$, into a (small) number of functions $f_{J}\left(P_{T}, y\right)$ which then combine to form the total uncertainty $\mathcal{E}_{\text {scale }}$.

Since the $f_{J}\left(P_{T}, y\right)$ functions represent independent sources of uncertainty, $\mathcal{E}_{\text {scale }}$ is the quadrature sum

$$
\begin{equation*}
\mathcal{E}_{\text {scale }}\left(P_{T}, y\right) \equiv \sqrt{\sum f_{J}\left(P_{T}, y\right)^{2}} \tag{9}
\end{equation*}
$$

We chose a set of functions $f_{J}\left(P_{T}, y\right)$ that satisfies Eq. (9).

FIG. 4 (color online). The estimate of the uncertainty $\mathcal{E}\left(P_{T}, y\right)=\mathcal{E}_{\text {scale }}$ due to the scale variation as given in Eq. (8) for the Tevatron $(\sqrt{s}=1960 \mathrm{GeV})$ with $y=\{0,1,2\}$. The calculation from the jet code is represented by the (blue) points, and the fit based on Eq. (9) is shown with the solid (red) curve.

FIG. 5 (color online). The estimate of the uncertainty $\mathcal{E}_{\text {scale }}$ due to the scale variation as given in Eq. (8) for the Tevatron ( $\sqrt{s}=$ 1960 GeV ) with $y=\{0,1,2\}$. The combined uncertainty $\mathcal{E}_{\text {scale }}$ is shown as the upper thick (red) curve, and the individual functions $f_{J}\left(P_{T}, y\right)$ are indicated below.

We take the $f_{J}\left(P_{T}, y\right)$ to depend on $y$ and on the ratio of $P_{T}$ to the quantity ${ }^{4}$

$$
\begin{equation*}
M(y)=\sqrt{s} e^{-y} \tag{10}
\end{equation*}
$$

For the set of $f_{J}\left(P_{T}, y\right)$ functions we choose

$$
\begin{align*}
& f_{1}\left(P_{T}, y\right)=\frac{9.62 \times 10^{-2}}{\log \left(M(y) / P_{T}\right)}, \\
& f_{2}\left(P_{T}, y\right)=\frac{2.89 \times 10^{-2} y^{2}}{\log \left(M(y) / P_{T}\right)}, \\
& f_{3}\left(P_{T}, y\right)=8.42 \times 10^{-2},  \tag{11}\\
& f_{4}\left(P_{T}, y\right)=0.842 \times 10^{-2} y^{2}, \\
& f_{5}\left(P_{T}, y\right)=1.68 \times 10^{-2} \log \left(\frac{15 P_{T}}{M(y)}\right) \\
& f_{6}\left(P_{T}, y\right)=0.336 \times 10^{-2} y^{2} \log \left(\frac{15 P_{T}}{M(y)}\right) .
\end{align*}
$$

[^259]These functions are illustrated in Fig. 5. The first two terms are singular as $P_{T} \rightarrow M(y)$. The first controls the singular behavior near $y=0$ while the second modifies the singular behavior for large $y$. The remaining terms constitute a polynomial in $\log \left(P_{T}\right)$ and $y^{2}$. Thus, we parametrize the $y$-dependence with the set of functions $\left\{1, y^{2}\right\}$, and the $P_{T}$-dependence with the set of functions $\{1 / L, 1, L\}$ where $L$ represents a logarithmic function of $P_{T}$. We believe that the parametrization in terms of these $2 \times 3=6$ functions is sufficient to reasonably describe the theoretical uncertainties.

Note that the coefficients of $f_{3}$ and $f_{4}$ are in the ratio $10: 1$ and the coefficients of $f_{5}$ and $f_{6}$ are in the ratio 5:1. While we could find an excellent fit without $f_{4}$ and $f_{6}$, we retain these terms to provide flexibility when one tries to fit the $\lambda_{J}$ coefficients to actual data.

We can perform a similar exercise for the LHC as well; these results will be compiled and presented in Sec. VII.

## IV. SUMMATION OF THRESHOLD LOGS

For parton-parton scattering near the threshold for the production of a jet with a given $P_{T}$, there is restricted phase space for real gluon emission. Thus, there is an incomplete

FIG. 6 (color online). The ratio of the two-loop threshold resummation contributions for jet production compared to the total NLO cross section $\sigma_{\text {resum }} / \sigma_{\text {NLO }}$ at the Tevatron $(\sqrt{s}=$ 1960 GeV ) vs $P_{T}$ in GeV . We have set the scales to $\mu_{\mathrm{F}}=\mu_{\mathrm{R}}=$ $P_{T} / 2$, and used $y=0$. The points are computed using the implementation of the 2-loop threshold resummation by Kidonakis and Owens [9].
cancellation of infrared divergences between real and virtual graphs, resulting in large logarithms $L$ inside the integration over parton momentum fractions. At $n$th order in $\alpha_{\mathrm{s}}$ these logarithms enter the cross section in the general form $\alpha_{\mathrm{s}}^{n} L^{2 n}$. The leading logarithms can be summed to all orders in $\alpha_{\mathrm{s}}$. We make use of the numerical results from Ref. [3], which has been implemented in the FASTNLO program [4].

Figure 6 displays the size of the threshold correction for Tevatron jet measurements at $y=0$. The curve is presented for the scale choice $\mu=P_{T} / 2$; we note that for this scale choice, the threshold correction is generally smaller than with other scale choices. ${ }^{5}$

We find the threshold corrections in this kinematic regime to be less than those discussed in the previous section (Sec. III) and shown in Fig. 5. As the threshold corrections also arise from uncomputed higher-order terms, these corrections are, in a sense, already accommodated by the larger uncertainty that we estimated from scale variation in Eq. (11). Indeed, the functions $f_{J}$ for $J=1$ and $J=2$ contain singularities for $P_{T} \rightarrow M(y)$ that are meant to incorporate the threshold singularities. For this reason, we will not add a separate $f_{J}\left(P_{T}, y\right)$ function in the expression for the total uncertainty $\mathcal{E}$ to represent the effects of threshold logarithms.

[^260]
## V. UNDERLYING EVENT AND HADRONIZATION

A separate source of uncertainties in jet measurements comes from what is colloquially known as "splash-in" and "splash-out" corrections. "Splash-in" corrections arise from the underlying event, which can deposit additional energy into the jet cone; we will refer to these more formally as underlying event (UE) corrections. "Splashout" corrections come from the hadronization process of the jet which may move some of the jet energy outside the defined jet cone. We will refer to these as hadronization corrections (HC).

In either case, the correction is modeled as adding an amount $\delta P_{T}$ to the observed transverse momentum (or transverse energy) of the jet. We denote the average over many events of $\delta P_{T}$ by $\left\langle\delta P_{T}\right\rangle$. A complete analysis of the UE and HC contributions was performed by Cacciari, Dasgupta, Magnea, Salam in Refs. [5-7]. We find this to be an entirely suitable method for our estimate of $\left\langle\delta P_{T}\right\rangle$, and we adapt their results in the following.

## A. Underlying event (UE)

We can parametrize the effect of the underlying event corrections on the apparent $P_{T}$ of the jet as

$$
\begin{equation*}
\left\langle\delta P_{T}\right\rangle_{\mathrm{UE}}=\Lambda_{\mathrm{UE}} \frac{1}{2} R^{2} \tag{12}
\end{equation*}
$$

where $R$ is the cone radius of the jet and $\Lambda_{\mathrm{UE}}$ is the average transverse energy per unit rapidity in the underlying event. Because we model the "splash-in" energy as random and uncorrelated with how the jet develops, the contribution from the underlying event will scale as the area of the jet cone-hence the factor of $R^{2}$ in Eq. (12). At Tevatron energies, Ref. [5] finds

$$
\begin{equation*}
\Lambda_{\mathrm{UE}}(1960 \mathrm{GeV}) \approx 3 \pm 1 \mathrm{GeV} \tag{13}
\end{equation*}
$$

Thus, the $\left\langle P_{T}\right\rangle$ shift from the underlying event corrections is given by

$$
\begin{equation*}
\left\langle\delta P_{T}\right\rangle_{\mathrm{UE}} \approx+0.7 \mathrm{GeV} \pm 0.3 \mathrm{GeV} \tag{14}
\end{equation*}
$$

for a jet cone with $R=0.7$.

## B. Hadronization correction (HC)

The $R$ dependence of hadronization correction is very different from that of the underlying event correction [57]. The smaller the jet cone is, the more likely it is that hadronization will spray hadrons out of the cone. Hence, we will parametrize these corrections as proportional to $1 / R$. Following Ref. [5], we write the hadronization correction as

$$
\begin{equation*}
\left\langle\delta P_{T}^{i}\right\rangle_{\mathrm{HC}}=-C_{i} \frac{2}{R} \mathcal{A}\left(\mu_{I}\right) \tag{15}
\end{equation*}
$$

where $\mathcal{A}\left(\mu_{I}\right)$ parametrizes the soft gluon radiation. Reference [5] takes $\mu_{I}=2 \mathrm{GeV}$, and finds $\mathcal{A}(2 \mathrm{GeV}) \approx$ 0.2 GeV . In Eq. (15), $C_{i}$ is a color factor that depends on
whether the jet is initiated by a quark, for which $C_{i}=$ $C_{\mathrm{F}}=4 / 3$, or by a gluon, for which $C_{i}=C_{\mathrm{A}}=3$. We thus need an estimate of the fraction of jets that are gluon jets. Using calculations from the literature [8], we estimate that, for the Tevatron in the low $P_{T}$ region, the fractions of quark and gluon jets are approximately

$$
f_{q} \approx \frac{2}{3}, \quad f_{g} \approx \frac{1}{3}
$$

Using these fractions, we can form a weighted average of the quark and gluon terms to obtain

$$
\begin{align*}
\left\langle\delta P_{T}\right\rangle_{\mathrm{HC}} & =f_{q}\left\langle\delta P_{T}^{q}\right\rangle_{\mathrm{HC}}+f_{g}\left\langle\delta P_{T}^{g}\right\rangle_{\mathrm{HC}} \\
& =-f_{q} \frac{2 C_{\mathrm{F}}}{R} \mathcal{A}\left(\mu_{I}\right)-f_{g} \frac{2 C_{\mathrm{A}}}{R} \mathcal{A}\left(\mu_{I}\right) \\
& \approx-1 \mathrm{GeV} \pm 0.5 \mathrm{GeV} . \tag{16}
\end{align*}
$$

Here, we have used a typical cone radius of $R=0.7$ and taken a conservative choice for the uncertainty of $50 \%$ of the correction.

## C. $\left\langle\delta P_{T}\right\rangle$ from the UE and HC

Combining the underlying event of Eq. (14) and the hadronization corrections of Eq. (16), the net $P_{T}$ shift is

$$
\begin{equation*}
\left\langle\delta P_{T}\right\rangle \approx-0.3 \mathrm{GeV} \pm 0.6 \mathrm{GeV} \tag{17}
\end{equation*}
$$

where we have added the separate uncertainties in quadrature.

The individual underlying event and hadronization results for $\left\langle\delta P_{T}\right\rangle$ are displayed in Fig. 7 for the Tevatron using the parametrizations of Eq. (14) and (16). The combined result for $\left\langle\delta P_{T}\right\rangle$, including the uncertainty band, is also displayed. The underlying event and hadronization

FIG. 7 (color online). We display the expected $P_{T}$ shift, $\left\langle\delta P_{T}\right\rangle$, in GeV vs jet cone radius $R$ for the UE, HC, and combined results (TOT) at the Tevatron. The calculation of the HC uses a combination of quark-initiated $\left(f_{q}=2 / 3\right)$ and gluon-initiated $\left(f_{g}=1 / 3\right)$ jets. The upper solid (blue) line represents the UE correction, and the lower solid (green) line represents the HC terms. The combination of these corrections (TOT) is represented by the central (red) band including the uncertainties. The vertical line corresponds to $R=0.7$.
corrections have opposite sign, and we note that for a jet cone radius of $R=0.7$, the two corrections nearly cancel each other.

## D. From $\left\langle\delta P_{\boldsymbol{T}}\right\rangle$ to $\boldsymbol{\delta} \boldsymbol{\sigma}$

The differential jet cross section can be approximated by a power law of the form

$$
\begin{equation*}
\frac{d \sigma\left(P_{T}\right)}{d P_{T}} \approx \frac{\mathrm{const}}{P_{T}^{n}} \tag{18}
\end{equation*}
$$

in the specific $P_{T}$ range of interest. For jets at the Tevatron in the intermediate $P_{T}$ range of $\sim[50,300] \mathrm{GeV}$, we find $n \approx 7$ as illustrated by Fig. 8.

The effect of the underlying event and hadronization corrections is to shift the jet $P_{T}$ from its value $P_{T}^{\text {pert }}$ at the NLO parton level to a new value

$$
P_{T}=P_{T}^{\text {pert }}+\left\langle\delta P_{T}\right\rangle,
$$

where $\left\langle\delta P_{T}\right\rangle$ is the average change in the transverse jet transverse momentum due to underlying event additions and hadronization subtractions from Eq. (17).

If we write the true differential cross section as a function $f$,

$$
\frac{d \sigma\left(P_{T}\right)}{d P_{T}} \equiv f\left(P_{T}\right)
$$

then $f$ is related to the perturbatively calculated function $f_{\text {pert }}$ by

$$
f\left(P_{T}\right) \approx f_{\text {pert }}\left(P_{T}^{\text {pert }}\right)=f_{\text {pert }}\left(P_{T}-\left\langle\delta P_{T}\right\rangle\right)
$$

We can perform a Taylor expansion about $P_{T}$ for small $\delta P_{T}$,

FIG. 8 (color online). Jet cross section $d^{2} \sigma / d P_{T} / d y$ vs $P_{T}$ in GeV with $y=0$ at the Tevatron in units of $\mathrm{nb} / \mathrm{GeV}$. The line is a power law fit with $n=7$; this describes the slope of the jet data in the range $P_{T} \approx[50,300] \mathrm{GeV}$.

$$
\begin{aligned}
f\left(P_{T}\right) & \approx f_{\text {pert }}\left(P_{T}-\left\langle\delta P_{T}\right\rangle\right) \\
& \approx f_{\text {pert }}\left(P_{T}\right)-\left\langle\delta P_{T}\right\rangle \frac{d f_{\text {pert }}^{\prime}\left(P_{T}\right)}{d P_{T}} \\
& =f_{\text {pert }}\left(P_{T}\right)\left\{1+n \frac{\left\langle\delta P_{T}\right\rangle}{P_{T}}\right\} .
\end{aligned}
$$

Here we have used the power law of Eq. (18) to replace $f^{\prime}\left(P_{T}\right)$ by $-n f\left(P_{T}\right) / P_{T}$. Thus, to first order we find ${ }^{6}$

$$
\begin{equation*}
\frac{d \sigma}{d P_{T}} \approx \frac{d \sigma_{\mathrm{pert}}}{d P_{T}}\left[1+n \frac{\left\langle\delta P_{T}\right\rangle}{P_{T}}+\cdots\right] \tag{19}
\end{equation*}
$$

so that the fractional correction is $n\left\langle\delta P_{T}\right\rangle / P_{T}$. Using $n \approx$ 7 and the estimate from Eq. (17) of $\left\langle\delta P_{T}\right\rangle$, we find that the fractional correction to the cross section is approximately

$$
7 \times \frac{-0.3 \mathrm{GeV} \pm 0.6 \mathrm{GeV}}{P_{T}} \approx-\frac{2 \mathrm{GeV}}{P_{T}} \pm \frac{4 \mathrm{GeV}}{P_{T}}
$$

Thus we estimate the fractional uncertainty from the underlying event and hadronization to be $4 \mathrm{GeV} / P_{T}$.

We account for this source of uncertainty by adding a new function $f_{J}\left(P_{T}, y\right)$ with $J=7$,

$$
\begin{equation*}
f_{7}\left(P_{T}, y\right)=\frac{4 \mathrm{GeV}}{P_{T}} \tag{20}
\end{equation*}
$$

for Tevatron jets in the $P_{T}$ range of $\sim[50,300] \mathrm{GeV}$.

## VI. SUMMARY FOR THE TEVATRON

We have described the correlated theoretical systematic uncertainty using a total of seven functions, as summarized in Table I. The net error at any one value of $\left\{P_{T}, y\right\}$ is obtained by adding these seven functions in quadrature

$$
\begin{equation*}
\mathcal{E}\left(P_{T}, y\right) \equiv \sqrt{\sum f_{J}\left(P_{T}, y\right)^{2}} \tag{21}
\end{equation*}
$$

We now summarize the complete set of contributions to the uncertainty of the differential jet cross section as a function of $\left\{P_{T}, y\right\}$ for the Tevatron:
$f_{1}\left(P_{T}, y\right)=\frac{9.62 \times 10^{-2}}{\log \left(M(y) / P_{T}\right)}, \quad f_{2}\left(P_{T}, y\right)=\frac{2.89 \times 10^{-2} y^{2}}{\log \left(M(y) / P_{T}\right)}$
$f_{3}\left(P_{T}, y\right)=8.42 \times 10^{-2}, \quad f_{4}\left(P_{T}, y\right)=0.842 \times 10^{-2} y^{2}$,
$f_{5}\left(P_{T}, y\right)=1.68 \times 10^{-2} \log \left(\frac{15 P_{T}}{M(y)}\right)$,
$f_{6}\left(P_{T}, y\right)=0.336 \times 10^{-2} y^{2} \log \left(\frac{15 P_{T}}{M(y)}\right)$,
$f_{7}\left(P_{T}, y\right)=\frac{4 \mathrm{GeV}}{P_{T}}$.
We display these results in Fig. 9. For $P_{T} \gtrsim 100 \mathrm{GeV}$, the perturbative uncertainties are dominant, and slowly rise

[^261]TABLE I. A compilation of the source of uncertainties $\left(f_{J}\right)$ that comprise the total jet cross section uncertainty $\mathcal{E}$. The perturbative uncertainties arise from the higher, uncalculated, orders of perturbation theory and are estimated using the $\left\{\mu_{\mathrm{F}}, \mu_{\mathrm{R}}\right\}$ scale variation of the calculated cross section. The nonperturbative uncertainties are an estimate of the underlying event and hadronization corrections.

| Uncertainty $f_{J}$ | Source |
| :--- | :---: |
| $\left\{f_{1}, f_{2}, f_{3}, f_{4}, f_{5}, f_{6}\right\}$ | perturbative |
| $f_{7}$ | nonperturbative |

with increasing $P_{T}$; this results holds across the full $y$-range, but the rise with $P_{T}$ is more pronounced at large $y$. For $P_{T} \lesssim 100 \mathrm{GeV}$, the uncertainty from the UE and HC terms become increasingly important as $P_{T}$ decreases.

## VII. THEORY ERRORS AT THE LHC

Having demonstrated the method for determining the theoretical systematic uncertainty at the Tevatron, we perform a parallel analysis for the Large Hadron Collider (LHC).

## A. Perturbative uncertainty

We again estimate the error from not having calculated beyond NLO by using the dependence of the NLO cross section on the scales $\left\{\mu_{\mathrm{R}}, \mu_{\mathrm{F}}\right\}$, just as in the Tevatron case, and this yields the functions $\left\{f_{1}, f_{2}, f_{3}, f_{4}, f_{5}, f_{6}\right\}$ summarized in Eq. (27) at the end of this section.

## B. Underlying event and hadronization

We proceed as in Sec. V for the Tevatron, accounting for the changed circumstances at the LHC. We first need to estimate the error in the determination of the contribution to the average jet transverse momentum, $\left\langle\delta P_{T}\right\rangle$, arising from the underlying event and from hadronization.

The underlying event contribution to $\left\langle\delta P_{T}\right\rangle$ is determined by the parameter $\Lambda_{\mathrm{UE}}$ in Eq. (12). Consistently with Refs. [5-7], for the LHC we take $\Lambda_{\mathrm{UE}}(14 \mathrm{TeV}) \approx$ $10 \pm 4 \mathrm{GeV}$, and obtain

$$
\begin{equation*}
\left\langle\delta P_{T}\right\rangle_{\mathrm{UE}} \approx+2.5 \mathrm{GeV} \pm 1 \mathrm{GeV} \tag{23}
\end{equation*}
$$

For the contribution to $\left\langle\delta P_{T}\right\rangle$ from hadronization, we use Eq. (16) with $\mathcal{A}\left(\mu_{I}\right) \approx 0.2 \mathrm{GeV}$ as before. For the fractions $f_{q}$ and $f_{g}$ of quark and gluon jets in the relatively low $P_{T}$ region where the hadronization corrections are significant, we use

$$
f_{q} \approx \frac{1}{3}, \quad f_{g} \approx \frac{2}{3} .
$$

Using these fractions, we can form a weighted average of the quark and gluon terms and estimate the hadronization contribution to $\left\langle\delta P_{T}\right\rangle$ to be

$$
\begin{equation*}
\left\langle\delta P_{T}\right\rangle_{\mathrm{HC}}=-1.4 \mathrm{GeV} \pm 0.7 \mathrm{GeV} \tag{24}
\end{equation*}
$$

FIG. 9 (color online). A compilation of the uncertainties for jet production at the Tevatron $(\sqrt{s}=1960 \mathrm{GeV})$ for $y=\{0,1,2\}$. The numeric label corresponds to the error components summarized in Eq. (27). The upper thick (red) line is the quadrature sum of the individual errors.

Combining the underlying event and hadronization contributions, we estimate

$$
\begin{equation*}
\left\langle\delta P_{T}\right\rangle \approx+1 \mathrm{GeV} \pm 1.2 \mathrm{GeV} \tag{25}
\end{equation*}
$$

where we have added the separate uncertainties in quadrature.

The results for the underlying event and hadronization contribution to $\left\langle\delta P_{T}\right\rangle$ are displayed in Fig. 10 for the LHC using the parametrizations of Eq. (24) and (23) but with a variable cone size $R$.

The correction to $\left\langle\delta P_{T}\right\rangle$ determines the correction to the cross section via Eq. (19). For this, we need the power $n$ that describes the approximate power law fall off of the cross section. As illustrated in Fig. 11, a power law with $n \approx 6$ describes the data over the range $P_{T} \approx$ $[100,1000] \mathrm{GeV}$. Using $n \approx 6$ and the estimate from Eq. (25) of $\left\langle\delta P_{T}\right\rangle$, we find that the fractional correction to the cross section is approximately

FIG. 10 (color online). We display the expected $P_{T}$ shift, $\left\langle\delta P_{T}\right\rangle$, in GeV vs jet cone radius $R$ for the $\mathrm{UE}, \mathrm{HC}$, and combined results (TOT) at the LHC. The calculation of the HC uses a combination of quark-initiated $\left(f_{q}=1 / 3\right)$ and gluon-initiated ( $f_{g}=2 / 3$ ) jets. The upper solid (blue) line represents the UE correction, and the lower solid (green) line represents the HC terms. The combination of these corrections (TOT) is represented by the central (red) band including the uncertainties. The vertical line corresponds to $R=0.7$.

$$
6 \times \frac{1 \mathrm{GeV} \pm 1.2 \mathrm{GeV}}{P_{T}} \approx \frac{6 \mathrm{GeV}}{P_{T}} \pm \frac{7 \mathrm{GeV}}{P_{T}}
$$

Thus we estimate the fractional uncertainty from the underlying event and hadronization to be $7 \mathrm{GeV} / P_{T}$. We include this in the estimate of systematic theoretical errors by including a function $f_{7}\left(P_{T}\right)$ given by

$$
\begin{equation*}
f_{7}\left(P_{T}\right)=\frac{7 \mathrm{GeV}}{P_{T}} \tag{26}
\end{equation*}
$$

for LHC jets in the range $P_{T} \approx[100,1000] \mathrm{GeV}$.

## C. Summary: LHC

We now summarize the complete set of contributions to the uncertainty of the differential jet cross section as a function of $\left\{P_{T}, y\right\}$ for the LHC:

FIG. 11 (color online). Jet cross section $d^{2} \sigma / d P_{T} / d y$ vs $P_{T}$ in GeV with $y=0$ at the LHC $(\sqrt{s}=14 \mathrm{TeV})$ in units of $\mathrm{nb} / \mathrm{GeV}$. The line is a power law fit with $n=6$; this describes the slope of the jet data in the range $P_{T} \approx[100,1000] \mathrm{GeV}$.

FIG. 12 (color online). A compilation of the uncertainties for jet production at the $\operatorname{LHC}(\sqrt{s}=14,000 \mathrm{GeV})$ for $y=\{0,1,2\}$. The numeric label corresponds to the error components summarized in Eq. (27). The upper thick (red) line is the quadrature sum of the individual errors.
$f_{1}\left(P_{T}, y\right)=\frac{4.56 \times 10^{-2}}{\log \left(M(y) / P_{T}\right)}, \quad f_{2}\left(P_{T}, y\right)=\frac{1.24 \times 10^{-2} y^{2}}{\log \left(M(y) / P_{T}\right)}$
$f_{3}\left(P_{T}, y\right)=5.36 \times 10^{-2}, \quad f_{4}\left(P_{T}, y\right)=0.536 \times 10^{-2} y^{2}$,
$f_{5}\left(P_{T}, y\right)=1.07 \times 10^{-2} \log \left(\frac{15 P_{T}}{M(y)}\right)$,
$f_{6}\left(P_{T}, y\right)=0.214 \times 10^{-2} y^{2} \log \left(\frac{15 P_{T}}{M(y)}\right)$,
$f_{7}\left(P_{T}, y\right)=\frac{7 \mathrm{GeV}}{P_{T}}$.
We display these results in Fig. 12. In the central rapidity $(y \sim 0)$ region for $P_{T} \gtrsim 500 \mathrm{GeV}$ the perturbative uncertainties are dominant and slowly rise with increasing $P_{T}$, while for $P_{T} \lesssim 500 \mathrm{GeV}$ the nonperturbative uncertainties become increasingly important. For $y=2$, the transition $P_{T}$ is closer to 300 GeV than 500 GeV .

## VIII. CONCLUSIONS

As the LHC prepares to take data, it is important that we be able to determine whether a physics signal is consistent with the standard model. For example, if we observe a signal that is inconsistent with the standard model predic-
tion, but this inconsistency includes only experimental errors, we cannot claim this is "new physics" until we demonstrate it is also inconsistent including both experimental and theoretical errors. This paper provides a framework to quantitatively make such a determination in the case of jet physics. Similarly, this paper provides a framework to quantitatively fit parton distribution functions to Tevatron and LHC jet data, including estimated errors from the theory.

The framework that we provide involves functions $f_{J}\left(P_{T}, y\right)$ that represent independent contributions to the theory error. We note that other authors might estimate the errors differently and thus produce different functions $f_{J}\left(P_{T}, y\right)$. We hope that this will happen and that the merit of different choices will be debated.

# Regularization, Renormalization, and Dimensional Analysis: Dimensional Regularization meets Freshman E8BM 

Fredrick Olness ${ }^{a, b}$ \& Randall Scalise ${ }^{a}$<br>${ }^{a}$ Department of Physics, Southern Methodist University, Dallas, TX 75275-0175, U.S.A. and<br>${ }^{b}$ Theoretical Physics Division, Physics Department, CERN, CH 1211 Geneva 23, Switzerland

#### Abstract

We illustrate the dimensional regularization technique using a simple problem from elementary electrostatics. We contrast this approach with the cutoff regularization approach, and demonstrate that dimensional regularization preserves the translational symmetry. We then introduce a Minimal Subtraction $(M S)$ and a Modified Minimal Subtraction $(\overline{M S})$ scheme to renormalize the result. Finally, we consider dimensional transmutation as encountered in the case of compact extra-dimensions.

## A. Introduction and Motivation

In 1999, Gerardus 't Hooft and Martinus J.G. Veltman received the Nobel Prize in Physics "for elucidating the quantum structure of electroweak interactions in physics." In particular, they demonstrated that the nonabelian electroweak theory could be consistently renormalized to yield unique and precise predictions.

A key ingredient for their demonstration was the development of the dimensional regularization technique.[1, 2, 3] That is, instead of working in precisely $D=4$ spacetime dimensions, they generalized the dimension to be a continuous variable so they could compute the theory in $\mathrm{D}=4.01$ or $\mathrm{D}=3.99$ dimensions. ${ }^{1}$

An important property of the dimensional regularization is that it respects gauge and Lorentz symmetries; ${ }^{2}$ this is in contrast to the other regularization schemes (e.g., cutoff schemes, etc.) which violate these symmetries. The symmetries of the electroweak theory play an critical role in determining the dynamics of the particles and their interactions. Because it respects these symmetries, dimensional regularization has become a essential tool for the calculation of field theories.

While dimensional regularization is an powerful and

elegant technique, most examples and applications of dimensional regularization are in the context of complex higher-order Quantum Field Theory (QFT) calculations involving gauge and Lorentz symmetries. However, the virtues of dimensional regularization can be exhibited without the "distractions" of the associated QFT complexities.

In the present paper, we will apply the dimensional regularization method to a problem from an elementary undergraduate physics course, namely the electric potential of an infinite line of charge. [5, 6] The example is simple enough for the undergraduate to understand, yet contains many of concepts we encounter in a true QFT calculation. We will contrast the symmetry-preserving dimensional regularization approach with a symmetryviolating cutoff approach.

Imagining a variable number of dimensions can be a productive exercise. To explain the weak nature of the gravitational force physicists have recently posited the existence of "Extra Dimensions." Having considered space-time dimensions in the neighborhood of $D=4$, we briefly contemplate wider excursions of $D=4,5,6, \ldots$ dimensions.

## II. DIMENSION ANALYSIS: THE PYTHAGOREAN THEOREM

To illustrate utility of dimensional regularization and dimensional analysis, we warm-up with a pre-example. Our goal will be to demonstrate the Pythagorean Theorem, and our method will be dimensional analysis.
