5.2 Theory publications - Hornbostel ..... 2340

## 1. Overview

This grant covered an umbrella program of research in high-energy particle physics at Southern Methodist University during the period 2004-2013. The experimental program evolved during that time. At its early stages it included research on the CLEO experiment at CESR (Coan, Stroynowski, Ye), D0 experiment at Tevatron (Kehoe), preparation for the BTEV experiment at Fermilab (Coan) and construction and commissioning of the Liquid Argon Calorimeter for the ATLAS experiment at LHC (Stroynowski, Ye). In the last three years the program concentrated on the ATLAS experiment at LHC (Kehoe, Sekula, Stroynowski, Ye), D0 experiment at Tevatron (Kehoe) and NOvA experiment at Fermilab (Coan). Professor Sekula had a short-term independent grant for which he is submitting a separate report. The theoretical physics program included work on non-perturbative methods in the light cone representation (McCartor (deceased)), lattice calculations (Hornbostel), and determination of parton distribution functions (Olness). A summary of the accomplishments emphasizing results from the past three years is provided separately for each of the tasks.

## 2. ATLAS.

The SMU group has been among the founding members of the US ATLAS program. Stroynowski co-authored the 1994 LOI submission. Ye joined in 1997, Kehoe in 2004 and Sekula in 2009. During the detector construction phase SMU was responsible for the optical data links and parts of the front-end electronics of the Liquid Argon Calorimeter. Stroynowski and Ye are part of the ATLAS Liquid Argon Collaboration. Maintenance of the links and the handling of their operational problems remains their primary responsibility. Stroynowski has been the US-ATLAS Level-2 manager for the Liquid Argon Calorimeter system during the detector design, construction, installation and commissioning. He relinquished his responsibilities in 2010 to devote his time to data analysis. Ye lead the electronics group at SMU. His R\&D program resulted in the world's fastest ASIC serializer chips, exceeding 5 Gbps , designed for HEP applications. His program is on track towards a goal of 200 Gbps per Front-End Board planned for the ATLAS detector upgrade. In 2011 Ye was appointed as the Level-2 manager for the US-ATLAS LAr upgrade program. He also coordinates US efforts with our European colleagues. In addition, Ye has been elected as the ATLAS convener in the joint ATLAS-CMS optoelectronics working group. During the commissioning and operations phase, our SMU group's responsibilities expanded to the areas of the Trigger and Data Acquisition and to the detector operations and Data Quality. Kehoe established the initial TDAQ organization for the Liquid Argon calorimeter and its connection to the overall ATLAS system. He was appointed a convener of the Liquid Argon Calorimeter TDAQ/Data Quality performance group for 2005-2008. His primary focus has been physics analysis, and has been appointed co-convenor of the H $\rightarrow$ WW Theory study group. Kehoe and Sekula are now members of the ATLAS TDAQ Collaboration. Sekula worked on trigger performance for the 2011-2012 run and explored the calorimeter trigger changes required for the Phase I detector upgrade. He has been appointed a co-convener of the ATLAS supersymmetric Higgs study group. The overall ATLAS effort at SMU was shared among the maintenance and operation tasks of the experiment, a significant involvement in data analyses and R\&D towards the ATLAS upgrade.

### 2.1 Recent Research Activities and Accomplishments

Even though the individual faculty members have well-defined areas of responsibility, there is a significant internal collaboration and sharing of effort to fulfill ATLAS requirements towards the operation of the experiment, shifts and in the sharing of expertise in data analyses. During the last three years Sekula supervised postdoc Aidan Randle-Conde and graduate student Tingting Cao. Stroynowski supervised postdocs David Joffe, Julia Hoffman and some of the work of Ana Firan and graduate students Rozmin Daya, Renat Ishmukhametov and Ryan Rios and shared with Ye the supervision of Andy Liu. Ye supervised postdocs Hulin Wang, shared the supervision of postdoc Ana Firan and led the electronics group of Andy Liu, Annie Xiang, Datao Gong and Kent Liu. Finally, Kehoe supervised, on the ATLAS experiment, postdocs Haleh Hadavand, Peter Renkel, software engineer Sami

Kama, and graduate students Yuri Ilchenko, Pavel Zarzhitski, Azeddine Kasmi and Kamile Dindar. The group size was largest in 2010 and has shrunk in the following year due to graduations and departures. In 2012 the base program supported 3 postdocs and 1 graduate student. Kama, Liu, Xiang and Gong were supported by the ATLAS Project and by the Versatile Link Project funds. The group shared the experiment's operations tasks that included shifts, software development and improvements and creation of various monitoring displays for the ATLAS Control Room.

ATLAS has been a very productive experiment. At the time of this writing there have been over 250 papers published in the refereed journals and about 490 conference submissions. The discovery of the Higgs boson is considered to be the main accomplishment of the last three years. In addition, however, no phenomena expected from physics beyond the Standard Model have been observed in the energy range below 1 TeV . Since the beginning of data taking SMU group has been very active in several data analyses described in the following sections. There have been significant contributions to 16 ATLAS publications, 26 conference papers and a large number of internal ATLAS support notes. These, together with work on the electronics developments ( 6 papers) are described in the following sections. Additional notes and presentations not discussed in the following sections are listed in Refs. [J1, M1-M10]. Only papers that have been published and had significant SMU contribution are appended to this report.

In the following we describe work done under individual supervisions. The collaborative efforts are cross-referenced with names attached to the titles.

### 2.2. Stroynowski (with Joffe, Hoffman, Firan, Daya, Ishmukhametov, Rios and Ye)

After 14 years of service Stroynowski relinquished in 2010 his responsibilities as the US-ATLAS Level-2 manager for the Liquid Argon Calorimeter system to devote more time to data analysis. He spent his 2010/2011 sabbatical leave at CERN. He applied his knowledge of the calorimeter to physics analyses with signatures of electrons, photons and highly ionizing particles. Early work included: the development of the software for the reconstruction of gamma conversions; measurements of single- and double-photon spectra; improvements of the electron identification near the edges of the detector; improvement of the track-cluster matching using a Gaussian Sum Filter; and to the searches for the Higgs boson signal in two photon and four lepton final states and searches for the high mass dilepton resonances and other signatures of physics beyond the Standard Model. The focus of recent work has been on the Higgs search in the 4 -lepton final state ( $4 \mathrm{e}, 2 \mathrm{mu} 2 \mathrm{e}$ and 4 mu ). This work resulted in a large number of internal ATLAS notes and significant contributions to many conference and journal papers. The calorimetry signals expertise was applied also to a number of analyses with large groups of collaborators as described later. Finally, Stroynowski served on an editorial board for the 2011 ATLAS paper on excited lepton searches and was an internal reviewer of several general ATLAS and specialized Liquid Argon calorimeter papers,
conference notes and posters and participated in US ATLAS reviews of computing and LAr Calorimeter upgrade.

## Detector Operations and Service Work

a) Optical links (with Ye and Liu)

The maintenance of the LAr optical data links remains a major hardware responsibility of the SMU group as part of US ATLAS M\&O program. Shortly after the closure of the detector in 2009 we observed failures of the links that were identified as due to the catastrophic failures of the VCSELs on the transmitter (OTx) units. Extensive studies concluded that the failures were due to humidity penetrating broken packaging of the VCSELs that had been damaged during OTx assembly. The spectrum width of a VCSEL was found to be a good indicator of its lifetime. About 70 Front End Boards that exhibited narrow optical spectrum (i.e. had OTx suspected to be affected by humidity) were replaced with spares during the December 2010 shutdown and no new OTx failures were observed since then.
b) Detector operations (with Hoffman, Rios, Ishmukhametov, Daya and Firan)

Hardware-related work included development of the calorimeter control panels for the ATLAS Control Room and calibration and cross-talk measurement of the LAr calorimeter readout channels. Rios developed a series of control and monitoring panels for the high- and low-voltage systems and an overall shifter panel. These had to be periodically updated for each new release of the TDAQ software. Rios was an on-line expert for the 2009-2011 run periods and developed a number of automatic recovery procedures for several types of detector failures. These increased the data taking efficiency to close to 99\%. For the 2011-2012 runs Rios and Hoffman became Shift Leaders for the 14 person ATLAS shift crews. Firan took a substantial number of calorimeter data quality monitoring shifts.
c) Software developments (with Joffe, Hoffman, Daya and Ishmukhametov)

1. Ishmukhametov used the LAr readout calibration system to measure the cross talk between the 173,000 individual readout channels. The procedure was developed in 2009 and the results were re-checked in 2010. Tables of the cross-talk corrections are installed in the calorimeter software.
2. Joffe wrote the original package for the reconstruction of gamma conversions. The maintenance and update of this package has been taken over by the ATLAS e/gamma Working Group [Ref. A1].
3. Ishmukhametov developed specialized software to handle missing calorimeter readout channels due to failures of the optical data links for the 2010 data.
4. Hoffman coordinated software documentation for the ATLAS e/gamma Working Group. She ensures that all software package information used for physics analyses is current and relevant. This documentation is used by hundreds of users.
d) Electron identification (with Hoffman and Rios)

The study of electron identification was initiated in 2009 initially as the calibration of its energy using the Z boson signature and later in the context of Higgs decays to 4 leptons. Initial work emphasized enhancing the acceptance. Hoffman developed a method for the identification of electrons initially in the crack region between the barrel and end cap calorimeters and later within all edges of the detector. This method allowed for identification of electrons with incomplete showers or imperfect tracks and was incorporated into the general ATLAS software. It is maintained, improved and adapted to the changing run conditions by the e/gamma performance group. Further improvement was obtained by the introduction of a Gaussian Sum Filter (GSF)-based method to correct the electron trajectory for bremsstrahlung. The GSF uses a sum of Gaussian distributions to approximate the Bethe-Heitler distribution to model bremsstrahlung energy loss. Hoffman and Rios made numerous studies to validate the track parameters of electrons reconstructed using a GSF on data and MC. This resulted in better matching of tracks with calorimeter clusters and significantly increased electron identification efficiency [B2].
e) Photon Identification (with Joffe, Daya and Ishmukhametov)

Daya, Ishmukhametov and Joffe developed a measurement of the rate of electronphoton misidentification. The completely data-driven method relied on observation of a peak in the electron-photon invariant mass at the location of the Z pole. The misidentification rate was calculated from the magnitude of this peak, due to the fact that the "photon" came from misidentification of one electron in $\mathrm{Z} \rightarrow$ ee decay [A1]. This method has been used by Daya and Ishmukhametov for all photon spectra measurements in 2010-2012 and for the $\mathrm{H} \rightarrow \gamma \gamma$ searches. For early 2010 data the misidentification rate was found to be $\left(8.1 \pm_{\text {stat }} 2.0 \pm_{\text {syst }} 0.5\right) \%$. Initially, $86 \%$ of fake photons from electron misidentification came from the converted photon recovery procedure that resulted in objects being classified simultaneously as both photons and electrons. It was found that the high misidentification rate from photon recovery occurs predominately in those regions where there are dead or partially dead b-layer tracking modules in the detector. The misidentification rate has been further reduced in 2012 due to improved efficiency of the track-cluster matching for electrons using the GSF.

## Physics analyses

a) Measurement of the prompt photon cross section with the ATLAS detector (with Joffe, Daya, Ishmukhametov and Hadavand)

The measurement of the prompt photon and diphoton cross sections depends crucially on the estimate of the background due to fake photons. Daya and Ishmukhametov continued their work on electron-photon misidentification to calculate the impurity of the photon sample from electrons coming predominantly from Z and W decays. This provided a systematic error on the central value of
photon purity used to calculate the cross section. Ishmukhametov calculated the systematic uncertainty related to the loss in acceptance arising from the fact that photon candidates in problematic detector regions were not used in the analysis. To account for this effect in physics analyses, an object quality flag was assigned for each reconstructed electron or photon. This flag was based on the location of the core of the electromagnetic cluster of a given particle in relation to the dead or disabled detector region. For physics analyses done with direct electrons or photons, only particles passing object quality requirements were considered. The fraction of particles that are rejected due to this cut is usually calculated based on Monte Carlo samples of corresponding physics process, for which the object quality cut is also applied. Ishmukhametov studied the systematic uncertainty on applying MC based acceptance loss to the signal from data. He found this uncertainty to be on the level of 0.5\% for photons in early collision data. This work was documented in a number of ATLAS internal notes and presentations [A1-A11], was the basis of Ishmukhametov's Ph.D. thesis [A12], and was used in three publications [A13-A15].
b) Search for Higgs boson in the diphoton channel (with Daya and Ishmukhametov)

The technique of the data-driven electron-photon misidentification was also used for the search for $\mathrm{H} \rightarrow \gamma \gamma$ decays in the 2010 and 2011 data. Daya studied the contribution to the fully reducible background from the Drell-Yan process, where both electrons in the decay are misidentified as photons. This contribution was found to be $\sim 0(1 \%)$ of the total background. Ishmukhametov performed a Monte Carlo study of the effect of an increase in the photon energy resolution on the exclusion limit that can be set on the SM Higgs in the diphoton channel. To test this, the Higgs mass was reconstructed using photons that had their energies changed by $0.5 \%$ in one scenario and $1 \%$ in another. This procedure resulted in a "smeared" Higgs mass with broadened resolution. The effect on the Higgs exclusion was found to be a degradation of $8 \%$ of the expected limit. This work is documented in the ATLAS notes and conference presentations [C1-9] and the publication [C10]. It did not continue in 2012 due to graduations and departures.
c) Search for Higgs boson decays to 4 leptons (with Hoffman and Rios, Cao and Sekula)

The search for the Higgs boson in its decays to 4 leptons (electrons or muons) has been at the center of the group's attention for the past three years. Since a discovery is always made with the smallest number of events, the effort has been concentrated at maximizing the detection acceptance and efficiency and on the study of backgrounds. Hoffman and Rios took part in various tasks vital to the Higgs Working Group and had leading roles in optimization of electron identification, signal selection efficiency, and background rejection algorithms. These included managing the technical aspects of a cut-flow optimization and acceptance challenge, calculating final signal efficiency, systematic uncertainties for exclusion limits for both electrons and muons, and validation of an algorithm that accounts for the effects of bremsstrahlung on electrons (the GSF, discussed above).

To maximize the signal identification acceptance Hoffman and Rios studied in 2010 the cases where one or two leptons had been of a lesser quality or one of the leptons was in the forward region where there is not tracking information. For these " $2+2$ " and " $3+1$ " cases, where the second number refers to "imperfect electrons", the trade-off between the signal and the background was established. Many of the results were used to improve electron identification package that uses 32 parameters of the calorimeter signal shapes and track properties for the electron selection. For the 2011-2012 conferences, Hoffman and Rios continued analysis optimization and studied systematic uncertainties, trigger efficiencies, and Monte Carlo generator comparisons between PYTHIA and POWHEG for signal samples. They also coordinated an acceptance challenge for the group - ensuring the proper interpretation and application of selection criteria. In March 2012 they organized workshop that produced data selection criteria for the summer 2012 version of the analysis. For the discovery paper they estimated the systematic errors for the signal and background measurements and provided input to the global statistical analyses for Higgs mass exclusion ranges leading to eventual discovery of the Higgs signal.

This work resulted in a number of internal notes, paper and presentations at all major conferences in 2010-2012 [D1-D18], Rios' Ph.D. thesis [D19], and several publications [D20-D23]. The discovery paper has been published in [D23]. Hoffman has been an author on a substantial fraction of the supporting notes and was the coordinator and editor of the fermiophobic Higgs study. The searches culminated in 2012 with an unambiguous observation of the Higgs-like particle. The papers describing the discovery are listed in Ref [D24] for the 4-lepton final state and Ref.[D23] for the combination of all significant decay modes. The follow-up study of the spin-parity assignment of the new particle is given in Ref.[D25].

Figure 1: Plots for the summer 2012 data: left) The distribution of the four-lepton invariant mass. The signal expectation for a SM Higgs with $\mathbf{m H}=125 \mathrm{GeV}$ is also shown. center) Combined search results: (a) The observed 95\% CL upper limit on the signal strength as a function of $\mathbf{m H}$ and the expectation under the background-only hypothesis. (b) The observed local $\mathbf{p 0}$ as a function of $\mathbf{m H}$ and the expectation for a SM Higgs boson signal hypothesis. (c) The best-fit signal strength as a function of $\mathbf{m H}$. The band indicates the approximate $\mathbf{6 8 \%} \mathrm{CL}$. right) The ratio of the expected and observed $95 \%$ CL upper limits on the Standard Model Higgs boson production cross section.

In the fall of 2012, the results obtained for the Higgs decays to 4 leptons were combined with those for other decay channels leading to unambiguous discovery of the Higgs-like particle. The next obvious question was what is the spin-parity of this new particle. That has been best studied in the H->ZZ*->4 lepton decay final state where there are 5 observables describing angular distributions of the decays of each of the vector boson and relative arrangement of the decay planes. The results submitted to the 2013 Moriond conference [D24-25] showed a clear preference for the JP = 0+ assignment consistent with the expectations for the Standard Model Higgs boson.
d) Study of heavy bosons and search for a narrow di-electron resonance (with Daya and Ishmukhametov)

For the early data Daya and Ishmukhametov contributed to the observation of the W and Z bosons in the electron channel. They also participated in the measurement of the W and Z inclusive cross section measurements [I1-I4]. Later, Daya worked with Stroynowski on the searches for a high mass, sequential Z boson decaying into a pair of electrons. This was an effort of a large group of collaborators. Daya's work was concentrated on the detailed studies of electron identification performance for the data sample with two high $p_{T}$ electron candidates and the development of a datadriven method of estimating the "di-jet" background. Here, jets consist mostly of randomly overlapping electromagnetic showers from e.g., neutral pion decays with a charged pion track. This causes pion-electron misidentification. Other backgrounds are due to $t \bar{t}$ decays, WW, WZ and ZZ decays and the Drell-Yan process
[I5-I12]. The search for the signature of the sequential boson in the forwardbackward asymmetry of the decay electrons was the basis of Daya's Ph.D. thesis. [I13]

The di-electron spectrum showed excellent agreement with the estimated background. [I14-I15].

Figure 2: Dielectron invariant mass. Data points are shown in black. Various background estimates are shown in colors. The expectations for the sequential Z' bosons with masses of 1000,1250 and 1500 GeV are shown as unfilled colored histograms.

The data allowed us to set cross-section limits as function of Z' mass and these can be interpreted in terms of particular models. For the 2011 data these 95\% CL exclusions were: for the sequential SM-like Z' at $\mathrm{M}<1.83 \mathrm{TeV}$, and for an E6 modellike Z' at $\mathrm{M}<1.64 \mathrm{TeV}$.
e) Search for long-lived highly ionizing particles (with Firan and Ye)

The search for long-lived, highly ionizing particles was led at SMU by Firan. She originally designed the search for magnetic monopoles in her 2008 Ph.D. thesis [H1]. The signature of such a particle in ATLAS consists in the Inner Detector of track that has high-energy deposition due to ionization and manifests as a high fraction of TRT hits. The track is then matched with a narrow shower in the electromagnetic calorimeter.

This work was done together with groups from York and Oxford Universities and documented in Refs. [H2-H7].

The initial search was performed for massive, highly ionizing particles with lifetimes in excess of 100 ns (HIPs), using $3.1 \mathrm{pb}^{-1}$ of $p p$ collision data taken at $\sqrt{s}=7$. No events passed the selection criteria. Cross section upper limits between 1.2 pb and 11.5 pb have been extracted for HIPs with electric charges between $6 e$ and $17 e$ and masses between 200 GeV and 1000 GeV , were obtained under two kinematic assumptions: a generic isolated HIP in a fiducial range of $\eta$ and kinetic energy, or a

Drell-Yan fermion pair-production mechanism. In the resulting publication [H8] HIP mass ranges above 800 GeV were probed for the first time at a particle collider.

The signal of the magnetic monopole is characterized by a heavy ionization in its passage through matter and a trajectory that will bend in the $\mathrm{r}-\mathrm{z}$ plane but will be a straight line in the $\mathrm{x}-\mathrm{y}$ plane. The main effort of Firan for over two years was to correctly generate, simulate and propagate magnetic monopoles within the framework of the ATLAS Monte Carlo in order to obtain acceptance and efficiency for signal selection. She created and tested software package capable of generating magnetic monopole events with different masses and different magnetic charges for two production mechanisms: the Drell-Yan process and the two-photon process. This software became a part of the official MadGraph generator. For the detector response simulation and the propagation of the magnetic monopole through ATLAS, a new version of the GEANT G4Monopole package was created. This includes the correct propagation of a magnetically charged particle in the magnetic field present in the Inner Detector. A correction for the saturation effect due to high ionization in the material (Birk's Law) was calculated using the heavy ion collision data recorded by ATLAS. An analysis of $2 \mathrm{fb}^{-1}$ of 7 TeV data yielded no events passed the selection criteria. This allowed for the extraction of upper limits on the production cross section that extended to higher masses and significantly improved on the Tevatron limits. The paper published in Phys. Rev. Letters [H9].

Figure 3: Upper limits on the monopole production cross sections at 95\% confidence level. The solid line is the limit for single monopoles in the fiducial region and the dashed line is the limit assuming the kinematic distributions from Drell-Yan (DY) monopole pair production.

## f) Azimuthal Decorrelation in Dijet Events

The radiation of multiple quarks and gluons is one of the more complex aspects of perturbative quantum chromodynamics (pQCD). The proper description of radiative processes is crucial for a wide range of precision measurements as well as searches for new physical phenomena (SUSY, Higgs, etc.), where the influence of

QCD radiation is unavoidable or even for verifying various theoretical models. Hoffman and Rios, together with the BNL group, studied the azimuthal decorrelation, $\Delta \Phi$ of the leading (in $p_{T}$ ) jets in Monte Carlo simulation and data. In particular, they focused on two effects on the $\Delta \Phi$ distribution: when the z-position of the primary vertex was shifted by several millimeters, and and when there was an increase in multiple pp interactions per bunch crossing (in-time pile-up). In both cases, for the-amount-of data analyzed, the effects were negligible. Their work was part of a larger study that measured $\Delta \Phi$ in central high- $p_{T}$ di-jet events measured with the ATLAS detector. The main conclusion from the larger study is that results from an NLO pQCD calculation and from several Monte Carlo event generators provide a reasonable description of the normalized differential cross section. The results of this study were documented in the internal notes and conference papers [F1-F4] and published in Ref. [F5].
2.3.Ye (with Goldin, A. Liu, Xiang, Gong, K. Liu, Randle-Conde, Wang, Stroynowski, and Sekula)
a) Overview of past and current contributions

Ye is an experimentalist with the ATLAS collaboration. His primary recent work has been on detector readout. He supervises the research staff of the SMU OptoElectronic Laboratory. His work within the laboratory focuses on projects for ATLAS upgrades and for ATLAS operation. Ye's physics analysis effort has focused on two primary areas: the search for the Higgs boson via its $\mathrm{H} \rightarrow \mathrm{Z} \gamma$ decay channel and the search for a Dirac magnetic monopole.

Since 2011 Ye has been appointed the US ATLAS Level-2 manager for the Liquid Argon Calorimeter upgrade in which he works with groups from University of Arizona, Columbia University Nevis Lab, Brookhaven National Lab, Stony Brook University, University of Pennsylvania, and SMU. Ye is also the co-coordinator of the Joint ATLAS-CMS Opto Working Group that meets twice a year to address common issues in optical links in both experiments. One ATLAS-CMS common R\&D project, the Versatile Link (VL) [ $\mathrm{N}-6$ ], has evolved from this working group to develop radiation tolerant optical transceivers at $5 \mathrm{~Gb} / \mathrm{s}$ for the LHC upgrade. SMU is one of the three founding members in the VL collaboration. Collaborating with FNAL, ANL, UMN and OSU, SMU is leading the efforts in HEP to develop radiation-tolerant 10 $\mathrm{Gb} /$ s optical transmitters to answer the demands of $\mathrm{n} \times 100 \mathrm{~Gb} /$ s per front-end board in future HEP experiments.
b) Detector readout electronics and SMU's responsibility in ATLAS Operation:

Ye joined ATLAS in 1998, working with groups from CPPM, IPSC Grenoble, KTH, IPAS and SMU on the optical link system that reads out the LAr [ $\mathrm{N}-1$ ]. He later became the coordinator of this optical link group and led the project to its completion. In this project the SMU group gained valuable experience and expertise in high-speed serial data transmission over fiber optics for HEP experiments. We developed the capability to conduct irradiation tests on integrated circuits, optical transmitters and optical fibers [ $\mathrm{N}-2$ ], as well as system design and integration for fiber optics.

The LAr optical link system operates at $1.6 \mathrm{~Gb} / \mathrm{s}$ per fiber and has 1524 fibers with a total data bandwidth over $2.4 \mathrm{~Tb} / \mathrm{s}$. The transmitting side of the link resides inside the ATLAS detector. Hence it must withstand the significant radiation dose estimated for the 10-year operation at or above the design luminosity. This optical link is the state-of-the-art currently in use in HEP experiments. The SMU group (Ye together with the research staff and Stroynowski) has been responsible for this link system's maintenance and operation (M\&0) since the link's commissioning.

SMU was an integral part of the team that diagnosed and resolved one of the major challenges we have encountered in operating these links in the ATLAS Detector environment. The team was a task force led by the ATLAS electronics coordinator, and worked in close collaboration with groups in LAr and in other detector subsystems such as the Inner Tracker. It was observed that the optical transmitter (the OTx with a Vertical Cavity Surface Emitting LASER, or VCSEL) could sometimes fail. We investigated VCSEL failures caused by Electro-Static-Discharge (ESD) and by moisture in the ambient environment. Shown in Figure 5 is the VCSEL optical spectrum width (an indicator of the health of the device) subjected to different ESD. It is clear that the backward ESD does more damage to the emitting optical power. The ESD is introduced through a Human Body Model ESD circuit.

Figure 4: Optical spectrum of the VCSEL subject to ESD. The left plot lists results of forward ESD at $0 \mathrm{~V}, 500 \mathrm{~V} 700 \mathrm{~V}$ and 1100 V (from top down) while the right plot backward ESD at $0 \mathrm{~V}, 200 \mathrm{~V}, 300 \mathrm{~V}$ and 500 V .

The SMU group also conducted a life-test of one OTx operated in ambient air. As shown in Figure 6 below, the width of the VCSEL spectrum decreases with time, a clear indication that the OTx cannot operate stably with moisture in ambient air. This life-test is still ongoing at SMU with a large number of devices to gain statistical confidence.

Figure 5: VCSEL optical spectrum width as a function of time

We participated in the campaign of replacing all the optical transmitters that have weakened VCSELs with spares during the 2010 winter shutdown. Using the facility at SMU, we re-screened the spares with improved QA procedures. After this campaign, we no longer have problems with the OTx. The SMU group also provided a backup solution to this problem with the design of a new optical transmitter that has a redundant channel (the Dual-OTx), as shown in Figure 7. In the photo the Dual-OTx (top), which has the same electrical footprint as the OTx, is compared with one (bottom) that is currently in use.

Figure 6: Diagram and photo of the Dual-0Tx

This new design has been fully evaluated, and is now awaiting the collaboration's decision on a production to rebuild the spares. The SMU group is committed to the M\&O of the ATLAS LAr optical link system. By actively participate in the LAr upgrade program, this group maintains the expertise and equipment for high-speed serial data transmission, in particular over fiber optics, for HEP. This is vital for our commitment in the M\&0.
c) SMU's involvement in ATLAS upgrades and general R\&D for HEP
(i) The R\&D work on ASIC and components: As stated in the Letter of Intent to ATLAS, the phase-1 upgrade "will allow ATLAS to maintain low $P_{T}$ trigger thresholds for isolated leptons by increasing the granularity of the calorimeters involved in the Level-1 trigger". In this upgrade a new LAr Trigger Digitizing Board (LTDB) will be developed. Each LTDB will digitize calorimeter signals and send the digital information to the back-end via optical links with an aggregated data bandwidth above $200 \mathrm{~Gb} / \mathrm{s}$ per LTDB. A new data processing unit based on the FPGA architecture will also be developed to extract information for the Level-1 trigger.

The R\&D projects at SMU are supported by the US-ATLAS Operation to find solutions for the data transmission in the LAr trigger upgrade (phase-1) and for the whole LAr readout electronics upgrade (phase-2). In both cases we need optical links that withstand the LAr detector front-end radiation for the design luminosity and the expected operation lifetime after these LHC upgrade phases. The link's transmitting side must fit in the power dissipation constraint set by the existing cooling system, and must be highly reliable due to lack of frequent access for maintenance and repairing.

Other than this R\&D for a particular application, we are also supported through DOE's generic R\&D (Ye with BNL and Xiang with FNAL) to develop optical transmitters for future calorimeters. In these R\&D projects, plus the one that is supported by a DOE ADR grant (Ye, 2008-2010), we have identified a commercial 0.25 micron Silicon-on-Sapphire CMOS technology for ASIC developments in HEP [ $\mathrm{N}-3$ ]. This ADR project at SMU follows the efforts in DMILL, GaAs. It is in parallel to the evaluations in SiGe, the 0.25 and 0.13 micron CMOS technology carried out in the HEP community to study IC technologies for HEP experiments. Based on the SOS technology, we have successfully prototyped designs of a $16-\mathrm{to}-1,5 \mathrm{~Gb} / \mathrm{s}$ singlechannel serializer [ $\mathrm{N}-4$ ] and a 4.9 GHz phase-locked-loop for fast clock synthesizing
[ $\mathrm{N}-5$ ]. Shown in Figure 8 are the picture of the prototype chip $\left(3 \times 3 \mathrm{~mm}^{2}\right)$ and measured eye diagram of this serializer.

Figure 7: a photograph of the prototype chip which hosts the serializer, the phase-locked-loop (PLL) and several other designs. The 2:1 multiplexing unit in the serializer is visible in the upper left corner of the chip. In the lower right corner one finds the two wire loops functioning as inductors in the PLL. The eye diagram was measured at $5 \mathrm{~Gb} / \mathrm{s}$.

In June 2012, we submitted designs of a 2-channel array serializer, a single channel 50 Ohm VCSEL driver and an open-drain 4-channel array VCSEL driver, all designed to operate at $8 \mathrm{~Gb} / \mathrm{s}$ per channel. This represents the highest speed of such data transmission ever designed in HEP. The layout of this prototype chip is shown Figure 9. The test of these designs will start in 2013.

Figure 8: layout of the prototype chip submitted in June 2012. The 2-channel array serializer with its PLL clock unit takes most part of the chip area. The laser drivers are on the right side of the chip, with the 4-channel array VCSEL driver visible in the lower right corner

As mentioned above, the SMU team is collaborating with FNAL and several other US institutions to develop $10 \mathrm{~Gb} / \mathrm{s}$ per channel radiation-tolerant optical transmitters to meet the challenges of high data rates in future detector front-end readout. In this R\&D project, SMU takes two approaches, one based on TOSA (packaged VCSEL or Transmit Optical Sub-Assembly) and the other based on array optics, to strike a balance among constraints in channel and system reliability, power consumption and heat management, optical coupling efficiency, and cost. In the same line of optical link developments and in the framework of the Versatile Link Common Project, we collaborate with a group in Oxford, UK (ATLAS Inner Tracker) on fiber and passive component identifications and evaluations [ $\mathrm{N}-8$ ]. In the VL project, SMU is responsible for studies that provide link system level design guidelines [N-7]. All of these efforts have already been proven to be helpful and cost-saving in the particular optical link design for LAr phase-1 upgrade.
(ii) Ye's responsibility as the US ATLAS Level-2 manager: as a managerial duty Ye works closely with US and international institutions that are interested and contributing to the LAr upgrades, in particular the phase-1 LAr trigger upgrade. The US institutions lead the efforts to upgrade the front-end by designing a full digital trigger board. The US is also a key player in developments for the back-end electronics. SMU takes sole responsibility for the transmitting side of the optical link system, and works with European collaborators on the link's receiving end. All these R\&Ds involve component or subsystem developments such as the analog front-end (UPenn, BNL), the analog to digital converter ASIC (Nevis), the LOC ASIC, the optical data link and the GBT, VTRx based control link (SMU), and the back-end FPGA based data processer (UAZ, BNL, and SUNYSB); they also involve system level design and demonstration. In March 2012 at SLAC the US LAr team in the upgrade had an internal review in which the reviewing committee commended the efforts and achievements of the team. We are on-track in preparation for CD reviews and for a construction phase starting in 2014. On the international side, the LAr collaboration is aiming for an ATLASTechnical Design Review in mid-2013. From a technical standpoint, we plan to construct a full-scale demonstrator system (front- and backend boards and the optical link between them) with ASICs and COTS, and install the demonstrator LTDB inside ATLAS during the 2013-14 shutdown (the LS1) period. This demonstrator will be a vital step from which we gain experience and guidance in components and system developments towards the final installation during the 2018 shutdown (the LS2). Prioritized by US-ATLAS, projects in the phase-1 LAr trigger upgrade are on-track.
(iii) SMU in LAr phase-1 upgrade: SMU plays an important role in the LAr phase-1 upgrade. Ye with his group is responsible for developing the SOS based LOC ASIC chipset (several designs), and the optical data link that transmit digitized trigger data from the front-end LTDB to the back-end sPU, which is the FPGA-based super Processing Unit that provides processed information for the Level- 1 Trigger. We
also develop the GBT, VTRx-based control link that provides clock, configuration, control and monitoring to the front-end electronics. The LTDB will replace the function of the present analog Trigger Tower Build Board (TBB); the control link will replace functions that are currently provided by two boards in the front-end crate: the Controller Board and the Monitoring Board. The data rate from one LTDB will be above $200 \mathrm{~Gb} / \mathrm{s}$, 2 orders of magnitude higher than the current state-of-art: $1.6 \mathrm{~Gb} / \mathrm{s}$ from one Front-End Board (the FEB) in LAr.

Aside from difficulties in high data rate and in the radiation tolerance requirement from the increased design luminosities of the LHC upgrade, challenges in this upgrade also come from constraints such as the cooling capacity that will be kept unchanged. For example, with more than 100 times increase in data rate, the power dissipation budget to the optical link will only be allowed to increase by a factor of 10. In these regards, we have successfully prototyped ASIC designs that will meet the requirements for the upgrade. We are also working on a few final prototypes that will lead us towards the packaged IC chips that will be used in the optical link of the LTDB.
d) Physics analyses with ATLAS data:

Searching for Dirac magnetic monopole (Firan, Stroynowski, and Ye): This work was a collaborative effort within the SMU ATLAS group and was described in section 1.2e.

Searching for Higgs via $\mathrm{H} \rightarrow \mathrm{Z} \gamma$ final states (Goldin, Randle-Conde, Sekula, Wang, and Ye): Ye initiated this work at SMU with postdoctoral fellow Daniel Goldin. This is a channel that may contribute to the search for Standard Model Higgs with decays into $\gamma \gamma$ and ZZ (4 leptons final states), it may also probe physics beyond the SM should an enhancement in the number of events be observed in data. Such an enhancement might indicate new particles in place of the W and Top loop.

Goldin carried out MC studies that include the feasibility of Higgs associated production with a Z or a W in which the Higgs decays into $\mathrm{H} \rightarrow \mathrm{Z} \gamma$. Goldin's work stopped for lack of data and he later moved to a Tevatron experiment with a different institution. In early 2012 this work was resumed at SMU with Aidan Randle-Conde (postdoc), graduate students and later joined by Hulin Wang (postdoc starting in August 2012). Sekula, Ye and Stroynowski are also active in this search. Although the branching fraction for the $\mathrm{Z} \gamma$ final state is similar to that for Higgs
decay to two photons, the background from QCD mediated decays are more severe and the limits obtained in the search done so far have been about a factor of 6 larger than those predicted by the Standard Model.

### 2.4. Kehoe (with Hadavand, Dindar, Kama, Kasmi)

Kehoe studies the mechanism of electroweak symmetry breaking primarily through the measurement of the top quark mass and the search for the Higgs boson in diboson events. Significant contributions in jet energy calibration and trigger and data quality (DQ) software support this effort. ATLAS Higgs studies leverage D0 top research, partly via common signatures and analysis techniques.

ATLAS Detector Operations:
Thousands of cores in the High Level Trigger (HLT) execute trigger and monitoring algorithms using a modified ATLAS Athena framework. Since 2005, Kehoe led a US ATLAS project developing key elements of the monitoring side of the trigger system, including the DQ Monitoring Framework (DQMF) with UC Irvine, and the Gatherer. In 2010, Kehoe and Sekula formally joined TDAQ as a group at SMU. Kehoe now focuses on the challenges posed for by multi-core CPUs and 64-bit software, which requires redesign of the core Trigger software.
a) Data Quality (Hadavand, Renkel, Kama, Kehoe, Kasmi): SMU develops the central online application, 'Gatherer', that employs a variety of algorithms to centrally sum or merge monitoring output for final DQ. Renkel maintained Gatherer and implemented several improvements such as allowing fine time granularity down to one luminosity block. Kama took over development in late 2010 and upgraded its interaction with ATLAS Run Control. Renkel, Kasmi and Kehoe developed a software test bed that established the acceptable CPU and memory performance of the Gatherer and its scalability for increased numbers of histogram providers. Later tests by Kama in new HLT nodes pointed to future scalability challenges. Partly due to this exercise, Kama developed with Kehoe, Renkel and Hadavand a proposal for a new 'MonInfoGatherer' (MIG) application. The designed framework splits the control structures from information handling and summation methods. The latter is exposed as an API that enables gathering as a plug-in for other applications. This greatly enhances scalability when many-core processors are used by enabling gathering within each HLT node. The framework approach also provides easy extensibility, letting custom containers and summation methods to be easily implemented. Kama presented this proposal at a TDAQ Software week and implemented MIG in stages. A fully functional MIG has been included in TDAQ releases and is recently running at Point1 in parallel with the monolithic Gatherer. Side-by-side tests indicate similar performance in the current HLT, while MIG has the plug-in capability needed for the future.

SMU Calorimeter monitoring continued in 2010 with development by Hadavand of improved Athena algorithms for reconstructed topological clusters, towers and cells, including monitoring of jets from CaloTowers. Her tools were used by CaloGlobal, LAr, Tile and Jet/Etmiss shifters for final DQ sign-off, and she and Kehoe took shifts during the period. She also maintained and updated the package of DQ algorithms used in DQMF [M.9] including adding helper algorithms to facilitate development in online and offline contexts. Kama performed code inspections of the important HistMon and OHP services. DQ is performed in Tier0 using DQMF connected to offline-specific services, including a web-based display used by all offline shifters. Kama took over web-display development in 2010/2011. He improved stability and incorporated many new features, including flexibility to choose histograms by stream or run. Kama was the primary on-call expert for the offline DQ which was a major responsibility to maintain the operation and software of the system. He made several substantial improvements, including easing DQ configuration, improving DQ application task management, bookkeeping and improving speed and efficiency of DQ production, and automating error reporting to experts. Kama supported users during this time, creating an archived DQ help mailing list and arranging a Good Monitoring Practices Workshop. His work greatly improved the stability of the offline DQ. The contributions of several SMU members who built and operated various elements of the DQ were key to the rapid ability to analyze new data for the recent Higgs observation.
b) Trigger Core Software and Performance Optimization (Kama):

ATLAS software must be restructured to take maximum advantage of current and future hardware architectures. Current challenges include implicit serialization of processing, or lack of vectorization. Following our efforts on Gatherer performance, Kama was asked to test reconstruction algorithms. He identified to the developers two bottlenecks where reordering the objects in memory would reduce cache misses, and vectorization of calculations reduce CPU stalls. He currently serves as the TDAQ representative to the A-Team which pursues solutions for these kinds of challenges. Multiprocessing overcomes the limitation posed by highly multi-core processors. To facilitate multiprocessing in the HLT ('HLTMP'), Kama works with the new implementation of a multiprocessing Athena ('AthenaMP') from the ATeam. He created a new set of packages including a HelloWorld application and a test bed for HLTMP implementation. The results confirmed the potential of using MP in the online environment and observed memory sharing was compatible with offline AthenaMP. The Data Flow evolution includes the 'HLTPU' application which incorporates the function of both Level 2 and Event Filter. Kama implemented a dummy multiprocessing HLTMPPU that simulates an HLTPU by consuming CPU similarly to real event processing which is necessary for testing TDAQ. He is now co-convenor on the TDAQ side of a new Future Software Technologies Forum for a broad discussion of computing solutions for Phase 0 through 2 upgrades.

ATLAS Physics Analyses:

Figure 9: Background-subtracted $m_{T}$ distribution in ATLAS $1 l+E_{T m i s s}$ events

Kehoe studies diboson (VV) events with a goal to search for the Higgs boson. This started in 2007 with searches in diphoton events for evidence of extra dimensions because LHC gives a dramatic increase in sensitivity over the Tevatron, even at modest integrated luminosity. To provide broad search sensitivity to the Higgs mass and to enable possible study of Higgs properties, however, he focused on the search for Higgs $\rightarrow \mathrm{WW} \rightarrow \mathrm{l} v \mathrm{l} v$. Such a search also shares many attributes with Kehoe's study of $t \bar{t}$ pairs at the Tevatron.
a) Extra Dimensions in 2g Events (Hadavand, Dindar-Yagci, Kehoe): We collaborated in the search for evidence of Universal Extra Dimensions (UED) in $\gamma \gamma^{+}$ $\mathrm{E}_{\text {Tmiss }}$ events in the first $3 \mathrm{pb}^{-1}$ of 2010 data. Dindar and Kehoe performed several comparisons of data with the total expected background in background-rich control regions. A template fit yielded the first accurate estimate of photon purity in the MC background sample [K.1]. Dindar tested different background normalization methods and the effect of pileup. Her comparisons and $c^{2}$ calculations were a focus of the Editorial Board (EB) and necessitated a final systematic uncertainty. Hadavand worked on identifying an optimal event selection and led many cross checks of expected event yield vs. event selection step that were important during group review. She studied the high $\mathrm{p}_{\mathrm{T}}$ photon efficiency to provide systematic uncertainties when the background was extrapolated into the signal region, and to provide one due to dead OTX's. Hadavand was interim editor and convenor when the primary coordinator was absent. No signal was observed and the limit exceeded the Tevatron's [K.2].

We searched for the RS graviton with the first $36 \mathrm{pb}^{-1}$, which our earlier studies showed to be competitive. Hadavand continued her emphasis on photon efficiency and OTX systematics from the UED analysis. This helped her optimize the estimation of background in the signal region. She and Dindar demonstrated that loosening the identification would maximize significance while keeping background in control. Dindar and Kehoe completed a study of the impact of coupling $\left(k / M_{p l}\right)$, which specifies the graviton width, and mass ( $\mathrm{M}_{\mathrm{G}}$ ) on signal distributions to develop a signal model. Hadavand developed a frequentist unbinned maximum likelihood fit using signal and background parametrizations. She guided Dindar to finish the implementation of this method for her dissertation [K.5], including parametrization of the signal. The resulting limit was slightly higher than the published method and surpassed the Tevatron sensitivity for $\mathrm{M}_{\mathrm{G}}>1 \mathrm{TeV}$ [K.4]. We followed this with analysis in $2.12 \mathrm{fb}^{-1}$. Hadavand contributed to the treatment of background
kinematic shapes, use of pseudoexperiments in testing the analysis performance, and making the use of PDFs more consistent. She implemented at SMU the Bayesian Analysis Toolkit used by the dilepton analyses and extracted limits. She also led the way to identify and resolve inconsistent results from different fitting methods. Hadavand was editor of the analysis support note [K.3], and co-editor of the paper. No signal was observed and the resulting limit is $\mathrm{M}_{\mathrm{G}}>0.8 \mathrm{TeV}$ for $\mathrm{k} / \mathrm{M}_{\mathrm{pl}}=0.01$ [K.6].
b) Search for Higgs $\rightarrow$ WW (Kehoe): Kehoe focused on the production of VV backgrounds for the Higgs search. This entailed overlapping work in the Higgs and SM WW groups. Kehoe worked on the determination of the WW cross section in 7 TeV collisions with technical assistance from BNL to get started. He performed the first estimation of the internal conversion $\mathrm{Wg}^{*}$ background using recently available MadGraph D3PDs, which showed this background to be at least as large as the Wg background. At the time, an NLO calculation was not available to obtain the normalization, so Kehoe compared the kinematics of Alpgen Wg and MadGraph Wg* events. He demonstrated the $\mathrm{g}^{*}$ mass ( $\mathrm{m}_{\mathrm{g}^{*}}$ ) spectrum was extremely low, even after event selection cuts, resulting in leptonic kinematics very similar to Wg . These results motivated preliminarily using the $k$-factor from Wg events in the 0 -jet bin with a large uncertainty. He also estimated the overlap of $\mathrm{Wg}^{*}$ and WZ processes. Kehoe coordinated with students from Michigan to estimate the other diboson backgrounds (WZ, Wg, ZZ), and he did the final calculation of combined statistical and systematic uncertainties. Kehoe wrote the VV background and MC portions of the SM WW support note [I.16] , the basis for presentation at Moriond [I.17]. In parallel, he presented his work on $\mathrm{Wg} / \mathrm{g}^{*}$ to the Higgs $\rightarrow \mathrm{WW}$ subgroup and contributed to that group's Planning document for 2012 analysis [E.1].

He focused in the $\mathrm{H} \rightarrow \mathrm{WW}$ group putting the $\mathrm{W}->\gamma^{*}$ on a better footing and on ensuring sufficient MC samples existed. In the former case, he studied filter thresholds so new Alpgen Wg samples greatly reduced the statistical error while being fully efficient. Kehoe's comparison of Pythia 6 and Pythia 8 variants of these samples demonstrated a problem with the Pythia 8 production so this showering was not used for final analysis. To normalize $\mathrm{W} \gamma^{*}$, Kehoe studied the correlation between $\mathrm{m}_{\mathrm{g}^{*}}$ and event kinematics. To compare with LO MCFM calculations by colleagues at Oxford and Roma Tre, he determined LO MadGraph cross sections under different mass and kinematic selections. The MCFM NLO calculation was unstable when $\mathrm{m}_{\mathrm{g}}{ }^{\lll} 1 \mathrm{GeV}$. Kehoe worked with colleagues to establish a mass range and kinematic selection from which to determine NLO cross sections. His observation of the independence of event kinematics on $\mathrm{m}_{\mathrm{g}^{*}}$ if $\mathrm{m}_{\mathrm{g}^{*}}<$ few GeV was instrumental in convincingly extrapolating a normalization for $\mathrm{m}_{\mathrm{g}} \times 0.5 \mathrm{GeV}$ into the lower mass range. A systematic uncertainty was extracted from these studies. In addition to use in the $\mathrm{H} \rightarrow \mathrm{WW}$ analysis, Kehoe ported these results and samples to the final 7 TeV SM WW cross section analysis where he repeated his VV calculation and editing roles [I.16, I.18]. He estimated several contributions to be negligible in $\mathrm{H} \rightarrow$ WW EB review: $\tau$ decays, photon FSR, and $\mathrm{W}+\mathrm{J} / \psi$ background. Kehoe was co-
editor of the $\mathrm{H} \rightarrow \mathrm{WW}$ Theory supporting note [E.2]. Upon unblinding, a 3.3s excess above background was observed with a $l l+E_{T m i s s}$ transverse mass ( $\mathrm{m}_{\mathrm{T}}$ ) distribution (see Figure 10) [E.2-7]. This contributed to the ATLAS total 5.9s observation of what appears to be the SM Higgs boson [D.23].

Kehoe also performed a study detailing differences in modeled jet multiplicity between $\mathrm{W} \gamma$ and $\mathrm{W} \gamma^{*}$ events. This was used in the systematic uncertainty for the discovery analysis, and was the basis for the reweighting approach developed in fall. Further efforts involved working with Oxford colleagues on a scheme by which Sherpa was used to model very low mass diphoton pairs. These results were presented in updates at HCP 2012 and Moriond 2013. Kehoe remained as Theory note editor, and was appointed as co-convenor of the Theory group.

Kehoe also joined the Snowmass effort to work on projections for ttH production with emphasis on $\mathrm{H} \rightarrow \mathrm{WW}$. He worked on the initial signal-to-background estimates with U. of Texas colleagues, and co-organized a Snowmass workshop on the topics. He convened a preliminary meeting in March and summarized the results and status from several groups at the April Energy Frontier meeting at BNL.

Other ATLAS Activities (Dindar, Kasmi, Kehoe with Stroynowski): The jet energy scale (JES) is important to many analyses in proton collisions. Kehoe continued an earlier JES role to prepare the report as Chair of the Review Panel for the 2009 Hadronic Calibration workshop, and to coordinate the $\gamma+$ jet session of the 2010 Pisa workshop. This placed $\gamma+$ jet as an important component of the ATLAS JES [M.10]. Kehoe advised Kasmi in the context of the wider SMU effort as he finished his analysis and dissertation on ZZ and $\mathrm{H} \rightarrow \mathrm{ZZ}$ production using topo-clusters and no tracking [I.19].

### 2.5. Sekula (with Cao, Randle-Conde, Wang, and Ye)

Sekula joined the SMU ATLAS group in 2009. Since then, he has become involved in work on the ATLAS trigger, simulation of the ATLAS trigger upgrade, and data analysis. He has earned increasing leadership roles in the physics analysis community. His primary interests are in the search for additional Higgs bosons in nature, the understanding of the properties and implications of the new state at 126 GeV , and in the effect of increasing luminosity and pile-up on trigger performance and response. These and future plans are all described below.

ATLAS Operations and Technical Work
In addition to trigger desk shifts in the ATLAS Control Room and remote data quality shifts, the primary contributions of Cao, Randle-Conde, and Sekula have been to the ATLAS TDAQ effort. These are described below.

## a) Predicting pileup effects on ATLAS trigger rates (Cao, Randle-Conde,

 Sekula)Our key technical contribution has been to understand how increasing luminosity, and thus increasing proton-proton collisions per bunch crossing ("in-time pile-up," henceforth referred to as "pile-up"), will affect ATLAS trigger rates. We have focused on developing predictive mechanisms. This information helps many members of ATLAS involved in routine operations, from the ATLAS Trigger Menu Group to the Trigger Desk Shifter, make informed decisions about alterations to trigger prescales and the trigger menu; such changes can have profound impacts on all aspects of physics analysis.

The number of pile-up collisions occurring at a given luminosity is a Poisson process, centered on a mean value given by $\mu=(L \sigma) /(f N)$, where $L$ is the instantaneous luminosity, $\sigma$ is the cross-section

Figure 10: (top) The integrated ATLAS luminosity in each year, 2010-2012. (bottom) The average collisions per bunch crossing. for proton-proton interactions, $f$ is the bunch frequency, and $N$ is the number of colliding proton bunches. For instance, for typical operating conditions present in early 2012 ( $\mathrm{L}=6 \times 10^{33} / \mathrm{cm}^{2} / \mathrm{s}$ ), $\mathrm{N}=1380$, $\mathrm{f}=11,245 \mathrm{~Hz}$, and $\sigma_{\mathrm{pp}}{ }^{\text {inelastic }}=70 \mathrm{mb}$ ) this meant a mean number of pile-up collisions was typically expected to be $\langle\mu>=27$, in good agreement with the measured values shown in alterations to trigger pre-scales and the trigger menu; such changes chave profound impacts on all aspects of physics analysis.

## b) Prediction of trigger rates with increasing pile-up (Randle-Conde, Sekula)

Postdoctoral fellow Randle-Conde has played a key role in predicting trigger rates with pile-up in the ATLAS Trigger Rates Group. Sekula initiated this project within the ATLAS Trigger Rates Group in 2010, and in 2011-2012 Randle-Conde was the leading contributor and developer of this predictive mechanism and framework; since 2011, others have become involved in aspects of the project, including Graduate Student Cao.

The importance of accounting properly for pile-up effects on trigger rates is illustrated in Figure 11 for one of the more challenging Level-1 triggers: the missing
energy significance. We see that without including the pile-up effects in trigger rate scaling, it is impossible to make reasonable predictions for the behavior of the trigger across a run (divided into luminosity blocks). Work has continued over the 2011-2012 running period and key triggers, including electromagnetic and missing energy triggers, can all now be predicted to within a few percent of the true value as a function of time during a run.

The importance of understanding trigger scaling cannot be understated. Deviations from the predicted trigger rate have been used to diagnose problems in ATLAS subsystems. For instance, recent running in the spring of 2012 saw the advent of high trigger rates due to electronics problems in one of the subsystems. The problem was observed by noting the difference from the expected trigger rate for a given set of running conditions, and then quickly reported to the subsystem and the Run Control shifter in the ATLAS Control Room. In addition, the Trigger Menu Group uses this information to decide on pre-scales and how they will be

Figure 11: A comparison of trigger rates for a particularly challenging trigger - the Level-1 computation of missing energy significance. Without a correction for pileup effects, we see that ATLAS is essentially unable to make any reasonable rate prediction. altered during running conditions to maximize data-taking and minimize dead-time.

This work has become routine and is expected to continue through the end of datataking in 2013. Other activities, described below, are then expected to become a central focus of Sekula's trigger work.

## c) ATLAS Control Room Trigger Desk Prediction vs. Measured Trigger Rate Monitoring (Cao)

Graduate student Cao began her contributions to the ATLAS Experiment in the fall of 2011, initiating a project to connect the trigger rate predictions to the Trigger Rate Presenter (TRP), a tool commonly used by both online Trigger experts and the ATLAS

Figure 12: The Trigger Rate Presenter showing Graduate Student Cao's framework for displaying rates, predictions, and comparison flags.

Control Room Trigger Desk Shifter to diagnose and resolve trigger issues.

Cao's project was to develop software adapters to deliver information needed for trigger rate prediction (obtained from online databases) to the TRP. This would allow the TRP to display predictions for the Level-1, Level-2, and Event Filter trigger systems. These predictions could then be compared to the actual rates, also displayed in the TRP. Cao's software was designed to summarize the prediction and its comparison with the real rate using a "flag" - she chose to use the number of standard deviations ("nSigma") between the prediction and the real rate. This allows the shifter to then sort the table of trigger lines by their nSigma values and isolate those with the largest deviations. Her finished project is shown in Figure 12; while much of her effort was the development of software "behind-the-scenes," the TRP panel is the visual conclusion to her work. This effort was well-regarded by both the ATLAS Trigger Online group and Trigger Rates Group.

## d) Trigger Upgrade Studies - Physics Impacts (Cao, Sekula)

The trigger is expected to undergo several upgrades during the lifetime of the ATLAS Experiment. Efforts are currently underway to develop "topological triggers" for the Phase 1 ATLAS Upgrade; rather than focusing on just the kinematics of single objects or object pairs, these triggers would focus on the angles and energies of multiple objects. In addition, efforts to develop a track trigger are underway and there is a plan to expand the Level-1 readout granularity of the calorimeter for Phase 2. While the physics impacts of the

Super-Cell definition

Figure 13: Definition of a Trigger "Super Cell," needed for high-granularity calorimeter readout studies. topological triggers are being wellstudied within ATLAS, there is still the question of the physics impacts of upgrades like a track trigger or a higher-granularity readout from the calorimeter.

Sekula began the study of increased calorimeter granularity on tau triggers in 2011 and came to some preliminary conclusions in 2012. Using what were then considered "very high-pileup" simulations samples with an average of 46 protonproton collisions per crossing, Sekula studied the possibility of using high-level tau identification variables in hardware at Level-1. The goal was not to define the hardware specifications needed to implement such a scheme, but rather to focus on whether such a scheme has a positive and meaningful physics impact.

These efforts narrowly focused on the question of whether or not a highergranularity calorimeter readout in the Level-1 trigger would allow for better discrimination of hadronic tau decays from quark and gluon jets. The parameters of such a higher-granularity readout are illustrated in Figure 13. The current trigger reads out the calorimeter in $\Delta \eta x \Delta \phi$ regions of size $0.1 \times 0.1$, which is about four times the area occupied by a single calorimeter cell ( $0.025 x 0.025$ ). Sekula investigated what would happen to tau triggers if one could read out the calorimeter using "Super Cells" (Figure 13), which are of size $0.025 \times 0.1$. This allows a more fine-grained definition of energy distribution variables, including the energy occupied by the core of an electromagnetic cluster ("Reta") and the isolation energy (the energy in a ring around the cluster).

Figure 14: the fraction of total energy in a ring around the central cluster core (Isolation Fraction). This was computed using energy in trigger Super Cells.

Using a 1 GeV energy digitization scale, Sekula and Cao defined these variables and used simulated samples of jets and highpT tau leptons to see how well they could be separated while keeping the Level-1 pT thresholds as low as possible. The overall goals of this study were to select taus with a sufficiently high efficiency (90-98\%) while also keeping the single-tau trigger within a 20 kHz rate budget for the overall trigger. An example of one of these variables, the "Isolation Fraction" (the ratio of energy in a ring around the central cluster core to the total energy of the cluster) is shown in Figure 14.

The conclusions of this preliminary study were promising, but raised a number of new questions that still need to be addressed. We found that if we could define such energy shape variables in the Level- 1 trigger, we could reduce the trigger rate by $40 \%$ while maintaining a lower pT threshold and a tau trigger efficiency of $90 \%$. However, a $40 \%$ reduction was not sufficient to achieve the goal of maintaining the tau trigger rate at 20 kHz . The best trigger rate we could achieve for a still-low pT threshold was for $\mathrm{pT}>40 \mathrm{GeV}$, and that rate was 40 kHz - still a factor of 2 too high to be reasonable for a future trigger scenario.

## e) Future Directions in Tau Trigger Studies

The ATLAS upgrade physics impact study raised important questions that need to be addressed:

The study was done using ROOT files, and rebuilding trigger towers from a combination of current Level-1 "Regions of Interest" and the calorimeter cells present in those regions. This is not how a future trigger would work. It would,
instead, START from Super Cells and define trigger towers and regions of interest. To address this problem, the study needs to be done by first implementing highgranularity software tools into ATLAS ATHENA so that ROOT files with the full trigger simulation using Super Cells can be produced. This is a significant amount of software work and was not possible in 2012 due to other commitments.

The study was done using a 1 GeV digitization scale for Super Cell energy. However, it's necessary to explore other scales ( $0.25 \mathrm{GeV}, 0.5 \mathrm{GeV}$, for instance). These may allow for better control of the long tails seen in the energy shape variables computed using the Super Cells.

A new effort is required determine how a future track trigger and a highergranularity calorimeter readout might work together to enhance hadronic tau triggering at Level-1. This is a fruitful but unexplored area of the project, and would require significant time investment to advance it.

The goal is to restart work on this area in 2012-2014 during the end of data taking and the long shutdown period. We envision a postdoctoral fellow taking the lead in this effort.

## ATLAS Physics Analysis

a) The measurement of $\mathrm{H} \rightarrow \mathrm{Z} \gamma$ (Randle-Conde, Sekula, Wang, Ye)

This measurement effort was described earlier, in section 2.4b, and is a collaboration within the SMU ATLAS group.
b) The Search for an Electrically Charged Higgs Boson ( $\mathrm{H}^{ \pm}$) (Randle-Conde, Sekula)

The discovery of a particle that is so-far consistent with the Standard Model Higgs Boson has raised a number of important questions for the field. Kehoe, Sekula, Stroynowki, and Ye are all invested in measuring the properties of this new particle by understanding its decay modes and decay rates, as well as its spin and CP quantum numbers. In addition to this critical effort, Sekula is advancing the frontier of the search for additional Higgs bosons in nature.

The existence of Dark Matter is a challenge to the Standard Model. If Dark Matter is composed of particles, those particles are not described by the SM. If the Higgs mechanism is the means by which subatomic particles acquire mass, then we are left with a key question: what Higgs boson gives mass to the Dark Matter? The SM Higgs boson is an insufficient answer to this question, as it has only enough couplings to give mass to the particles described by the SM. The search for additional Higgs bosons now takes on more urgency, and Sekula is leading an effort to find an electrically charged Higgs boson.

There are many popular extensions of the SM, most of them based in the framework of supersymmetry. In any of these extensions, at least one new Higgs field doublet is added to the SM Higgs doublet; this results in at least 5 physical Higgs boson states, two of which are always electrically charged. The observation of an electrically charged Higgs boson would be unambiguous evidence of physics beyond the Standard Model.

In addition, a decade's long effort by the B-Factories, BaBar and Belle, has yielded branching fractions for the decays $B \rightarrow X \tau^{ \pm} v$ which have strong tension with the SM predictions. Here, "X" can be either nothing or a charm meson (e.g. D or D*). The same tension is simply not present for the decays of charm mesons to these taulepton final states. This suggests that heavy flavor decays to heavy lepton final states are not well-described by the Standard Model, leaving room for contributions from a charged Higgs boson.

## Search for a low-mass $\mathbf{H}^{ \pm}$using $t \bar{t} \rightarrow W^{+} b H^{-} \bar{b}$

Figure 15: (left) the MET distribution fitted using a QCD and non-QCD template. (right) The final composition of the 2011 data, with signal overlaid.

## c) Light charged Higgs production and decay (Randle-Conde, Sekula)

The ATLAS Collaboration created a special Higgs subgroup, HSG6, in 2011 solely for the purpose of advancing the search for the charged Higgs. Randle-Conde and Sekula had become involved in this search in late 2010 and were among the first members of the ATLAS Collaboration to study, in a data-driven way, the backgrounds that would be a challenge to this search. Our focus was on the production of top pairs and their subsequent decay to the following final state:
$t \bar{t} \rightarrow W^{+} b H^{-} \bar{b} \rightarrow(j j) j_{b}\left(\tau_{h} v\right) j_{b}$
where " j " denotes a light-quark jet, "jb" denotes a bottom-quark jet, " $\tau_{\mathrm{h}}$ " denotes a hadronically decaying tau lepton, and the neutrinos in the final states of the $\mathrm{H}^{ \pm}$and
the tau decays manifest as missing transverse energy (MET). This "all-hadronic" mode is attractive in that it accesses a large portion of the possible final states of decay (the hadronic branching fractions of the W and the $\tau$ are typically twice as large as the leptonic branching fractions). However, the mode at first appears to be a significant challenge due to the presence of only hadrons in the final state.

Sekula and Randle-Conde were responsible for significant portions of the analysis. SMU took a lead role in developing the baseline cut selection, the QCD background estimate, and the evaluation of systematic uncertainties. In addition, Sekula was appointed by the HSG6 subconvener to be the analysis leader of the allhadronic final state effort, and was selected as one of three co-editors for the publication (one from each channel used in the search). The final publication included three independent topologies in the search: the all-hadronic topology (denoted "tau+jets") and two lepton-based topologies ("tau+lepton," accounting for leptonic W decays, and "lepton+jets," accounting for leptonic tau decays).

Randle-Conde's primary contribution was the measurement of the QCD background. The key variable at the end of this analysis is the "transverse mass" of the tau and missing energy system, computed using
$m_{T}^{2}=p_{T}^{\tau} E_{T}^{\text {miss }}(1-\cos \phi)$, where $\phi$ is the angle in the transverse plane between the tau momentum and the MET. This variable has a threshold at the mass of the parent particle; if the tau and MET arise from a W boson, this distribution has a threshold at the W mass. Multi-jet QCD background

Figure 16: (left) the model-independent $95 \%$ CL exclusion on the brancl (right) The MSSM exclusion in the mh-max scenar contributes to the distribution in a way that must be determined from data, as simulation of this background is usually (1) unreliable and (2) of insufficient statistical significance to draw conclusions. Randle-Conde developed a data-driven method where he inverted the tau lepton identification and required that events have no b-tagged jets in them. This produced a subsample enriched in QCD background, from which a template of the MET shape could be made. This template could then be fitted to the nominal MET shape in our signal sample to determine the fraction of the MET distribution occupied by QCD background. Finally, the QCD fraction could be fixed from the fit and the transverse mass QCD contribution determined. All of this is illustrated in Figure 15. These results appeared in a series of conference notes and internal ATLAS notes [L1-L4], culminating in the first ATLAS publication on the subject in spring 2012 [L5]. The published results were also presented by Randle-Conde and Sekula at conferences [L6-L7].

The tau+jets final state was the single most sensitive topology of the three that were combined for the publication (Figure 16).

#### Abstract

A search for the Standard Model Higgs boson in the two photon decay channel is reported, using $1.08 \mathrm{fb}^{-1}$ of proton-proton collision data at a centre-of-mass energy of 7 TeV recorded by the ATLAS detector. No significant excess is observed in the investigated mass range of $110-150 \mathrm{GeV}$. Upper limits on the cross-section times branching ratio of between 2.0 and 5.8 times the Standard Model prediction are derived for this mass range.

## 1. Introduction

The search for the Standard Model Higgs boson [1-3] is one of the key goals of the Large Hadron Collider (LHC) at CERN. The allowed Higgs boson mass ( $m_{H}$ ) is constrained at the $95 \%$ confidence level by a lower limit of 114.4 GeV from the LEP experiments [4] and an excluded region between 156 and 177 GeV from the Tevatron experiments [5,6]. First results have been reported by the ATLAS experiment in a variety of channels [7] and the CMS experiment [8] using the data recorded in 2010, which correspond to an integrated luminosity about thirty times smaller than the 2011 dataset used in this analysis.

In the low mass range, from the LEP limit to $m_{H} \approx 140 \mathrm{GeV}$, one of the most promising search channels at the LHC is the rare decay of the Higgs boson into a pair of photons. Despite the low branching ratio ( $\approx 0.2 \%$ ), this channel provides good experimental sensitivity in the mass region below 150 GeV . The results presented in this Letter are based on proton-proton collision data taken at $\sqrt{s}=7 \mathrm{TeV}$ by the ATLAS experiment between April and June 2011.

The data analysis proceeds by selecting photon pairs with tight identification and isolation cuts to minimize backgrounds other than direct diphoton production. A narrow peak in the reconstructed invariant mass distribution is searched for over a large, smooth background whose normalisation and shape are left free in a maximum likelihood fit. To increase the sensitivity, the sample is divided into five categories based on the presence of photon conversions and on the photon impact point on the calorimeter, with different invariant mass resolutions and signal-to-background ratios for the different categories.

[^0]The results of the fit are compared to the prediction from the Standard Model using the Higgs boson production cross-section and branching ratio from Ref. [9]. Limits on the production crosssection relative to the Standard Model value are then derived as a function of the hypothesised Higgs boson mass. Although with the current dataset the analysis is not yet sensitive to the predicted rate for a Standard Model Higgs boson, the limits on the yield in this decay channel improve on those obtained in the same channel by the Tevatron experiments [10-12], and are sensitive to possible enhancements in the Higgs boson production and decay rate compared with the Standard Model expectations.

## 2. Experimental setup and data set

The ATLAS detector is described in detail in Ref. [13]. The main subdetectors relevant to this analysis are the calorimeter, in particular its electromagnetic section, and the inner tracking detector.

The electromagnetic calorimeter is a lead-liquid argon sampling calorimeter with accordion geometry. It is divided into a barrel section covering the pseudorapidity ${ }^{1}$ region $|\eta|<1.45$ and two end-cap sections covering the pseudorapidity region $1.375<|\eta|<$ 3.2. It has three longitudinal layers. The first one, with a thickness between 3 and 5 radiation lengths, has a high granularity in $\eta$ (between 0.003 and 0.006 depending on $\eta$, with the exception of the regions $1.4<|\eta|<1.5$ and $|\eta|>2.4$ ), sufficient to provide discrimination between single photon showers and two photons from a $\pi^{0}$ decay. The second layer has a thickness of around 17 radiation lengths and a granularity of $0.025 \times 0.025$ in $\eta \times \phi$.

[^1]A third layer, with a thickness varying between 4 and 15 radiation lengths, is used to correct for leakage beyond the calorimeter for high energy showers. In front of the calorimeter, a thin presampler layer, covering $|\eta|<1.8$, is used to correct for fluctuations in upstream energy losses. The sampling term $a$ of the energy resolution, $\sigma(E) / E \approx a / \sqrt{E(\mathrm{GeV})}$, varies between $9 \%$ and $14 \%$ as a function of $|\eta|$ for unconverted photons [14]. It reaches up to $20 \%$ for converted photons near $|\eta|$ of 1.3 where the upstream material effect is the largest. The sampling term is the largest contribution to the resolution up to about 100 GeV , where the constant term starts to dominate. After $0.17 \mathrm{fb}^{-1}$ of data were accumulated, some calorimeter cells could not be read out. The affected region size is $\Delta \eta \times \Delta \phi \approx 1.5 \times 0.2$ in the barrel electromagnetic calorimeter, resulting in an acceptance loss for diphoton candidates of about $3 \%$. A hadronic sampling calorimeter is located behind the electromagnetic calorimeter. It is made of steel and scintillating tiles in the barrel section, and of copper and liquid argon in the end-cap.

The inner detector consists of three subsystems: at small radial distance $R$ from the beam axis ( $5<R<15 \mathrm{~cm}$ ), pixel silicon detectors are arranged in three cylindrical layers in the barrel and in three disks in each end-cap; at intermediate radii ( $30<R<$ 56 cm ), double layers of single-sided silicon microstrip detectors are used, organised in four cylindrical layers in the barrel and nine disks in each end-cap; at larger radii ( $56<R<107 \mathrm{~cm}$ ), a straw tracker with transition radiation capabilities is used. These three systems are immersed in a 2 T axial magnetic field. The silicon pixel and strip subsystems cover the range $|\eta|<2.5$, while the transition radiation tracker acceptance is limited to the range $|\eta|<2.0$. The inner detector allows reconstruction of secondary vertices, in particular of photon conversions occurring in the inner detector material up to a radius of $\approx 80 \mathrm{~cm}$.

The total amount of material in front of the first active layer of the electromagnetic calorimeter (including that in the presampler) varies between 2.5 and 6 radiation lengths as a function of pseudorapidity, excluding the transition region ( $1.37<|\eta|<1.52$ ) between the barrel and the end-caps.

Data used in this analysis were selected using a di-photon trigger with a 20 GeV transverse energy threshold on each photon. At the first trigger level, which uses reduced granularity, two clusters with transverse energies above 14 GeV are required in the electromagnetic calorimeter. At the higher trigger levels, loose photon identification cuts are applied using the full calorimeter granularity. This trigger has an efficiency greater than $99 \%$ for the signal after the final event selection.

In these data, the instantaneous luminosity varies between $\approx 10^{32} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ and $\approx 10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ with a bunch spacing of 50 ns. The average number of collisions per bunch crossing is around 6. Collisions in the same bunch crossing as the signal (in-time pileup) or in other bunch crossings within the detector sensitive time (out-of-time pileup) influence the event reconstruction. The inner detector is only sensitive to in-time pileup while the electromagnetic calorimeter is sensitive to pileup within a $\approx 450$ ns time window.

The application of beam, detector, and data-quality requirements to the recorded data results in a data sample corresponding to a total integrated luminosity of $(1.08 \pm 0.04) \mathrm{fb}^{-1}$ [15].

## 3. Simulated samples

The Higgs boson signal from the dominant gluon fusion production process (corresponding to $86 \%$ of the production crosssection for a Higgs boson with a mass of 120 GeV ) is generated with POWHEG [16]. MC@NLO [17] is used as a cross-check. POWHEG [18] is also used to generate the signal events from the
sub-leading vector boson fusion process ( $7 \%$ of the cross-section at 120 GeV ). For the other production modes, namely associated production with a $W$ or $Z$ boson or a $t \bar{t}$ pair, PYTHIA [19] is used.

The predicted signal is normalised using NNLO cross-sections for the gluon fusion process [20-24], the vector boson fusion process [25], the associated production with a $W$ or $Z$ boson [26] and NLO cross-section for the associated production with a $t \bar{t}$ pair [27]. The NLO electroweak corrections are applied to the gluon fusion [28,29], vector boson fusion [30,31], and the associated production with a $W$ or $Z$ boson [32] processes. The uncertainty on the theoretical cross-section is estimated [9] to be ${ }_{-15}^{+20} \%$, mostly due to the renormalisation and factorisation scale variations and the uncertainties in the parton distribution functions [33-36]. The Higgs boson decay branching fractions are taken from Refs. [9,37]. The uncertainty on the branching ratio to two photons is negligible compared with the cross-section uncertainty.

Signal events are generated in steps of 5 GeV for Higgs boson masses in the range of $110-150 \mathrm{GeV}$. PYTHIA and ALPGEN [38] have been chosen to generate the background samples, which are, however, only used for cross-checks and not to extract the final results.

All Monte Carlo (MC) samples are processed through a complete simulation of the ATLAS detector [39] using the GEANT4 programme [40]. Pileup effects are simulated by overlaying each MC event with a variable number of MC inelastic $p p$ collisions, taking into account both in-time and out-of-time pileup and the LHC bunch train structure. MC events are weighted to have the same distribution of average number of interactions per bunch crossing as in the data.

## 4. Photon reconstruction, event selection and backgrounds

### 4.1. Photon reconstruction

Photon reconstruction is seeded by energy clusters in the electromagnetic calorimeter with transverse energies exceeding 2.5 GeV in projective towers of size $0.075 \times 0.125$ in $\eta \times \phi$ made from the presampler and the three electromagnetic calorimeter layers. These energy clusters are then matched to tracks that are reconstructed in the inner detector and extrapolated to the calorimeter. Clusters without matching tracks are classified as unconverted photon candidates. Clusters matched to either pairs of tracks which are consistent with the hypothesis of a photon conversion or single tracks without hits in the pixel layer nearest to the beam pipe are considered as converted photon candidates. The photon reconstruction efficiency is $\approx 98 \%$.

The energy measurement is made in the electromagnetic calorimeter using a cluster size which depends on the photon classification. In the barrel, a size of $0.075 \times 0.125$ in $\eta \times \phi$ is used for unconverted photons and $0.075 \times 0.175$ for converted photon candidates, to account for the larger spread of the shower in $\phi$ for converted photons due to the magnetic field. In the end-cap, a cluster size of $0.125 \times 0.125$ is used for all candidates. A dedicated energy calibration [14] is applied to account for upstream energy losses, lateral leakage and longitudinal leakage, separately for converted and unconverted photon candidates.

The final energy calibration is determined from $Z \rightarrow e e$ decays, resulting in $\eta$-dependent correction factors of the order of $\pm 1 \%$. After this calibration procedure, the constant term in the energy resolution is estimated to be $1.1_{-0.6}^{+0.5} \%$ in the barrel region and $1.8_{-0.6}^{+0.5} \%$ in the end-cap region [41]. The energy resolution in the simulation is adjusted to match these values.

Photon identification is based on the lateral and longitudinal energy profiles of the shower in the calorimeter [42]. The photon candidate is required to deposit only a small fraction of its en-
ergy in the hadronic calorimeter. The transverse shower shape in the second layer of the electromagnetic calorimeter needs to be consistent with that expected for a single electromagnetic shower. Finally, the high granularity first layer is used to discriminate single photons from overlapping photon pairs from neutral meson decays produced in jet fragmentation, which are the main background source. Based on these criteria, a set of tight identification cuts, different for converted and unconverted candidates, is applied.

To take into account small differences in shower shapes between data and simulation, the shape variables are shifted in the simulation before the identification cuts are applied. The photon identification efficiency ranges typically from $75 \%$ to $90 \%$ for transverse energies between 25 and 100 GeV .

To increase the background rejection, an isolation cut is applied. The isolation variable [42] is computed by summing the transverse energy in calorimeter cells in a cone of radius 0.4 in the $\eta \times \phi$ space around the photon candidate. Cells in the electromagnetic calorimeter within $0.125 \times 0.175$ from the shower barycentre are excluded from the sum. The small photon energy leakage outside the excluded cells is evaluated as a function of the transverse energy in simulated samples and is subtracted from the isolation variable. To reduce the effect from the underlying event and pileup, the isolation is further corrected using a method suggested in Ref. [43]: for each of the two different pseudorapidity regions $|\eta|<1.5$ and $1.5<|\eta|<3.0$, low energy jets are used to compute an "ambient" energy density, which is then multiplied by the area of the isolation cone and subtracted from the isolation energy.

In the following, photon candidates having isolation transverse energies lower than 5 GeV are considered as isolated. The isolation cut efficiency is checked in data using a control sample of $Z \rightarrow e e$ events. The per-event efficiency of requiring both electrons to be isolated is found to be $3 \%$ lower in the data than in the simulated samples. In the MC, the isolation cut efficiency is found to be the same for $Z \rightarrow e e$ and $H \rightarrow \gamma \gamma$ events ( $\approx 93 \%$ ). The number of events predicted by the simulation after the isolation cut is therefore reduced by $3 \%$.

### 4.2. Event selection

Two photon candidates are required to pass tight identification criteria, to be isolated, and to be within the region $|\eta|<2.37$, excluding $1.37<|\eta|<1.52$, where the first calorimeter layer has high granularity. The highest and second highest photon transverse energies are required be above 40 and 25 GeV respectively. Both photons must be clear of problematic regions in the calorimeter. As the goal is to investigate Higgs boson mass hypotheses between 110 and 150 GeV , the invariant mass of the photon pair is required to be within $100-160 \mathrm{GeV}$. After these cuts 5063 events remain in the selected data sample.

The acceptance of the kinematic cuts, as estimated with generated photons in the MC signal samples, is $60 \%$ for the dominant gluon fusion process for a mass of 120 GeV . The overall event selection efficiency, taking into account both kinematic cut acceptance and reconstruction and identification efficiencies, is $39 \%$. The event selection efficiency is slightly larger in the vector boson fusion process. It is somewhat smaller in the associated production mode. It increases with the Higgs boson mass from $34 \%$ at 110 GeV to $43 \%$ at 150 GeV .

To enhance the sensitivity of the analysis, the data sample is split in five categories, with different invariant mass resolutions and different signal-to-background ratios:

- Unconverted central ( $8 \%$ of the candidates): Both photons are unconverted and in the central part of the barrel calorimeter

Table 1
Cross-section times branching ratio and expected numbers of signal events after all cuts (total and per category), for various Higgs boson masses and for an integrated luminosity of $1.08 \mathrm{fb}^{-1}$.

| $m_{H}[\mathrm{GeV}]$ | 110 | 120 | 130 | 140 | 150 |
| :--- | ---: | ---: | ---: | ---: | :---: |
| $\sigma \times$ BR [fb] | 45 | 43 | 37 | 27 | 16 |
| Signal yield | 17.0 | 17.6 | 15.8 | 12.1 | 7.7 |
| Unconverted central | 2.6 | 2.6 | 2.3 | 1.7 | 1.1 |
| Unconverted rest | 4.6 | 4.7 | 4.2 | 3.4 | 2.1 |
| Converted central | 2.0 | 2.0 | 1.7 | 1.3 | 0.8 |
| Converted transition | 2.3 | 2.2 | 2.1 | 1.5 | 1.0 |
| Converted rest | 5.6 | 6.0 | 5.6 | 4.2 | 2.7 |

( $|\eta|<0.75$ ). This is the category with the best invariant mass resolution and the best signal-to-background ratio;

- Unconverted rest ( $28 \%$ of the candidates): Both photons are unconverted and at least one photon does not lie in the central part of the barrel calorimeter;
- Converted central ( $7 \%$ of the candidates): At least one photon is converted and both photons are in the central part of the barrel calorimeter;
- Converted transition ( $16 \%$ of the candidates): At least one photon is converted and at least one photon is near the transition between barrel and end-cap calorimeter ( $1.3<|\eta|<1.75$ ). Given the larger amount of material in this region, the energy resolution, in particular for converted photons, can be significantly degraded;
- Converted rest ( $41 \%$ of the candidates): All other events with at least one converted photon.

Table 1 shows the cross-section times branching ratio to two photons, the expected total and per category signal yields for $1.08 \mathrm{fb}^{-1}$ for different Standard Model Higgs boson mass hypotheses. Using these categories improves the signal sensitivity of the analysis by around $15 \%$ for a 120 GeV Higgs boson mass compared with a fully inclusive analysis.

### 4.3. Invariant mass reconstruction

In addition to the energies, the angle between the photons is needed for the computation of the diphoton invariant mass. This angle is determined from the interaction vertex position and the photon impact points in the calorimeter. The resolution of the angle measurement is dominated by the reconstruction of the primary vertex $z$ position. The RMS vertex spread in the $z$ direction is $\approx 5.5 \mathrm{~cm}$, and a more accurate event-by-event estimate is performed to reduce the impact on the invariant mass resolution. Given the non-negligible level of pileup in the 2011 data, the determination of the vertex position is based only on the photon candidates, without relying on other charged tracks in the event. For converted photons with tracks having a precise measurement in the $z$ direction, the vertex position is estimated from the intercept of the line joining the reconstructed conversion position and the calorimeter impact point with the beam line. For all other photons, the vertex position is estimated from the shower position measurements in the first and second layers of the electromagnetic calorimeter, which can be used to calculate the photon direction. Finally, the vertex positions from both photons are combined taking also into account the average beam spot position in $z$. When both photons are unconverted, the typical vertex position resolution is $\approx 1.6 \mathrm{~cm}$ in $z$. The resolution is better in events with converted photons. The resulting impact of the angle measurement on the invariant mass resolution is negligible compared to the contribution from the photon energy resolution.

Fig. 1. Distribution of the reconstructed diphoton invariant mass of a simulated 120 GeV mass Higgs boson signal, for all categories together. The line shows the fit of the mass resolution using the function described in the text. The core component of the mass resolution is 1.7 GeV .

Fig. 1 shows the invariant mass distribution for simulated Higgs boson events with mass 120 GeV . The mass resolution for the signal is modelled by the sum of a Crystal Ball function [44] (for the bulk of the events which have a narrow Gaussian spectrum in the peak region and tails toward lower reconstructed mass) and a Gaussian distribution with a wide sigma (to model the far outliers in the distribution). The Crystal Ball function is defined as:
$N \cdot \begin{cases}e^{-t^{2} / 2} & \text { if } t>-\alpha_{C B}, \\ \left(\frac{n_{C B}}{\alpha_{C B}}\right)^{n_{C B}} \cdot e^{-\alpha_{C B}^{2} / 2} \cdot\left(\frac{n_{C B}}{\alpha_{C B}}-\alpha_{C B}-t\right)^{-n_{C B}} & \text { otherwise }\end{cases}$
where $t=\left(m_{\gamma \gamma}-\mu_{C B}\right) / \sigma_{C B}, N$ is a normalisation parameter, $\mu_{C B}$ is the peak of the narrow Gaussian distribution, $\sigma_{C B}$ represents the Gaussian resolution for the core component, and $n_{C B}$ and $\alpha_{C B}$ parametrise the non-Gaussian tail.

The core component of the mass resolution, $\sigma_{C B}$, ranges from 1.4 GeV in the "Unconverted central" category to 2.1 GeV in the "Converted transition" category. The non-Gaussian contributions to the mass resolution arise mostly from converted photons with at least one electron losing a significant fraction of its energy through bremsstrahlung in the inner detector material.

### 4.4. Sample composition

The main background components are the diphoton production, the photon-jet production with one fake photon from jets fragmenting into a high energy $\pi^{0}$, the dijet production with two fake photons, and Drell-Yan events where both electrons are misidentified as photons. A measurement of the diphoton production crosssection with 2010 ATLAS data can be found in Ref. [45], where the techniques used to estimate the purity of the sample are described in more detail. Although the final result does not rely on it, a quantitative understanding of the sample composition is an important cross-check of the diphoton selection procedure.

A method based on the use of control regions for two discriminating variables is applied to measure the contributions of fake photon background directly from the data. This method exploits relaxed isolation and photon identification cuts to estimate the fake components, by relying on the fact that the rejections from these two cuts are almost independent. It is a generalisation of the method used in Ref. [42]. The Drell-Yan background is estimated by measuring the probability for an electron to be reconstructed as a photon candidate with $Z$ events and applying this probability to the observed yield of Drell-Yan events at high mass.

The number of diphoton events in the $100-160 \mathrm{GeV}$ mass range is found to be $3650 \pm 100 \pm 290$, where the first uncertainty is sta-

Fig. 2. Diphoton, photon-jet, dijet and Drell-Yan contributions to the diphoton candidate invariant mass distribution, as obtained from a data-driven method. The various components are stacked on top of each other. The error bars correspond to the uncertainties on each component separately.
tistical and the second is systematic. The systematic uncertainty arises from the definition of the relaxed identification control region, the possible correlations between isolation and identification variables, and the fraction of real photons leaking into the background control regions. The extracted yields of photon-jet and dijet are $1110 \pm 60 \pm 270$ and $220 \pm 20 \pm 130$ events respectively. The Drell-Yan background, which is most prominent in the categories with at least one converted photon, is estimated to be $86 \pm 1 \pm 14$ events in the mass range of $100-160 \mathrm{GeV}$.

Fig. 2 shows the extracted components of the diphoton, photonjet, dijet and Drell-Yan processes. The purity of the sample (fraction of diphoton events) is about $72 \%$. The measurement of the purity has also been made separately in each category, and ranges from $69 \%$ to $83 \%$.

Other methods have been used to cross-check the purity estimate, in particular using template fits of the photon isolation distribution, where both signal and background templates are derived from data. The results are in agreement with the results quoted here.

## 5. Systematic uncertainties

Experimental systematic uncertainties affecting the extraction of the signal from the diphoton invariant mass distribution related to the modelling of the signal can be classified in two types: uncertainties affecting the predicted yield and uncertainties affecting the modelling of the mass resolution.

The uncertainties on the event yield are the following:

- The uncertainty from the photon reconstruction and identification efficiency amounts to $\pm 11 \%$ per event. It is estimated from data and MC differences in shower shape variables, the impact of additional material in front of the calorimeter and the impact of pileup on the photon shower shape variables.
- The uncertainty on the isolation cut efficiency is taken as the difference between data and MC found in $Z \rightarrow e e$ decays and amounts to $\pm 3 \%$ per event.
- The uncertainty on the photon trigger efficiency is $\pm 1 \%$. It comes from the uncertainty in the measurement of the trigger efficiency for diphoton candidates using control triggers and from possible differences between the trigger efficiency for photons from Higgs boson decays and all diphoton candidates.
- The uncertainty on the kinematic cut acceptance from the modelling of the Higgs boson transverse momentum distribu-
tion is investigated with HQT [46] and RESBOS [47,48], which account for all-orders soft-gluon resummation up to NNLL accuracy. The resulting uncertainty is found to be at the level of $\pm 1 \%$.
- The luminosity uncertainty is $3.7 \%$ [15].

The total uncertainty on the expected signal event yield is $\pm 12 \%$.
The uncertainties on the invariant mass resolution are the following:

- The uncertainty on the cluster energy resolution comes from the uncertainty on the sampling term, estimated to be $10 \%$, and from the uncertainty on the constant term, which is estimated using $Z \rightarrow$ ee decays. Both uncertainties are taken into account with their proper correlation from the Z control sample constraint. The uncertainty on the cluster energy resolution amounts to a $\pm 12 \%$ relative uncertainty on the diphoton invariant mass resolution.
- The uncertainty on the photon energy calibration arising from the extrapolation of the electron energy scale calibration is estimated from MC studies. The difference between the photon and the electron response in the calorimeter comes from the material in front of the active part of the calorimeter. The uncertainty is estimated using simulations with a different amount of material in front of the calorimeter and is found to be $\pm 6 \%$ on the mass resolution.
- The contribution of pileup fluctuations to the cluster energy measurement is checked using random clusters in randomly triggered bunch crossings, with a frequency corresponding to expectations from the instantaneous luminosity. The relative uncertainty on the mass resolution is found to be less than $3 \%$.
- The uncertainty on the resolution of the photon angle measurement is studied with $Z \rightarrow$ ee decays. The calorimeterbased direction measurement is compared with the much more precise track-based direction measurement. In the barrel calorimeter, the resolution measured in data agrees well with the one predicted by the simulation. In the end-cap region, the resolution measured in data is $\approx 20 \%$ worse than in the simulation. The impact of this difference is a $1 \%$ relative uncertainty on the diphoton mass resolution.

The total relative uncertainty on the diphoton invariant mass resolution is thus $\pm 14 \%$. This systematic uncertainty is applied to both the Crystal Ball and the wide Gaussian resolution parameters.

These systematic uncertainties are taken as fully correlated between the different categories. The impact of uncorrelated systematic uncertainties in the different categories and migration between categories has been investigated and found to be negligible.

The background is modelled by an exponentially falling invariant mass distribution. Systematic uncertainties arise from possible deviations of the background distribution from this assumed shape. This has been estimated by checking how accurately the chosen model fits different predicted diphoton mass distributions [49, 50] and comparing different functional forms for the background model. The resulting uncertainty is between $\pm 5$ events at 110 GeV and $\pm 3$ events at 150 GeV for a Higgs boson mass signal region about 4 GeV wide.

## 6. Results

The data are compared to background and signal-plus-background hypotheses using a profile likelihood test statistic as described in Refs. [7,51]. The exponentially falling invariant mass distribution used for the background model is determined by two

## Table 2

Fractions of background $\left(f_{b}\right)$, predicted signal $\left(f_{s}\right)$ and core Gaussian mass resolution $(\sigma)$ in each category for a Higgs boson mass hypothesis of 120 GeV . The fractions are normalised to the total yield summed over categories.

| Category | $f_{b}$ | $f_{s}$ | $\sigma(\mathrm{GeV})$ |
| :--- | ---: | :--- | :--- |
| Unconverted central | $7 \%$ | $15 \%$ | 1.4 |
| Unconverted rest | $29 \%$ | $27 \%$ | 1.6 |
| Converted central | $8 \%$ | $11 \%$ | 1.5 |
| Converted transition | $16 \%$ | $13 \%$ | 2.1 |
| Converted rest | $40 \%$ | $34 \%$ | 1.8 |

Fig. 3. Distribution of the reconstructed diphoton mass. All five diphoton categories have been combined. The exponential fit to the full sample of the background-only hypothesis, as well as the expected signal for a Higgs boson mass of 120 GeV with five times the Standard Model predicted yield, are also shown for illustration.
nuisance parameters per category (the normalisation and the exponential negative slope), which are left free in the unbinned fit. The signal is modelled with the mass resolution functions described above, one per category, fixing the fraction of events in each category to the MC predictions. Table 2 summarises the measured fractions of background events in each category, the predicted fractions of signal events and the predicted core Gaussian signal mass resolutions for a Higgs boson mass hypothesis of 120 GeV .

The fitted parameters for the signal are thus the overall signal strength relative to the Standard Model prediction and the nuisance parameters on the predicted event yield and mass resolution which have Gaussian constraints in the fit. The uncertainty on the predicted event yield includes both the experimental systematic uncertainties described in Section 5 and the uncertainty on the predicted cross-section described in Section 3. The systematic uncertainty on the background shape is included as another nuisance parameter with a Gaussian constraint in the fit. From this fit, the best estimate of the signal yield is extracted, as well as the likelihood ratio (profile likelihood) between any assumed signal yield (leaving the nuisance parameters free to maximise the likelihood) and the best estimate. The fit is performed in 1 GeV steps for the Higgs boson mass hypothesis, which is significantly smaller than the invariant mass resolution. The signal parameters for these fine mass steps are interpolated from the fully simulated samples.

Fig. 3 shows the reconstructed diphoton mass spectrum. No excess is visible. This is quantified by the $p$-value of the backgroundonly hypothesis, which gives the fraction of background-only experiments that would have a profile likelihood ratio of the zero signal hypothesis relative to the best-fitted signal strength at least as low as the one found in the data. Negative signals are not allowed in the fit, so $p$-values above 0.5 are truncated. This $p$-value is shown in Fig. 4(a) as a function of the hypothesised Higgs boson mass. The minimal $p$-value, corresponding to the largest back-

Fig. 4. (a) $p$-value ( $p_{0}$ ) of the background-only hypothesis as a function of the investigated Higgs boson mass; (b) $95 \%$ confidence level upper limits on a Standard Model Higgs boson production cross-section, relative to the Standard Model crosssection, as a function of Higgs boson mass hypothesis. The solid line shows the observed limit. The dashed line shows the median expected limit for background-only pseudo-experiments, with the bands indicating the expected fluctuations around this limit at the $1 \sigma$ and $2 \sigma$ levels.
ground upward fluctuation, is $\approx 5 \%$ and is found for a hypothesised mass of $\approx 128 \mathrm{GeV}$. The probability for such an excess to appear anywhere in the investigated mass range is around $40 \%$.

Exclusion limits on the inclusive production cross-section of a Standard Model Higgs boson relative to the Standard Model crosssection are derived. For this purpose, a modified frequentist approach $C L_{s}$ [52], corresponding to the ratio of $p$-values for the signal-plus-background and the background-only hypothesis for a given assumed signal strength is used. A given signal strength is excluded at $95 \%$ confidence level if its $C L_{s}$ is smaller than 0.05 . The confidence levels are computed using a large number of signal-plus-background pseudo-experiments, with different signal yields, and background-only pseudo-experiments. The results, including systematic uncertainties, are shown in Fig. 4(b). The impact of the experimental systematic uncertainties is about $5 \%$ on the expected limit for the mass hypothesis of 120 GeV .

The expected median limit in the case of no signal varies from 3.3 to 5.8 as a function of the Higgs boson mass. The variations of the observed limit, between 2.0 and 5.8 , are consistent with expected statistical fluctuations around the median limit.

## 7. Conclusions

A search for the Standard Model Higgs boson in the $H \rightarrow \gamma \gamma$ decay mode has been performed using an integrated luminosity of $1.08 \mathrm{fb}^{-1}$ recorded by the ATLAS experiment in 2011. A high purity diphoton sample is selected. No excess is found in the diphoton invariant mass distribution in the mass range of $110-150 \mathrm{GeV}$. The observed limit on the cross-section of a Standard Model-like Higgs
boson decaying into a pair of photons ranges between 2.0 and 5.8 times the Standard Model cross-section. These variations are compatible with statistical fluctuations around the expected limit for this data set. These limits are the most stringent to date in this channel.

## Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NLT1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

#### Abstract

A search for the Standard Model Higgs boson in the two photon decay channel is reported, using $1.08 \mathrm{fb}^{-1}$ of proton-proton collision data at a centre-of-mass energy of 7 TeV recorded by the ATLAS detector. No significant excess is observed in the investigated mass range of $110-150 \mathrm{GeV}$. Upper limits on the cross-section times branching ratio of between 2.0 and 5.8 times the Standard Model prediction are derived for this mass range.

## 1. Introduction

The search for the Standard Model Higgs boson [1-3] is one of the key goals of the Large Hadron Collider (LHC) at CERN. The allowed Higgs boson mass ( $m_{H}$ ) is constrained at the $95 \%$ confidence level by a lower limit of 114.4 GeV from the LEP experiments [4] and an excluded region between 156 and 177 GeV from the Tevatron experiments [5,6]. First results have been reported by the ATLAS experiment in a variety of channels [7] and the CMS experiment [8] using the data recorded in 2010, which correspond to an integrated luminosity about thirty times smaller than the 2011 dataset used in this analysis.

In the low mass range, from the LEP limit to $m_{H} \approx 140 \mathrm{GeV}$, one of the most promising search channels at the LHC is the rare decay of the Higgs boson into a pair of photons. Despite the low branching ratio ( $\approx 0.2 \%$ ), this channel provides good experimental sensitivity in the mass region below 150 GeV . The results presented in this Letter are based on proton-proton collision data taken at $\sqrt{s}=7 \mathrm{TeV}$ by the ATLAS experiment between April and June 2011.

The data analysis proceeds by selecting photon pairs with tight identification and isolation cuts to minimize backgrounds other than direct diphoton production. A narrow peak in the reconstructed invariant mass distribution is searched for over a large, smooth background whose normalisation and shape are left free in a maximum likelihood fit. To increase the sensitivity, the sample is divided into five categories based on the presence of photon conversions and on the photon impact point on the calorimeter, with different invariant mass resolutions and signal-to-background ratios for the different categories.

[^3]The results of the fit are compared to the prediction from the Standard Model using the Higgs boson production cross-section and branching ratio from Ref. [9]. Limits on the production crosssection relative to the Standard Model value are then derived as a function of the hypothesised Higgs boson mass. Although with the current dataset the analysis is not yet sensitive to the predicted rate for a Standard Model Higgs boson, the limits on the yield in this decay channel improve on those obtained in the same channel by the Tevatron experiments [10-12], and are sensitive to possible enhancements in the Higgs boson production and decay rate compared with the Standard Model expectations.

## 2. Experimental setup and data set

The ATLAS detector is described in detail in Ref. [13]. The main subdetectors relevant to this analysis are the calorimeter, in particular its electromagnetic section, and the inner tracking detector.

The electromagnetic calorimeter is a lead-liquid argon sampling calorimeter with accordion geometry. It is divided into a barrel section covering the pseudorapidity ${ }^{1}$ region $|\eta|<1.45$ and two end-cap sections covering the pseudorapidity region $1.375<|\eta|<$ 3.2. It has three longitudinal layers. The first one, with a thickness between 3 and 5 radiation lengths, has a high granularity in $\eta$ (between 0.003 and 0.006 depending on $\eta$, with the exception of the regions $1.4<|\eta|<1.5$ and $|\eta|>2.4$ ), sufficient to provide discrimination between single photon showers and two photons from a $\pi^{0}$ decay. The second layer has a thickness of around 17 radiation lengths and a granularity of $0.025 \times 0.025$ in $\eta \times \phi$.

[^4]A third layer, with a thickness varying between 4 and 15 radiation lengths, is used to correct for leakage beyond the calorimeter for high energy showers. In front of the calorimeter, a thin presampler layer, covering $|\eta|<1.8$, is used to correct for fluctuations in upstream energy losses. The sampling term $a$ of the energy resolution, $\sigma(E) / E \approx a / \sqrt{E(\mathrm{GeV})}$, varies between $9 \%$ and $14 \%$ as a function of $|\eta|$ for unconverted photons [14]. It reaches up to $20 \%$ for converted photons near $|\eta|$ of 1.3 where the upstream material effect is the largest. The sampling term is the largest contribution to the resolution up to about 100 GeV , where the constant term starts to dominate. After $0.17 \mathrm{fb}^{-1}$ of data were accumulated, some calorimeter cells could not be read out. The affected region size is $\Delta \eta \times \Delta \phi \approx 1.5 \times 0.2$ in the barrel electromagnetic calorimeter, resulting in an acceptance loss for diphoton candidates of about $3 \%$. A hadronic sampling calorimeter is located behind the electromagnetic calorimeter. It is made of steel and scintillating tiles in the barrel section, and of copper and liquid argon in the end-cap.

The inner detector consists of three subsystems: at small radial distance $R$ from the beam axis ( $5<R<15 \mathrm{~cm}$ ), pixel silicon detectors are arranged in three cylindrical layers in the barrel and in three disks in each end-cap; at intermediate radii ( $30<R<$ 56 cm ), double layers of single-sided silicon microstrip detectors are used, organised in four cylindrical layers in the barrel and nine disks in each end-cap; at larger radii ( $56<R<107 \mathrm{~cm}$ ), a straw tracker with transition radiation capabilities is used. These three systems are immersed in a 2 T axial magnetic field. The silicon pixel and strip subsystems cover the range $|\eta|<2.5$, while the transition radiation tracker acceptance is limited to the range $|\eta|<2.0$. The inner detector allows reconstruction of secondary vertices, in particular of photon conversions occurring in the inner detector material up to a radius of $\approx 80 \mathrm{~cm}$.

The total amount of material in front of the first active layer of the electromagnetic calorimeter (including that in the presampler) varies between 2.5 and 6 radiation lengths as a function of pseudorapidity, excluding the transition region ( $1.37<|\eta|<1.52$ ) between the barrel and the end-caps.

Data used in this analysis were selected using a di-photon trigger with a 20 GeV transverse energy threshold on each photon. At the first trigger level, which uses reduced granularity, two clusters with transverse energies above 14 GeV are required in the electromagnetic calorimeter. At the higher trigger levels, loose photon identification cuts are applied using the full calorimeter granularity. This trigger has an efficiency greater than $99 \%$ for the signal after the final event selection.

In these data, the instantaneous luminosity varies between $\approx 10^{32} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ and $\approx 10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ with a bunch spacing of 50 ns. The average number of collisions per bunch crossing is around 6. Collisions in the same bunch crossing as the signal (in-time pileup) or in other bunch crossings within the detector sensitive time (out-of-time pileup) influence the event reconstruction. The inner detector is only sensitive to in-time pileup while the electromagnetic calorimeter is sensitive to pileup within a $\approx 450$ ns time window.

The application of beam, detector, and data-quality requirements to the recorded data results in a data sample corresponding to a total integrated luminosity of $(1.08 \pm 0.04) \mathrm{fb}^{-1}$ [15].

## 3. Simulated samples

The Higgs boson signal from the dominant gluon fusion production process (corresponding to $86 \%$ of the production crosssection for a Higgs boson with a mass of 120 GeV ) is generated with POWHEG [16]. MC@NLO [17] is used as a cross-check. POWHEG [18] is also used to generate the signal events from the
sub-leading vector boson fusion process ( $7 \%$ of the cross-section at 120 GeV ). For the other production modes, namely associated production with a $W$ or $Z$ boson or a $t \bar{t}$ pair, PYTHIA [19] is used.

The predicted signal is normalised using NNLO cross-sections for the gluon fusion process [20-24], the vector boson fusion process [25], the associated production with a $W$ or $Z$ boson [26] and NLO cross-section for the associated production with a $t \bar{t}$ pair [27]. The NLO electroweak corrections are applied to the gluon fusion [28,29], vector boson fusion [30,31], and the associated production with a $W$ or $Z$ boson [32] processes. The uncertainty on the theoretical cross-section is estimated [9] to be ${ }_{-15}^{+20} \%$, mostly due to the renormalisation and factorisation scale variations and the uncertainties in the parton distribution functions [33-36]. The Higgs boson decay branching fractions are taken from Refs. [9,37]. The uncertainty on the branching ratio to two photons is negligible compared with the cross-section uncertainty.

Signal events are generated in steps of 5 GeV for Higgs boson masses in the range of $110-150 \mathrm{GeV}$. PYTHIA and ALPGEN [38] have been chosen to generate the background samples, which are, however, only used for cross-checks and not to extract the final results.

All Monte Carlo (MC) samples are processed through a complete simulation of the ATLAS detector [39] using the GEANT4 programme [40]. Pileup effects are simulated by overlaying each MC event with a variable number of MC inelastic $p p$ collisions, taking into account both in-time and out-of-time pileup and the LHC bunch train structure. MC events are weighted to have the same distribution of average number of interactions per bunch crossing as in the data.

## 4. Photon reconstruction, event selection and backgrounds

### 4.1. Photon reconstruction

Photon reconstruction is seeded by energy clusters in the electromagnetic calorimeter with transverse energies exceeding 2.5 GeV in projective towers of size $0.075 \times 0.125$ in $\eta \times \phi$ made from the presampler and the three electromagnetic calorimeter layers. These energy clusters are then matched to tracks that are reconstructed in the inner detector and extrapolated to the calorimeter. Clusters without matching tracks are classified as unconverted photon candidates. Clusters matched to either pairs of tracks which are consistent with the hypothesis of a photon conversion or single tracks without hits in the pixel layer nearest to the beam pipe are considered as converted photon candidates. The photon reconstruction efficiency is $\approx 98 \%$.

The energy measurement is made in the electromagnetic calorimeter using a cluster size which depends on the photon classification. In the barrel, a size of $0.075 \times 0.125$ in $\eta \times \phi$ is used for unconverted photons and $0.075 \times 0.175$ for converted photon candidates, to account for the larger spread of the shower in $\phi$ for converted photons due to the magnetic field. In the end-cap, a cluster size of $0.125 \times 0.125$ is used for all candidates. A dedicated energy calibration [14] is applied to account for upstream energy losses, lateral leakage and longitudinal leakage, separately for converted and unconverted photon candidates.

The final energy calibration is determined from $Z \rightarrow e e$ decays, resulting in $\eta$-dependent correction factors of the order of $\pm 1 \%$. After this calibration procedure, the constant term in the energy resolution is estimated to be $1.1_{-0.6}^{+0.5} \%$ in the barrel region and $1.8_{-0.6}^{+0.5} \%$ in the end-cap region [41]. The energy resolution in the simulation is adjusted to match these values.

Photon identification is based on the lateral and longitudinal energy profiles of the shower in the calorimeter [42]. The photon candidate is required to deposit only a small fraction of its en-
ergy in the hadronic calorimeter. The transverse shower shape in the second layer of the electromagnetic calorimeter needs to be consistent with that expected for a single electromagnetic shower. Finally, the high granularity first layer is used to discriminate single photons from overlapping photon pairs from neutral meson decays produced in jet fragmentation, which are the main background source. Based on these criteria, a set of tight identification cuts, different for converted and unconverted candidates, is applied.

To take into account small differences in shower shapes between data and simulation, the shape variables are shifted in the simulation before the identification cuts are applied. The photon identification efficiency ranges typically from $75 \%$ to $90 \%$ for transverse energies between 25 and 100 GeV .

To increase the background rejection, an isolation cut is applied. The isolation variable [42] is computed by summing the transverse energy in calorimeter cells in a cone of radius 0.4 in the $\eta \times \phi$ space around the photon candidate. Cells in the electromagnetic calorimeter within $0.125 \times 0.175$ from the shower barycentre are excluded from the sum. The small photon energy leakage outside the excluded cells is evaluated as a function of the transverse energy in simulated samples and is subtracted from the isolation variable. To reduce the effect from the underlying event and pileup, the isolation is further corrected using a method suggested in Ref. [43]: for each of the two different pseudorapidity regions $|\eta|<1.5$ and $1.5<|\eta|<3.0$, low energy jets are used to compute an "ambient" energy density, which is then multiplied by the area of the isolation cone and subtracted from the isolation energy.

In the following, photon candidates having isolation transverse energies lower than 5 GeV are considered as isolated. The isolation cut efficiency is checked in data using a control sample of $Z \rightarrow e e$ events. The per-event efficiency of requiring both electrons to be isolated is found to be $3 \%$ lower in the data than in the simulated samples. In the MC, the isolation cut efficiency is found to be the same for $Z \rightarrow e e$ and $H \rightarrow \gamma \gamma$ events ( $\approx 93 \%$ ). The number of events predicted by the simulation after the isolation cut is therefore reduced by $3 \%$.

### 4.2. Event selection

Two photon candidates are required to pass tight identification criteria, to be isolated, and to be within the region $|\eta|<2.37$, excluding $1.37<|\eta|<1.52$, where the first calorimeter layer has high granularity. The highest and second highest photon transverse energies are required be above 40 and 25 GeV respectively. Both photons must be clear of problematic regions in the calorimeter. As the goal is to investigate Higgs boson mass hypotheses between 110 and 150 GeV , the invariant mass of the photon pair is required to be within $100-160 \mathrm{GeV}$. After these cuts 5063 events remain in the selected data sample.

The acceptance of the kinematic cuts, as estimated with generated photons in the MC signal samples, is $60 \%$ for the dominant gluon fusion process for a mass of 120 GeV . The overall event selection efficiency, taking into account both kinematic cut acceptance and reconstruction and identification efficiencies, is $39 \%$. The event selection efficiency is slightly larger in the vector boson fusion process. It is somewhat smaller in the associated production mode. It increases with the Higgs boson mass from $34 \%$ at 110 GeV to $43 \%$ at 150 GeV .

To enhance the sensitivity of the analysis, the data sample is split in five categories, with different invariant mass resolutions and different signal-to-background ratios:

- Unconverted central ( $8 \%$ of the candidates): Both photons are unconverted and in the central part of the barrel calorimeter

Table 1
Cross-section times branching ratio and expected numbers of signal events after all cuts (total and per category), for various Higgs boson masses and for an integrated luminosity of $1.08 \mathrm{fb}^{-1}$.

| $m_{H}[\mathrm{GeV}]$ | 110 | 120 | 130 | 140 | 150 |
| :--- | ---: | ---: | ---: | ---: | :---: |
| $\sigma \times$ BR [fb] | 45 | 43 | 37 | 27 | 16 |
| Signal yield | 17.0 | 17.6 | 15.8 | 12.1 | 7.7 |
| Unconverted central | 2.6 | 2.6 | 2.3 | 1.7 | 1.1 |
| Unconverted rest | 4.6 | 4.7 | 4.2 | 3.4 | 2.1 |
| Converted central | 2.0 | 2.0 | 1.7 | 1.3 | 0.8 |
| Converted transition | 2.3 | 2.2 | 2.1 | 1.5 | 1.0 |
| Converted rest | 5.6 | 6.0 | 5.6 | 4.2 | 2.7 |

( $|\eta|<0.75$ ). This is the category with the best invariant mass resolution and the best signal-to-background ratio;

- Unconverted rest ( $28 \%$ of the candidates): Both photons are unconverted and at least one photon does not lie in the central part of the barrel calorimeter;
- Converted central ( $7 \%$ of the candidates): At least one photon is converted and both photons are in the central part of the barrel calorimeter;
- Converted transition ( $16 \%$ of the candidates): At least one photon is converted and at least one photon is near the transition between barrel and end-cap calorimeter ( $1.3<|\eta|<1.75$ ). Given the larger amount of material in this region, the energy resolution, in particular for converted photons, can be significantly degraded;
- Converted rest ( $41 \%$ of the candidates): All other events with at least one converted photon.

Table 1 shows the cross-section times branching ratio to two photons, the expected total and per category signal yields for $1.08 \mathrm{fb}^{-1}$ for different Standard Model Higgs boson mass hypotheses. Using these categories improves the signal sensitivity of the analysis by around $15 \%$ for a 120 GeV Higgs boson mass compared with a fully inclusive analysis.

### 4.3. Invariant mass reconstruction

In addition to the energies, the angle between the photons is needed for the computation of the diphoton invariant mass. This angle is determined from the interaction vertex position and the photon impact points in the calorimeter. The resolution of the angle measurement is dominated by the reconstruction of the primary vertex $z$ position. The RMS vertex spread in the $z$ direction is $\approx 5.5 \mathrm{~cm}$, and a more accurate event-by-event estimate is performed to reduce the impact on the invariant mass resolution. Given the non-negligible level of pileup in the 2011 data, the determination of the vertex position is based only on the photon candidates, without relying on other charged tracks in the event. For converted photons with tracks having a precise measurement in the $z$ direction, the vertex position is estimated from the intercept of the line joining the reconstructed conversion position and the calorimeter impact point with the beam line. For all other photons, the vertex position is estimated from the shower position measurements in the first and second layers of the electromagnetic calorimeter, which can be used to calculate the photon direction. Finally, the vertex positions from both photons are combined taking also into account the average beam spot position in $z$. When both photons are unconverted, the typical vertex position resolution is $\approx 1.6 \mathrm{~cm}$ in $z$. The resolution is better in events with converted photons. The resulting impact of the angle measurement on the invariant mass resolution is negligible compared to the contribution from the photon energy resolution.

Fig. 1. Distribution of the reconstructed diphoton invariant mass of a simulated 120 GeV mass Higgs boson signal, for all categories together. The line shows the fit of the mass resolution using the function described in the text. The core component of the mass resolution is 1.7 GeV .

Fig. 1 shows the invariant mass distribution for simulated Higgs boson events with mass 120 GeV . The mass resolution for the signal is modelled by the sum of a Crystal Ball function [44] (for the bulk of the events which have a narrow Gaussian spectrum in the peak region and tails toward lower reconstructed mass) and a Gaussian distribution with a wide sigma (to model the far outliers in the distribution). The Crystal Ball function is defined as:
$N \cdot \begin{cases}e^{-t^{2} / 2} & \text { if } t>-\alpha_{C B}, \\ \left(\frac{n_{C B}}{\alpha_{C B}}\right)^{n_{C B}} \cdot e^{-\alpha_{C B}^{2} / 2} \cdot\left(\frac{n_{C B}}{\alpha_{C B}}-\alpha_{C B}-t\right)^{-n_{C B}} & \text { otherwise }\end{cases}$
where $t=\left(m_{\gamma \gamma}-\mu_{C B}\right) / \sigma_{C B}, N$ is a normalisation parameter, $\mu_{C B}$ is the peak of the narrow Gaussian distribution, $\sigma_{C B}$ represents the Gaussian resolution for the core component, and $n_{C B}$ and $\alpha_{C B}$ parametrise the non-Gaussian tail.

The core component of the mass resolution, $\sigma_{C B}$, ranges from 1.4 GeV in the "Unconverted central" category to 2.1 GeV in the "Converted transition" category. The non-Gaussian contributions to the mass resolution arise mostly from converted photons with at least one electron losing a significant fraction of its energy through bremsstrahlung in the inner detector material.

### 4.4. Sample composition

The main background components are the diphoton production, the photon-jet production with one fake photon from jets fragmenting into a high energy $\pi^{0}$, the dijet production with two fake photons, and Drell-Yan events where both electrons are misidentified as photons. A measurement of the diphoton production crosssection with 2010 ATLAS data can be found in Ref. [45], where the techniques used to estimate the purity of the sample are described in more detail. Although the final result does not rely on it, a quantitative understanding of the sample composition is an important cross-check of the diphoton selection procedure.

A method based on the use of control regions for two discriminating variables is applied to measure the contributions of fake photon background directly from the data. This method exploits relaxed isolation and photon identification cuts to estimate the fake components, by relying on the fact that the rejections from these two cuts are almost independent. It is a generalisation of the method used in Ref. [42]. The Drell-Yan background is estimated by measuring the probability for an electron to be reconstructed as a photon candidate with $Z$ events and applying this probability to the observed yield of Drell-Yan events at high mass.

The number of diphoton events in the $100-160 \mathrm{GeV}$ mass range is found to be $3650 \pm 100 \pm 290$, where the first uncertainty is sta-

Fig. 2. Diphoton, photon-jet, dijet and Drell-Yan contributions to the diphoton candidate invariant mass distribution, as obtained from a data-driven method. The various components are stacked on top of each other. The error bars correspond to the uncertainties on each component separately.
tistical and the second is systematic. The systematic uncertainty arises from the definition of the relaxed identification control region, the possible correlations between isolation and identification variables, and the fraction of real photons leaking into the background control regions. The extracted yields of photon-jet and dijet are $1110 \pm 60 \pm 270$ and $220 \pm 20 \pm 130$ events respectively. The Drell-Yan background, which is most prominent in the categories with at least one converted photon, is estimated to be $86 \pm 1 \pm 14$ events in the mass range of $100-160 \mathrm{GeV}$.

Fig. 2 shows the extracted components of the diphoton, photonjet, dijet and Drell-Yan processes. The purity of the sample (fraction of diphoton events) is about $72 \%$. The measurement of the purity has also been made separately in each category, and ranges from $69 \%$ to $83 \%$.

Other methods have been used to cross-check the purity estimate, in particular using template fits of the photon isolation distribution, where both signal and background templates are derived from data. The results are in agreement with the results quoted here.

## 5. Systematic uncertainties

Experimental systematic uncertainties affecting the extraction of the signal from the diphoton invariant mass distribution related to the modelling of the signal can be classified in two types: uncertainties affecting the predicted yield and uncertainties affecting the modelling of the mass resolution.

The uncertainties on the event yield are the following:

- The uncertainty from the photon reconstruction and identification efficiency amounts to $\pm 11 \%$ per event. It is estimated from data and MC differences in shower shape variables, the impact of additional material in front of the calorimeter and the impact of pileup on the photon shower shape variables.
- The uncertainty on the isolation cut efficiency is taken as the difference between data and MC found in $Z \rightarrow e e$ decays and amounts to $\pm 3 \%$ per event.
- The uncertainty on the photon trigger efficiency is $\pm 1 \%$. It comes from the uncertainty in the measurement of the trigger efficiency for diphoton candidates using control triggers and from possible differences between the trigger efficiency for photons from Higgs boson decays and all diphoton candidates.
- The uncertainty on the kinematic cut acceptance from the modelling of the Higgs boson transverse momentum distribu-
tion is investigated with HQT [46] and RESBOS [47,48], which account for all-orders soft-gluon resummation up to NNLL accuracy. The resulting uncertainty is found to be at the level of $\pm 1 \%$.
- The luminosity uncertainty is $3.7 \%$ [15].

The total uncertainty on the expected signal event yield is $\pm 12 \%$.
The uncertainties on the invariant mass resolution are the following:

- The uncertainty on the cluster energy resolution comes from the uncertainty on the sampling term, estimated to be $10 \%$, and from the uncertainty on the constant term, which is estimated using $Z \rightarrow$ ee decays. Both uncertainties are taken into account with their proper correlation from the Z control sample constraint. The uncertainty on the cluster energy resolution amounts to a $\pm 12 \%$ relative uncertainty on the diphoton invariant mass resolution.
- The uncertainty on the photon energy calibration arising from the extrapolation of the electron energy scale calibration is estimated from MC studies. The difference between the photon and the electron response in the calorimeter comes from the material in front of the active part of the calorimeter. The uncertainty is estimated using simulations with a different amount of material in front of the calorimeter and is found to be $\pm 6 \%$ on the mass resolution.
- The contribution of pileup fluctuations to the cluster energy measurement is checked using random clusters in randomly triggered bunch crossings, with a frequency corresponding to expectations from the instantaneous luminosity. The relative uncertainty on the mass resolution is found to be less than $3 \%$.
- The uncertainty on the resolution of the photon angle measurement is studied with $Z \rightarrow$ ee decays. The calorimeterbased direction measurement is compared with the much more precise track-based direction measurement. In the barrel calorimeter, the resolution measured in data agrees well with the one predicted by the simulation. In the end-cap region, the resolution measured in data is $\approx 20 \%$ worse than in the simulation. The impact of this difference is a $1 \%$ relative uncertainty on the diphoton mass resolution.

The total relative uncertainty on the diphoton invariant mass resolution is thus $\pm 14 \%$. This systematic uncertainty is applied to both the Crystal Ball and the wide Gaussian resolution parameters.

These systematic uncertainties are taken as fully correlated between the different categories. The impact of uncorrelated systematic uncertainties in the different categories and migration between categories has been investigated and found to be negligible.

The background is modelled by an exponentially falling invariant mass distribution. Systematic uncertainties arise from possible deviations of the background distribution from this assumed shape. This has been estimated by checking how accurately the chosen model fits different predicted diphoton mass distributions [49, 50] and comparing different functional forms for the background model. The resulting uncertainty is between $\pm 5$ events at 110 GeV and $\pm 3$ events at 150 GeV for a Higgs boson mass signal region about 4 GeV wide.

## 6. Results

The data are compared to background and signal-plus-background hypotheses using a profile likelihood test statistic as described in Refs. [7,51]. The exponentially falling invariant mass distribution used for the background model is determined by two

## Table 2

Fractions of background $\left(f_{b}\right)$, predicted signal $\left(f_{s}\right)$ and core Gaussian mass resolution $(\sigma)$ in each category for a Higgs boson mass hypothesis of 120 GeV . The fractions are normalised to the total yield summed over categories.

| Category | $f_{b}$ | $f_{s}$ | $\sigma(\mathrm{GeV})$ |
| :--- | ---: | :--- | :--- |
| Unconverted central | $7 \%$ | $15 \%$ | 1.4 |
| Unconverted rest | $29 \%$ | $27 \%$ | 1.6 |
| Converted central | $8 \%$ | $11 \%$ | 1.5 |
| Converted transition | $16 \%$ | $13 \%$ | 2.1 |
| Converted rest | $40 \%$ | $34 \%$ | 1.8 |

Fig. 3. Distribution of the reconstructed diphoton mass. All five diphoton categories have been combined. The exponential fit to the full sample of the background-only hypothesis, as well as the expected signal for a Higgs boson mass of 120 GeV with five times the Standard Model predicted yield, are also shown for illustration.
nuisance parameters per category (the normalisation and the exponential negative slope), which are left free in the unbinned fit. The signal is modelled with the mass resolution functions described above, one per category, fixing the fraction of events in each category to the MC predictions. Table 2 summarises the measured fractions of background events in each category, the predicted fractions of signal events and the predicted core Gaussian signal mass resolutions for a Higgs boson mass hypothesis of 120 GeV .

The fitted parameters for the signal are thus the overall signal strength relative to the Standard Model prediction and the nuisance parameters on the predicted event yield and mass resolution which have Gaussian constraints in the fit. The uncertainty on the predicted event yield includes both the experimental systematic uncertainties described in Section 5 and the uncertainty on the predicted cross-section described in Section 3. The systematic uncertainty on the background shape is included as another nuisance parameter with a Gaussian constraint in the fit. From this fit, the best estimate of the signal yield is extracted, as well as the likelihood ratio (profile likelihood) between any assumed signal yield (leaving the nuisance parameters free to maximise the likelihood) and the best estimate. The fit is performed in 1 GeV steps for the Higgs boson mass hypothesis, which is significantly smaller than the invariant mass resolution. The signal parameters for these fine mass steps are interpolated from the fully simulated samples.

Fig. 3 shows the reconstructed diphoton mass spectrum. No excess is visible. This is quantified by the $p$-value of the backgroundonly hypothesis, which gives the fraction of background-only experiments that would have a profile likelihood ratio of the zero signal hypothesis relative to the best-fitted signal strength at least as low as the one found in the data. Negative signals are not allowed in the fit, so $p$-values above 0.5 are truncated. This $p$-value is shown in Fig. 4(a) as a function of the hypothesised Higgs boson mass. The minimal $p$-value, corresponding to the largest back-

Fig. 4. (a) $p$-value ( $p_{0}$ ) of the background-only hypothesis as a function of the investigated Higgs boson mass; (b) $95 \%$ confidence level upper limits on a Standard Model Higgs boson production cross-section, relative to the Standard Model crosssection, as a function of Higgs boson mass hypothesis. The solid line shows the observed limit. The dashed line shows the median expected limit for background-only pseudo-experiments, with the bands indicating the expected fluctuations around this limit at the $1 \sigma$ and $2 \sigma$ levels.
ground upward fluctuation, is $\approx 5 \%$ and is found for a hypothesised mass of $\approx 128 \mathrm{GeV}$. The probability for such an excess to appear anywhere in the investigated mass range is around $40 \%$.

Exclusion limits on the inclusive production cross-section of a Standard Model Higgs boson relative to the Standard Model crosssection are derived. For this purpose, a modified frequentist approach $C L_{s}$ [52], corresponding to the ratio of $p$-values for the signal-plus-background and the background-only hypothesis for a given assumed signal strength is used. A given signal strength is excluded at $95 \%$ confidence level if its $C L_{s}$ is smaller than 0.05 . The confidence levels are computed using a large number of signal-plus-background pseudo-experiments, with different signal yields, and background-only pseudo-experiments. The results, including systematic uncertainties, are shown in Fig. 4(b). The impact of the experimental systematic uncertainties is about $5 \%$ on the expected limit for the mass hypothesis of 120 GeV .

The expected median limit in the case of no signal varies from 3.3 to 5.8 as a function of the Higgs boson mass. The variations of the observed limit, between 2.0 and 5.8 , are consistent with expected statistical fluctuations around the median limit.

## 7. Conclusions

A search for the Standard Model Higgs boson in the $H \rightarrow \gamma \gamma$ decay mode has been performed using an integrated luminosity of $1.08 \mathrm{fb}^{-1}$ recorded by the ATLAS experiment in 2011. A high purity diphoton sample is selected. No excess is found in the diphoton invariant mass distribution in the mass range of $110-150 \mathrm{GeV}$. The observed limit on the cross-section of a Standard Model-like Higgs
boson decaying into a pair of photons ranges between 2.0 and 5.8 times the Standard Model cross-section. These variations are compatible with statistical fluctuations around the expected limit for this data set. These limits are the most stringent to date in this channel.

## Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NLT1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

## Keywords:

High-energy collider experiment
Long-lived particle
Highly ionising
New physics

#### Abstract

A search is made for massive highly ionising particles with lifetimes in excess of 100 ns , with the ATLAS experiment at the Large Hadron Collider, using $3.1 \mathrm{pb}^{-1}$ of $p p$ collision data taken at $\sqrt{s}=7 \mathrm{TeV}$. The signature of energy loss in the ATLAS inner detector and electromagnetic calorimeter is used. No such particles are found and limits on the production cross section for electric charges $6 e \leqslant|q| \leqslant 17 e$ and masses $200 \mathrm{GeV} \leqslant m \leqslant 1000 \mathrm{GeV}$ are set in the range $1-12 \mathrm{pb}$ for different hypotheses on the production mechanism.

## 1. Introduction

The observation of a massive long-lived highly ionising particle (HIP) possessing a large electric charge $|q| \gg e$, where $e$ is the elementary charge, would represent striking evidence for physics beyond the Standard Model. Examples of putative particles which can give rise to HIP signatures include $Q$-balls [1], stable micro black-hole remnants [2], magnetic monopoles [3] and dyons [4]. Searches for HIPs are made in cosmic rays [5] and at colliders [3]; recent collider searches were performed at LEP [6-8] and the Tevatron [9-12]. Cross sections and event topologies associated with HIP production cannot be reliably predicted due to the fact that the coupling between a HIP and the photon is so strong that perturbative calculations are not possible. Therefore, search results at colliders are usually quoted as cross section limits in a range of charge and mass for given kinematics [3]. Also, for the same reason, limits obtained at different collision energies or for different types of collisions cannot be directly compared; rather, they are complementary.

HIP searches are part of a program of searches at the CERN Large Hadron Collider (LHC) which explore the multi-TeV energy regime. Further motivation is provided by the gauge hierarchy problem, to which proposed solutions typically postulate the existence of hitherto unobserved particles with TeV-scale masses. HIPs at the LHC can be sought at the dedicated MoEDAL plastic-track experiment [13] or, as in this work, via their active detection at a multipurpose detector.

[^6]Due to their assumed large mass (hundreds of GeV), HIPs are characterised by their non-relativistic speed. The expected large amounts of energy loss per unit length ( $\mathrm{d} E / \mathrm{d} x$ ) through ionisation (no bremsstrahlung) are mainly due to the high particle charge, but also due to the low speed. The ATLAS detector is well suited to detect HIPs. A HIP with sufficient kinetic energy would leave a track in the inner detector tracking system of ATLAS and lose its energy on its way to and through the electromagnetic calorimeter, giving rise to an electron-like signature. The presence of a HIP can be inferred from measurements of the proportion of high-ionisation hits in the inner detector. In addition, assuming isolation, the lateral extent of the energy deposition in the calorimeter is a sensitive discriminant between HIPs and Standard Model particles.

The ranges of HIP charge, mass and lifetime for which unambiguous conclusions can be drawn are determined by the chosen trigger and event selections. The choice of an electromagnetic trigger limits the phase space to HIPs which stop in the electromagnetic calorimeter of ATLAS. The search is optimised for data collected at relatively low instantaneous luminosities (up to $10^{31} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ ), for which a low ( 10 GeV ) trigger transverse energy threshold is available. In the barrel region of the calorimeter, this gives access to energy depositions corresponding to HIPs with electric charges down to $6 e$. Standard electron reconstruction algorithms are used, which implies that tracks which bend like electrically charged particles are sought. Particles with magnetic charge, or electric charge above $17 e$, are not addressed here due to the bending along the beam axis in the case of a monopole, and due to effects from delta electrons and electron recombination in the active detector at the corresponding values of energy loss ( $\mathrm{d} E / \mathrm{d} x>2 \cdot 10^{3} \mathrm{MeV} / \mathrm{cm}$ ). For such types of HIPs, more detailed studies are needed to assess and minimise the impact of these
effects on the selection efficiency. The 1000 GeV upper bound in mass sensitivity is determined by trigger timing constraints, as a significantly heavier HIP (with charge 17e or lower) would be delayed by more than 12 ns with respect to $\beta=1$ when it stops in the electromagnetic calorimeter (this corresponds to $\beta<0.3$ ), and would thus risk being triggered in the next proton bunch crossing. The search is sensitive to HIP lifetimes larger than 100 ns since a particle which decays much earlier in the calorimeter (even after stopping) would spoil the signature of a narrow energy deposition.

## 2. The ATLAS detector

The ATLAS detector [14] is a multipurpose particle physics apparatus with a forward-backward symmetric cylindrical geometry and near $4 \pi$ coverage in solid angle. ${ }^{1}$ A thin superconducting solenoid magnet surrounding the inner part of the ATLAS detector produces a field of approximately 2 T along the beam axis.

Inner detector (ID) tracking is performed by silicon-based detectors and an outer tracker using straw tubes with particle identification capabilities based on transition radiation (Transition Radiation Tracker, TRT). The TRT is divided into barrel (covering the pseudorapidity range $|\eta|<1.0$ ) and endcap ( $0.8<|\eta|<2.0$ ) components. A track gives a typical number of straw hits of 36 . At the front-end electronics of the TRT, discriminators are used to compare the signal against low and high thresholds. While the TRT has two hit threshold levels, there is no upper limit to the amount of ionisation in a straw which will lead to a signal [15], guaranteeing that highly ionising particles would not escape detection in the TRT. Rather, they would produce a large number of high-threshold (HT) hits along their trajectories. The amount of ionisation in a straw tube needed for a TRT HT hit is roughly equivalent to three times that expected from a minimum ionising particle.

Liquid-argon sampling electromagnetic (EM) calorimeters, which comprise accordion-shaped electrodes and lead absorbers, surround the ID. The EM calorimeter barrel ( $|\eta|<1.475$ ) is used in this search. It is segmented transversely and divided in three layers in depth, denoted first, second, and third layer, respectively. In front of the accordion calorimeter a thin presampler layer is used to correct for fluctuations of energy loss. The typical cell granularity $(\Delta \eta \times \Delta \phi)$ of the EM barrel is $0.003 \times 0.1$ in the first layer and $0.025 \times 0.025$ in the second layer. The signal expected for a HIP in the considered charge range lies in a region in time and energy where the electronic response in EM calorimeter cells is well understood and does not saturate. The robustness of the EM calorimeter energy reconstruction has been studied in detail and pulse shape predictions are consistent with the measured signals [16].

The stopping power of a HIP in the ATLAS detector depends on its charge, mass and energy, as well as the material budget along its path. Details of the latter are given in Ref. [17] in terms of number of radiation lengths $X_{0}$, as a function of depth and pseudorapidity. The integrated radiation length between the interaction point and the exit of the TRT is $0.5 X_{0}$ at $\eta=0$ and $1.5 X_{0}$ at $|\eta|=1.3$. The additional amount of material before the first layer of the EM calorimeter is $2.0 X_{0}$ at $\eta=0$ and $3.5 X_{0}$ at $|\eta|=1.3$. The thicknesses of the first, second and third EM layers are $4.5 X_{0}$, $16.5 X_{0}$ and $1.5 X_{0}$ at $\eta=0$ and $3 X_{0}, 20 X_{0}$ and $5 X_{0}$ at $|\eta|=1.3$, respectively.

[^7]

Fig. 1. Distributions of pseudorapidity $\eta$ (top) and kinetic energy $E_{\text {kin }}$ (bottom) at origin for heavy fermions produced with the Drell-Yan process. The latter is given with a requirement of $|\eta|<1.35$. The distributions for the three different masses are normalised to the same number of entries.

## 3. Simulated event samples

Signal events are generated with the Pythia Monte Carlo (MC) event generator [18] according to the fermion pair production process: $p+p \rightarrow f+\bar{f}+X$. Ref. [19] is used for the parton distributions of the proton. Direct pair production implies that the HIPs are not part of a jet and thus isolated. A Drell-Yan-like production mechanism, modified to take into account the mass of the HIP [20], is used to model the kinematic properties of the HIPs. Generated $\eta$ distributions, as well as kinetic energy ( $E_{k i n}$ ) spectra in the central region ( $|\eta|<1.35$ ), are shown in Fig. 1 for the three mass points considered in this search.

An ATLAS detector simulation [21] based on Geant-4 [22] is used, where the particle interactions include secondary ionisation by delta electrons in addition to the standard ionisation process based on the Bethe-Bloch formula. A correction for electron-ion recombination effects in the EM calorimeter (Birks' correction) is applied, with typical visible energy fractions between 0.2 and 0.5 for the signal particles considered. Effects of delays are simulated, except for the ability to trigger slow-moving particles within the proton bunch crossing time, which is considered separately as a systematic uncertainty (see Section 6). Samples of approximately 20000 events are produced for HIPs with masses of 200, 500 and 1000 GeV . For each mass point, HIPs with charges $6 e, 10 e$ and $17 e$ are simulated.

A data-driven method is used in this work to estimate backgrounds surviving the final selections (see Section 4.2). However, in order to demonstrate that the distributions of the relevant observables are understood, a sample of simulated background events is used. The background sample, generated with Pythia [18] and labeled "Standard Model", consists mostly of QCD events in which
the hard subprocess is a strong 2 -to-2 process with a matrix element transverse momentum cut-off of 15 GeV , but also includes contributions from heavy quark and vector boson production. A true transverse energy larger than 17 GeV in a typical first level trigger tower is also required. This sample contains $4 \cdot 10^{7}$ events and corresponds roughly to an integrated luminosity of $0.8 \mathrm{pb}^{-1}$.

## 4. Trigger and event selection

The collected data sample corresponds to an integrated luminosity of $3.1 \pm 0.3 \mathrm{pb}^{-1}$, using a first level trigger based on energy deposits in the calorimeters. At the first level of the trigger, socalled trigger towers with dimension $\Delta \eta \times \Delta \phi=0.1 \times 0.1$ are defined. In each trigger tower the cells of the electromagnetic or hadronic calorimeter are summed. EM clusters with fixed size $\Delta \eta \times \Delta \phi=0.2 \times 0.2$ are sought and are retained if the total transverse energy ( $E_{T}$ ) in an adjacent pair of their four trigger towers is above 5 GeV . Further electron-like higher level trigger requirements are imposed on the candidate, including $E_{T}>10 \mathrm{GeV}$, a matching to a track in the ID and a veto on hadronic leakage [23]. The efficiency of this trigger for the data under consideration is measured to be $(94.0 \pm 1.5) \%$ for electrons with $E_{T}>15 \mathrm{GeV}$ and is well described by the simulation. The simulation predicts that a highly charged particle which stops in the EM barrel would be triggered with a similar efficiency or higher.

Offline electron candidates have cluster sizes of $\Delta \eta \times \Delta \phi=$ $0.075 \times 0.175$ in the EM barrel, with a matched track in a window of $\Delta \eta \times \Delta \phi=0.05 \times 0.1$ amongst reconstructed tracks with transverse momentum larger than 0.5 GeV . Identification requirements corresponding to "medium" electrons [24], implying track and shower shape quality cuts, are applied to the candidates. These cuts filter out backgrounds but have a negligible impact on the signal, for which the cluster width is much narrower than for typical electrons. The cluster energy is estimated correcting for the energy deposited outside the active calorimeter regions, assuming an EM shower.

Further offline selections on the cluster transverse energy ( $E_{T}>$ 15 GeV ) and pseudorapidity ( $|\eta|<1.35$ ) are imposed. The $E_{T}$ selection guarantees that the trigger efficiency is higher than $94 \%$ for the objects under study. The restriction of $|\eta|<1.35$ excludes the transition region between the EM calorimeter barrel and endcap, reducing the probability for backgrounds to fake a narrow energy deposition.

### 4.1. Selection cuts

A loose selection based on TRT and EM calorimeter information is also imposed on the candidates to ensure that the quality of the track and cluster associated to the electron-like object is good enough to ensure the robustness of the HIP selection variables, and to provide a data sample with which to estimate the background rate. Only candidates with more than 10 TRT hits are retained. In addition to the $E_{T}>15 \mathrm{GeV}$ cut for the EM cluster associated with the candidate, a significant fraction of the total cluster energy is required to be contained in six calorimeter cells among the first and second EM layers. This is done by requiring the summed energy in the three most energetic cells in each of the first and second layers to be greater than 2 and 4 GeV , respectively. Following these selections, 137503 candidates remain in the data.

Two sets of observables are used in the final selection. The ID-based observable is the fraction, $f_{H T}$, of TRT hits on the track which pass the high threshold. The calorimeter-based discriminants are the fractions of energies outside of the three most energetic cells associated to a selected EM cluster, in the first and second EM calorimeter layers: $w_{1}$ and $w_{2}$.

Fig. 2. Distribution of the fraction of TRT high-threshold hits for candidates satisfying the loose selection. Data (dots) are compared with area-normalised signal ( $|q|=10 e$ and $m=500 \mathrm{GeV}$, dashed line) and Standard Model background (shaded area) simulations. The dotted line shows the selection cut value.

The $f_{H T}$ distribution for loosely selected candidates is shown in Fig. 2. The data extend up to $f_{H T}=0.8$. The prediction of the signal simulation for a HIP of mass 500 GeV and charge $10 e$ is also shown. It peaks at $f_{H T} \sim 1$ and has a small tail extending into the Standard Model region.

The distributions of $w_{1}$ and $w_{2}$ also provide good discrimination between signal and background, as shown in Fig. 3. For a signal, energy is deposited only in the few cells along the particle trajectory (as opposed to backgrounds which induce showers in the EM calorimeter) and the distributions peak around zero for both variables. The shapes of the measured distributions are well described by the background simulation. A faint double-peak structure is visible in data and in background simulations for the $f_{H T}$, $w_{1}$ and $w_{2}$ distributions in Figs. 2 and 3, where the main peak (closest to the signal) corresponds to electrons and the secondary peak corresponds to hadrons which fake the electron identification signature.

Finally, the following HIP selection is made: $f_{H T}>0.65, w_{1}<$ 0.20 and $w_{2}<0.15$. For signal particles, these cuts reject only candidates in the tails of the distributions, and varying them has a minor impact on the efficiency; this feature is common to all considered charge and mass points. The cut values were chosen to yield a very small ( $\ll 1$ event) expected background (see Section 4.2) while retaining a high ( $\sim 96 \%$ ) efficiency for the signal. No candidates in data or in simulated Standard Model events pass this selection.

### 4.2. Data-driven background estimation

A data-driven method is used to quantify the expected background yield after the HIP selection. Potential backgrounds consist mainly of electrons. For Standard Model candidates, the ID and calorimeter observables are correlated in a way that further suppresses the backgrounds (see Fig. 4). The background estimation assumes that $f_{H T}$ is uncorrelated with $w_{1}$ and $w_{2}$ and is thus conservative.

The yield of particle candidates passing the loose selection $N_{\text {loose }}=137503$ can be divided into the following: $N_{0}, N_{1}, N_{f_{H T}}$, and $N_{w}$, which represent the number of candidates which satisfy both of the selections, neither of the selections, only the $f_{H T}$ selection, and only the $w_{1}$ and $w_{2}$ selections taken together, respectively. Even in the presence of a signal, $N_{1}, N_{f_{H T}}$ and $N_{w}$ would be dominantly composed of background events. The probability of a background candidate passing the TRT requirement is

Fig. 3. Distributions of $w_{1}$ and $w_{2}$ following the loose selection. Data (dots) are compared with area-normalised signal ( $|q|=10 e$ and $m=500 \mathrm{GeV}$, dashed lines) and Standard Model background (shaded area) simulations. Negative values are caused by pedestal fluctuations. Dotted lines show the selection cut values.
then $P_{f_{H T}}=\frac{N_{f_{H T}}}{\left(N_{1}+N_{f_{H T}}\right)}$ and the probability to pass the calorimeter requirements is $P_{w}=\frac{N_{w}}{\left(N_{1}+N_{w}\right)}$, leading to an expectation of the number of background candidates entering the signal region: $N_{b g}=N_{\text {loose }} P_{f_{H T}} P_{w}$. The data sample yields $N_{0}=0, N_{1}=137342$, $N_{f_{H T}}=18$ and $N_{w}=143$, leading to $P_{f_{H T}}=(1.3 \pm 0.3) \cdot 10^{-4}$ and $P_{w}=(1.0 \pm 0.1) \cdot 10^{-3}$. The expected number of background candidates surviving the selection, and thereby the expected number of background events, is thus $N_{b g}=0.019 \pm 0.005$. The quoted uncertainty is statistical.

## 5. Signal selection efficiency

### 5.1. Efficiencies in acceptance kinematic regions

The probability to retain a signal event can be factorised in two parts: acceptance (probability for a HIP in a region where the detector is sensitive) and efficiency (probability for this HIP to pass the selection cuts). The acceptance is defined here as the probability that at least one signal particle will be in the range $|\eta|<1.35$ and stop in the second or third layer of the EM calorimeter. If this condition is satisfied, the simulation predicts a high probability to trigger on, reconstruct and select the event. This corresponds to the dark region in Fig. 5, which shows the predicted selection efficiency mapped as a function of the initial HIP pseudorapidity and kinetic energy, in the case of $|q|=10 e$ and $m=500 \mathrm{GeV}$. Such acceptance kinematic regions can be parametrised with three values defining three corners of a parallelogram. These parameters are summarised in Table 1. For HIPs produced inside such regions, the

Fig. 4. Contours of $w_{2}$ versus $f_{H T}$ distributions following loose selection, showing the density of entries on a log scale. Data and signal Monte Carlo ( $|q|=10 e$ and $m=500 \mathrm{GeV}$ ) are shown, and no candidates in the data appear near the signal region. The correlation factor between $w_{2}$ and $f_{H T}$ in the data is positive (coefficient 0.15 ); the same trend is also true for the correlation between $w_{1}$ and $f_{H T}$ (coefficient 0.18 ).

Table 1
Kinetic energies (in GeV ) defining the acceptance kinematic ranges for HIPs with the masses and electric charges considered in this search. The three columns correspond to the lower left, lower right, and upper left corners of parallelograms in the ( $|\eta|, E_{k i n}$ ) plane.

| $\|q\|$ | $m[\mathrm{GeV}]$ | $E_{\text {kin }}^{\min }$ <br> $(\eta=0)$ | $E_{\text {kin }}^{\min }$ <br> $(\|\eta\|=1.35)$ | $E_{\text {kin }}^{\max }$ <br> $(\eta=0)$ |
| :---: | :---: | :---: | :---: | :---: |
| $6 e$ | 200 | 40 | 50 | 50 |
| $6 e$ | 500 | 50 | 70 | 70 |
| $6 e$ | 1000 | 60 | 130 | 80 |
| $10 e$ | 200 | 50 | 80 | 90 |
| $10 e$ | 500 | 80 | 110 | 130 |
| $10 e$ | 1000 | 110 | 150 | 180 |

| $17 e$ | 500 | 150 | 190 | 260 |
| $17 e$ | 1000 | 190 | 240 | 350 |

Table 2
Expected fractions of HIP candidates passing the final selection, assuming they are isolated and produced inside the acceptance regions defined by the values in Table 1. Uncertainties due to MC statistics are quoted; other systematic uncertainties are discussed in Section 6.

| $m[\mathrm{GeV}]$ | $\|q\|=6 e$ | $\|q\|=10 e$ | $\|q\|=17 e$ |
| :---: | :--- | :--- | :--- |
| 200 | $0.822 \pm 0.026$ | $0.820 \pm 0.015$ | $0.484 \pm 0.012$ |
| 500 | $0.868 \pm 0.021$ | $0.856 \pm 0.014$ | $0.617 \pm 0.011$ |
| 1000 | $0.558 \pm 0.019$ | $0.858 \pm 0.012$ | $0.700 \pm 0.012$ |

candidate selection efficiency is flat within $10 \%$ and takes values between 0.5 and 0.9 depending on the charge and mass (see Table 2 ). For $|q|=17 e$, the main source of inefficiency is the requirement on the number of TRT HT hits, which contributes up to $20 \%$ signal loss. This is largely due to the presence of track segments from delta electrons, which have a non-negligible probability to be chosen by the standard electron track matching algorithm. For low charges, inefficiencies are dominated by the cluster $E_{T}$ cut, typically accounting for $\sim 6 \%$ loss. Other contributions, like trigger, electron reconstruction, and electron identification, can each cause $1-6 \%$ additional inefficiency.

### 5.2. Efficiencies for Drell-Yan kinematics

The estimated fractions of signal events where at least one candidate passes the final selection, assuming they are produced

Fig. 5. Probability to pass all selection criteria as a function of pseudorapidity and kinetic energy at origin, for a HIP with charge $10 e$ and mass 500 GeV . The dark region corresponds to the kinetic range where the particle stops in or near the second layer of the EM calorimeter barrel and is parametrised with three energy values (dashed parallelogram, see Table 1).

Table 3
Expected fractions of signal events passing the final selection, assuming Drell-Yan kinematics. Uncertainties due to MC statistics are quoted; other systematic uncertainties are discussed in Section 6.

| $m[\mathrm{GeV}]$ | $\|q\|=6 e$ | $\|q\|=10 e$ | $\|q\|=17 e$ |
| :---: | :--- | :--- | :--- |
| 200 | $0.102 \pm 0.002$ | $0.175 \pm 0.003$ | $0.112 \pm 0.002$ |
| 500 | $0.150 \pm 0.003$ | $0.236 \pm 0.003$ | $0.193 \pm 0.003$ |
| 1000 | $0.133 \pm 0.002$ | $0.299 \pm 0.004$ | $0.237 \pm 0.004$ |

with Drell-Yan kinematics, are shown in Table 3 for the values of charge and mass considered in this search. The dominant source of loss ( $70-85 \%$ loss) is from the kinematic acceptance, i.e., the production of HIPs with $|\eta|>1.35$, as well as their stopping before they reach the second layer of the EM calorimeter, or after they reach the first layer of the hadronic calorimeter. The relative contributions from these various types of acceptance loss depend on mass and charge, as well as the kinematics of the assumed production model. The Drell-Yan production model implies that the fraction of HIPs produced in the acceptance region of pseudorapidity $|\eta|<1.35$ is larger with increasing mass (see Fig. 1). Also, with the assumed energy spectra (bottom plot in Fig. 1), the acceptance is highest for intermediate charges ( $|q|=10 e$ ), since HIPs with low charges tend to punch through the EM calorimeter and HIPs with high charges tend to stop before reaching it.

## 6. Systematic uncertainties

The major sources of systematic uncertainties affecting the efficiency estimation are summarised below. These mainly concern possible imperfections in the description of HIPs in the detector by the simulation.

- The recombination of electrons and ions in the sampling region of the EM calorimeter affects the measured current and thus the total visible energy. Recombination effects become larger with increasing $\mathrm{d} E / \mathrm{d} x$. In the ATLAS simulation, this is parametrised by Birks' law [25]. To estimate the uncertainty associated with the approximate modeling of recombination effects, predictions from the ATLAS implementation of Birks' correction [26] are compared to existing data of heavy ions punching through a layer of liquid argon [27-29]. In the range $2 \cdot 10^{2} \mathrm{MeV} / \mathrm{cm}<\mathrm{d} E / \mathrm{d} x<2 \cdot 10^{3} \mathrm{MeV} / \mathrm{cm}$, which corresponds to typical HIP energy losses in the EM calorimeter for the

Table 4
Relative systematic uncertainties in efficiency, combining in quadrature all the effects described in the text.

| $m[\mathrm{GeV}]$ | $\|q\|=6 e$ | $\|q\|=10 e$ | $\|q\|=17 e$ |
| :---: | :--- | :--- | :--- |
| 200 | $25 \%$ | $11 \%$ | $9 \%$ |
| 500 | $17 \%$ | $10 \%$ | $9 \%$ |
| 1000 | $28 \%$ | $10 \%$ | $9 \%$ |

charges and masses under consideration, the uncertainty in the simulated visible energy fraction is $\pm 15 \%$. This introduces between $4 \%$ and $23 \%$ uncertainty in the signal selection efficiency. The impact is largest for charge $6 e$, for which a lower visible energy would be more likely to push the candidate below the 15 GeV cluster $E_{T}$ threshold.

- The fraction of HIPs which stop in the detector prior to reaching the EM calorimeter is affected by the assumed amount of material in the Geant-4 simulation. Varying the material density within the assumed uncertainty range ( $\pm \sim 10 \%$ [30]), independently in the ID and EM calorimeter volumes, leads to a $6 \%$ uncertainty in signal acceptance.
- The modeling of inactive or inefficient EM calorimeter regions in the simulation results in a $2 \%$ uncertainty in the signal efficiency.
- Cross-talk effects between EM calorimeter cells affect the $w_{1}$ and $w_{2}$ variables and this may not be accurately described by the simulation for large energy depositions per cell. The resulting uncertainty in signal efficiency is $2 \%$.
- Secondary ionisation by delta electrons affects the track reconstruction and the calorimeter energy output. The amount of delta electrons in ATLAS detectors as described in Geant-4 depends on the cutoff parameter (the radius beyond which delta electrons are considered separate from the mother particle). Varying this parameter results in a $3 \%$ uncertainty in the signal efficiency.
- For clusters delayed by more than 10 ns with respect to the expected arrival time of a highly relativistic particle, which corresponds to $\beta<0.37$, there is a significant chance that the event is triggered in the next bunch crossing by the first level EM trigger. In most of the mass and charge range considered in this search, more than $99 \%$ of the particles which are energetic enough to reach the EM calorimeter and pass the event selection are in the high-efficiency range $\beta>0.4$. The only exception is $|q|=6 e$ and $m=1000 \mathrm{GeV}$, for which the $\beta$ distribution after selection peaks between 0.32 and 0.47 . The trigger efficiency loss is corrected for, resulting in an additional $25 \%$ uncertainty for this particular case.
- Uncertainties in the choice of parametrisation for the parton density functions (pdfs) of the proton have an impact on the event kinematics. To test this effect, events were generated (see Section 3) with 7 different pdfs from various sources [19, 31-34]. Assuming that acceptance variations due to the choice of pdf are Gaussian, the resulting relative uncertainty in the acceptance is $3 \%$.
- The relative uncertainty in efficiency due to MC statistics is of the order of $2 \%$.

Other effects, like event pile-up and electron pick-up by positively charged particles, have been investigated and found to be negligible. Efficiency systematics are dominated by Birks' correction. The relative uncertainties in the signal selection efficiencies (Tables 2 and 3), obtained by adding all effects in quadrature, are shown in Table 4.

The systematic uncertainty in the absolute integrated luminosity is $11 \%$ [35].

Table 5
Inclusive HIP cross section upper limits (in pb) at 95\% confidence level for isolated long-lived massive particles with high electric charges produced in regions of pseudorapidity and kinetic energy as defined in Table 1. Efficiencies in Table 2 and uncertainties in Table 4 were used in the cross section limit calculation.

| 500 | 1.2 | 1.2 | 1.6 |
| 1000 | 2.2 | 1.2 | 1.5 |

Table 6
Pair production cross section upper limits (in pb) at $95 \%$ confidence level for longlived massive particles with high electric charges, assuming a Drell-Yan mechanism. Efficiencies in Table 3 and uncertainties in Table 4 were used in the cross section limit calculation.

| $m[\mathrm{GeV}]$ | $\|q\|=6 e$ | $\|q\|=10 e$ | $\|q\|=17 e$ |
| :---: | :---: | :--- | :--- |
| 200 | 11.5 | 5.9 | 9.1 |
| 500 | 7.2 | 4.3 | 5.3 |
| 1000 | 9.3 | 3.4 | 4.3 |

## 7. Upper limit on the cross section

A very low ( $\ll 1$ event) background yield is expected and no events are observed to pass the selection. Knowing the integrated luminosity ( $3.1 \mathrm{pb}^{-1}$ ) and the selection efficiency for various model assumptions (Tables 2 and 3 ), cross section limits are obtained. This is done using a Bayesian statistical approach with a uniform prior for the signal and the standard assumption that the uncertainties in integrated luminosity (11\%) and efficiency (Table 4) are Gaussian and independent. The limits are presented in Table 5 (for a particle produced in the acceptance kinematic region defined by Table 1) and in Table 6 (assuming Drell-Yan kinematics).

These limits can be approximately interpolated to intermediate values of mass and charge. Also, the limits quoted in Table 5 can be used to extract cross section limits for any given model of kinematics by correcting for the acceptance (fraction of events with at least one generated HIP in the ranges defined by Table 1): such a procedure yields conservative limits thanks to the fact that candidates beyond the sharp edges of the acceptance regions defined in Table 1 can also be accepted.

## 8. Summary

A search has been made for HIPs with lifetimes in excess of 100 ns produced in the ATLAS detector at the LHC using $3.1 \mathrm{pb}^{-1}$ of $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$. The signature of high ionisation in an inner detector track matched to a narrow calorimeter cluster has been used. Upper cross section limits between 1.2 pb and 11.5 pb have been extracted for HIPs with electric charges between $6 e$ and $17 e$ and masses between 200 GeV and 1000 GeV , under two kinematics assumptions: a generic isolated HIP in a fiducial range of pseudorapidity and kinetic energy, or a Drell-Yan fermion pair production mechanism. HIP mass ranges above 800 GeV [11] are probed for the first time at a particle collider. These limits are the first constraints obtained on long-lived highly charged particle production at LHC collision energies.

#### Abstract

This Letter presents a search for high mass $e^{+} e^{-}$or $\mu^{+} \mu^{-}$resonances in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ at the LHC. The data were recorded by the ATLAS experiment during 2010 and correspond to a total integrated luminosity of $\sim 40 \mathrm{pb}^{-1}$. No statistically significant excess above the Standard Model expectation is observed in the search region of dilepton invariant mass above 110 GeV . Upper limits at the $95 \%$ confidence level are set on the cross section times branching ratio of $Z^{\prime}$ resonances decaying to dielectrons and dimuons as a function of the resonance mass. A lower mass limit of 1.048 TeV on the Sequential Standard Model $Z^{\prime}$ boson is derived, as well as mass limits on $Z^{*}$ and $E_{6}$-motivated $Z^{\prime}$ models.

A search for high mass resonances decaying into $e^{+} e^{-}$or $\mu^{+} \mu^{-}$pairs is presented based on an analysis of $7 \mathrm{TeV} p p$ collision data recorded with the ATLAS detector [1]. Among the possibilities for such resonances, this Letter focuses on new heavy neutral gauge bosons ( $Z^{\prime}, Z^{*}$ ) [2-4]; other hypothetical states like a Randall-Sundrum spin-2 graviton [5] or a spin-1 techni-meson [6] are not discussed here, though this analysis is also sensitive to them.

The benchmark model for $Z^{\prime}$ bosons is the Sequential Standard Model (SSM) [2], in which the $Z^{\prime}\left(Z_{\text {SSM }}^{\prime}\right)$ has the same couplings to fermions as the $Z$ boson. A more theoretically motivated model is the Grand Unification model in which the $E_{6}$ gauge group is broken into $S U(5)$ and two additional $U(1)$ groups [7]. The lightest linear combination of the corresponding two new neutral gauge bosons, $Z_{\psi}^{\prime}$ and $Z_{\chi}^{\prime}$, is considered the $Z^{\prime}$ candidate: $Z^{\prime}\left(\theta_{E_{6}}\right)=Z_{\psi}^{\prime} \cos \theta_{E_{6}}+Z_{\chi}^{\prime} \sin \theta_{E_{6}}$, where $0 \leqslant \theta_{E_{6}}<\pi$ is the mixing angle between the two gauge bosons. The pattern of spontaneous symmetry breaking and the value of $\theta_{E_{6}}$ determines the $Z^{\prime}$ couplings to fermions; six different models [2,7] lead to the specific $Z^{\prime}$ states named $Z_{\psi}^{\prime}, Z_{N}^{\prime}, Z_{\eta}^{\prime}, Z_{I}^{\prime}, Z_{S}^{\prime}$ and $Z_{\chi}^{\prime}$ respectively. Because of different couplings to $u$ and $d$ quarks, the ranking of the production cross sections of these six states is different in $p \bar{p}$ and $p p$ collisions. In this search, the resonances are assumed to have a narrow intrinsic width, comparable to the contribution from the

[^8]detector mass resolution. The expected intrinsic width of the $Z_{\mathrm{SSM}}^{\prime}$ as a fraction of the mass is $3.1 \%$, while for any $E_{6}$ model the intrinsic width is predicted to be between $0.5 \%$ and $1.3 \%$ [8].

Production of a $Z^{*}$ boson $[4,9]$ could also be detected in a dilepton resonance search. The anomalous (magnetic moment type) coupling of the $Z^{*}$ boson leads to kinematic distributions different from those of the $Z^{\prime}$ boson. To fix the coupling strength, a model with quark-lepton universality, and with the total $Z^{*}$ decay width equal to that of the $Z_{\text {SSM }}^{\prime}$ with the same mass, is adopted [10,11].

Previous indirect and direct searches have set constraints on the mass of $Z^{\prime}$ resonances [12-16]. The $Z_{S S M}^{\prime}$ is excluded by direct searches at the Tevatron with a mass lower than $1.071 \mathrm{TeV}[17,18]$. The large center of mass energy of the LHC provides an opportunity to search for $Z^{\prime}$ resonances with comparable sensitivity using the $2010 p p$ collision data. CMS has very recently excluded a $Z_{\text {SSM }}^{\prime}$ with a mass lower than 1.140 TeV [19].

The three main detector systems of ATLAS [1] used in this analysis are the inner tracking detector, the calorimeter, and the muon spectrometer. Charged particle tracks and vertices are reconstructed with the inner detector (ID) which consists of silicon pixel, silicon strip, and transition radiation detectors covering the pseudorapidity range $|\eta|<2.5$. ${ }^{1}$ It is immersed in a homogeneous

[^9]2 T magnetic field provided by a superconducting solenoid. The latter is surrounded by a finely-segmented, hermetic calorimeter that covers $|\eta|<4.9$ and provides three-dimensional reconstruction of particle showers using lead-liquid argon sampling for the electromagnetic compartment followed by a hadronic compartment which is based on iron-scintillating tiles sampling in the central region and on liquid argon sampling with copper or tungsten absorbers for $|\eta|>1.7$. Outside the calorimeter, there is a muon spectrometer with air-core toroids providing a magnetic field. Three sets of drift tubes or cathode strip chambers provide precision $(\eta)$ coordinates for momentum measurement in the region $|\eta|<2.5$. Finally, resistive-plate and thin-gap chambers provide muon triggering capability.

The data sample used in this analysis was collected during 2010. Application of detector and data quality requirements leads to an available integrated luminosity of $39 \mathrm{pb}^{-1}$ and $42 \mathrm{pb}^{-1}$ for the electron and muon analyses respectively.

Triggers requiring the presence of at least one electron or muon above a transverse momentum ( $p_{\mathrm{T}}$ ) threshold were used to identify the events recorded for full reconstruction. The thresholds varied from 14 to 20 GeV for electrons and 10 to 13 GeV for muons depending on the luminosity. The overall trigger efficiency at the $Z$ peak is $100 \%$ with negligible uncertainty for dielectron events and $(98.2 \pm 0.3) \%$ for dimuon events, for the selection criteria presented below. The trigger-level bunch-crossing identification of very high transverse energy electron triggers relies on a special algorithm implemented in the first-level calorimeter trigger hardware; its performance was checked with calibration data and the resulting systematic uncertainty on the trigger efficiency is ${ }_{-2}^{+0} \%$. Collision candidates are selected by requiring a primary vertex with at least three associated charged particle tracks, consistent with the beam interaction region.

In the $e^{+} e^{-}$channel, two electron candidates are required with transverse energy $E_{T}>25 \mathrm{GeV},|\eta|<2.47$; the region $1.37 \leqslant|\eta| \leqslant$ 1.52 is excluded because it corresponds to a transition region between the barrel and endcap calorimeters which has degraded energy resolution. Electron candidates are formed from clusters of cells reconstructed in the electromagnetic calorimeter. Criteria on the transverse shower shape, the longitudinal leakage into the hadronic calorimeter, and the association to an inner detector track are applied to the cluster to satisfy the Medium electron definition $[20,21]$. The electron energy is obtained from the calorimeter measurements and its direction from the associated track. A hit in the first layer of the pixel detector is required (if an active pixel layer is traversed) to suppress background from photon conversions. In addition, a fiducial cut removes events with electrons near problematic regions of the electromagnetic calorimeter during the 2010 run, reducing the acceptance by $6 \%$. The two electron candidates are not required to have opposite charge because of possible charge mis-identification either due to bremsstrahlung or to the limited momentum resolution of the inner detector at very high $p_{\mathrm{T}}$. For these selection criteria, the overall event acceptance for a $Z^{\prime} \rightarrow e^{+} e^{-}$of mass 1 TeV is $60 \%$.

In the $\mu^{+} \mu^{-}$channel, two muon candidates of opposite charge are required, each satisfying $p_{\mathrm{T}}>25 \mathrm{GeV}$. These muons are required to be within the trigger acceptance of $|\eta|<2.4$. Muon tracks are reconstructed independently in both the inner detector and muon spectrometer. The momentum is taken from a combined fit to the measurements from both subsystems. To obtain optimal momentum resolution, the muons used in this analysis are

[^10]required to have at least three hits in each of the inner, middle, and outer detectors of the muon system, and at least one hit in the non-bend plane. Residual misalignments of the muon detectors, which could cause a degradation of the momentum resolution, were studied with cosmic rays and with collision data in which the muons traversed overlapping sets of muon chambers. The effect of the misalignments, and the intrinsic position resolution, are included in the simulation and correspond to a resolution of $(20 \pm 4) \%$ for 1 TeV muons for the present data set. Studies of muons from $W$ decays verified that the observed momentum spectrum agrees with the simulation up to $p_{\mathrm{T}}=300 \mathrm{GeV}$ above which the event numbers are sparse. To suppress background from cosmic rays, the muons are also required to satisfy selections on the impact parameter, $\left|d_{0}\right|<0.2 \mathrm{~mm} ; z$ coordinate with respect to the primary vertex (PV), $\left|z_{0}-z(\mathrm{PV})\right|<1 \mathrm{~mm}$; and on the $z$ position of the primary vertex, $|z(\mathrm{PV})|<200 \mathrm{~mm}$. To reduce the background from jets, each muon is required to be isolated such that $\sum p_{\mathrm{T}}(\Delta R<0.3) / p_{\mathrm{T}}(\mu)<0.05$, where $\sum p_{\mathrm{T}}(\Delta R<0.3)$ is the sum of the $p_{\mathrm{T}}$ of the other tracks in a cone $\Delta R<0.3$ around the direction of the muon $\left(\Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \varphi)^{2}}\right)$. The overall event acceptance is $40 \%$ for a $Z^{\prime} \rightarrow \mu^{+} \mu^{-}$of mass 1 TeV . The primary reason for the lower acceptance compared to the electron channel is the requirement that hits are observed in all three layers of muon chambers, which reduces coverage in some regions of $\eta$. It is expected that this acceptance difference will be recovered in the future.

For both channels, the dominant background originates with the $Z / \gamma^{*}$ (Drell-Yan) process, which has the same final state as $Z^{\prime}$ or $Z^{*}$ production. In the $e^{+} e^{-}$channel, the second largest background arises from QCD jet production including $b$ quarks (referred to below as QCD background); above $m_{e^{+} e^{-}}=110 \mathrm{GeV}$, the next largest backgrounds are $t \bar{t}$ and $W+$ jets events. In the $\mu^{+} \mu^{-}$channel, in order of dominance the backgrounds are Drell-Yan production, followed by $t \bar{t}$ and diboson ( $W W, W Z$ and $Z Z$ ) production; the QCD and $W+$ jets backgrounds are negligible.

Expected signal and backgrounds, with the exception of the QCD component, are evaluated with simulated samples and normalized with respect to one another using the highest-order available cross section predictions. The $Z^{\prime}$ signal and $Z / \gamma^{*}$ processes are generated with PYthia 6.421 [22] using MRST2007 LO* [23] parton distribution functions (PDFs). The $Z_{S S M}^{\prime}$ was used as the benchmark signal model and this signal sample was generated with Pythia using Standard Model couplings. $Z^{*}$ events are generated with CompHEP [24] using CTEQ6L1 [25] PDFs followed by Pythia for parton showering and underlying event generation. The diboson processes are generated with Herwig 6.510 [26,27] using MRST2007 LO* PDFs. The $W+$ jets background is generated with Alpgen [28] and the $t \bar{t}$ background with MC@NLO 3.41 [29]. For both, Jimmy 4.31 [30] is used to describe multiple parton interactions and Herwig to describe the remaining underlying event and parton showers. CTEQ [25] parton distribution functions are used. For all samples, final state photon radiation is handled by Рнотоs [31] and the interaction of particles and the response of the detector are carried out using full detector simulation [32] based on Geant4 [33].

The $Z / \gamma^{*}$ cross section is calculated at next-to-next-to-leading order (NNLO) using PHOZPR [34] with MSTW2008 parton distribution functions [35]. The ratio of this cross section to the leadingorder cross section can be used to determine a mass dependent QCD K-factor which is applied to the results of the leading-order simulations. The same QCD K-factor is applied to the $Z^{\prime}$ signal. However, the QCD K-factor is not applied to the leading-order $Z^{*}$ cross section since the $Z^{*}$ model uses an effective Lagrangian with a different Lorentz structure. Higher-order weak corrections (beyond the photon radiation included in the simulation) are
calculated using HORACE $[36,37]$, yielding a weak K-factor due to virtual heavy gauge boson loops. The weak K-factor is not applied to the $Z^{\prime}$ or $Z^{*}$ signal since it is not universal, but depends on the coupling of the $W$ and $Z$ bosons to the $Z^{\prime}$ or $Z^{*}$. The diboson cross section is known to next-to-leading order (NLO) with an uncertainty of $5 \%$. The $W+$ jets cross section is calculated at NLO, and rescaled to the inclusive NNLO calculation, resulting in $30 \%$ uncertainty when at least one parton with $E_{T}>20 \mathrm{GeV}$ accompanies the $W$ boson. The $t \bar{t}$ cross section is predicted at approximate-NNLO, with $10 \%$ uncertainty [38-40]. Cross section uncertainties are estimated from PDF error sets and from variation of renormalization and factorization scales in the cross section calculation.

To estimate the QCD background in the $e^{+} e^{-}$sample, a combination of three different techniques is used. In the "reversed electron identification" technique, a sample of events where both electrons pass the Loose electron identification selections [20,21] but fail the Medium selections is used to determine the shape of the QCD background as a function of invariant mass $m_{e^{+}} e^{-}$. This template shape, and the sum of the Drell-Yan, diboson, $t \bar{t}$ and $W+$ jets backgrounds, are fitted to the observed $m_{e^{+} e^{-}}$distribution to determine the normalization of the QCD contribution. In the second technique [21], the isolation distribution for the electrons (energy in the calorimeter in a cone of $\Delta R<0.4$ around the electron track after subtracting the electron cluster energy) is fitted to a signal template, corresponding to electrons from either $Z$ or $Z^{\prime} \mid Z^{*}$ production, plus a background template; the latter is determined from the data by reversing electron identification selections. The third technique relates, via a matrix inversion, the measured number of events passing Loose or Medium, plus first-pixel-layer hit, identification requirements for each of the two electrons (i.e. four different categories of events) to the true number of real and fake electron combinations in the sample [41,42]. To combine the measurements from each of these estimates and obtain the QCD background in the high $-m_{e^{+} e^{-}}$region, a fit in several bins of $m_{e^{+}} e^{-}$above 110 GeV is performed using a power-law function of $m_{e^{+} e^{-}}$with the parameters being the exponent and the integral number of events with $m_{e^{+} e^{-}}>110 \mathrm{GeV}$. The background in any given region of $m_{e^{+} e^{-}}$is then obtained from an integral of this function; the corresponding uncertainty is obtained by propagating the statistical and systematic uncertainties for each of the background estimation methods. A small additional systematic uncertainty related to a small bias in the fit for low statistics and variations when different functions were used is also taken into account. The power law function gives a conservative estimate of the QCD background at very large $m_{e^{+} e^{-}}$, as it falls less rapidly than other functional forms used to fit dijet invariant mass distributions [43].

QCD backgrounds in the $\mu^{+} \mu^{-}$sample can be produced by pion and kaon decay in flight or from semi-leptonic decays of $b$ and $c$ quarks. The former is suppressed by the small decay probability of a high- $p_{\mathrm{T}}$ pion or kaon. The background from semi-leptonic decays of $b$ and $c$ quarks is evaluated using the $\sum_{B D} p_{\mathrm{T}}(\Delta R<0.3) / p_{\mathrm{T}}(\mu)$ isolation variable. A simulated sample of $b \bar{b}$ and $c \bar{c}$ events is shown to reproduce the isolation distribution of the muon candidates, after all selection cuts except isolation are applied. This simulated QCD sample is normalized to the data in the region $\sum p_{\mathrm{T}}(\Delta R<0.3) / p_{\mathrm{T}}(\mu)>0.1$, and then used to predict the background passing the final selection criterion of $\sum p_{\mathrm{T}}(\Delta R<0.3) / p_{\mathrm{T}}(\mu)<0.05$. A systematic uncertainty of $50 \%$ is assigned to the QCD background to cover the difference between the number of non-isolated muons predicted by the simulation and the number observed in the data.

A direct estimate of background from cosmic rays in the muon channel is obtained by observing the rate, and mass distribution, of

Fig. 1. Dielectron invariant mass ( $m_{e^{+} e^{-}}$) distribution after final selection, compared to the stacked sum of all expected backgrounds, with three example $Z_{\text {SSM }}^{\prime}$ signals overlaid. The bin width is constant in $\log m_{e^{+} e^{-}}$and the ratio of the upper to lower bounds of each bin is 1.07 .
events satisfying $3<\left|z_{0}-z(\mathrm{PV})\right|<200 \mathrm{~mm}$ or $\left|d_{0}\right|>0.3 \mathrm{~mm}$. The number of events in the final sample is obtained by scaling to the number expected to pass the $\left|d_{0}\right|<0.2 \mathrm{~mm}$, and $\left|z_{0}-z(\mathrm{PV})\right|<$ 1 mm selection criteria. The total cosmic ray background above $m_{\mu^{+} \mu^{-}}=70 \mathrm{GeV}$ is thus estimated to be $0.004 \pm 0.002$ events.

Finally, while the primary estimate of the $t \bar{t}$ background is taken from Monte Carlo for both channels as discussed above, a data-driven cross-check of the $t \bar{t}$ background was also performed. The $e \mu$ final state with dilepton invariant mass $>100 \mathrm{GeV}$ provides an enriched sample of $t \bar{t}$ fully leptonic events. After correcting for relative efficiencies, it provides a direct estimate from data of the $t \bar{t} \rightarrow e^{+} e^{-}, \mu^{+} \mu^{-}$backgrounds. The results, which have relatively large statistical uncertainties due to the limited number of events, are in good agreement with the Monte Carlo prediction.

The observed invariant mass distributions, $m_{e^{+} e^{-}}$and $m_{\mu^{+} \mu^{-}}$, are compared to the expectation of the SM backgrounds. To make this comparison, the sum of the Drell-Yan, $t \bar{t}$, diboson and $W+$ jets backgrounds (with the relative contributions fixed according to the respective cross sections) is scaled such that when added to the data-driven QCD background, the result agrees with the observed number of data events in the $70-110 \mathrm{GeV}$ mass interval. The advantage of this approach is that the uncertainty on the luminosity, and any mass independent uncertainties in efficiencies, cancel between the $Z^{\prime} \mid Z^{*}$ and the $Z$ in the limit computation presented below. The integrated Drell-Yan cross section at NNLO above a generator-level dilepton invariant mass of 60 GeV is ( $0.989 \pm 0.049$ ) nb.

Fig. 1 presents the invariant mass ( $m_{e^{+} e^{-}}$) distribution after final selection while Table 1 shows the number of data events and estimated backgrounds in bins of reconstructed $e^{+} e^{-}$invariant mass. The dielectron invariant mass distribution is well described by the prediction from SM processes.

Similarly, Fig. 2, and Table 2 show the results for the $\mu^{+} \mu^{-}$ sample. Again, there is good agreement with the prediction from SM processes. Figs. 1 and 2 also display expected $Z_{\text {SSM }}^{\prime}$ signals for three masses around 1 TeV . Expected $Z^{*}$ signals (not shown) have a similar shape and approximately $40 \%$ higher cross section. Three events in the vicinity of $m_{e^{+} e^{-}}=600 \mathrm{GeV}$ and a single event at $m_{\mu^{+} \mu^{-}}=768 \mathrm{GeV}$ are observed in the data. The $p$-value which quantifies, in the absence of signal, the probability of observing an excess anywhere in the search region $m_{\ell^{+} \ell^{-}}>110 \mathrm{GeV}(\ell=e$ or $\mu$ ), with a significance at least as great as that observed in the

Fig. 2. Dimuon invariant mass ( $m_{\mu^{+} \mu^{-}}$) distribution after final selection, compared to the stacked sum of all expected backgrounds, with three example $Z_{\text {SSM }}^{\prime}$ signals overlaid. The bin width is constant in $\log m_{\mu^{+} \mu^{-}}$and the ratio of the upper to lower bounds of each bin is 1.07 .
data is evaluated [44]. Since the resulting $p$-values are $5 \%$ and $22 \%$ for the electron and muon channels, respectively, no statistically significant excess above the predictions of the SM has been observed.

Given the absence of a signal, an upper limit on the number of $Z^{\prime}$ events is determined at the $95 \%$ confidence level (C.L.) using a Bayesian approach [44]. The invariant mass distribution of the data is compared to templates of the expected backgrounds and varying amounts of signal at varying pole masses in the 0.132.0 TeV range, a technique used in Ref. [45]. A likelihood function is defined as the product of the Poisson probabilities over all mass bins in the search region, where the Poisson probability in each bin is evaluated for the observed number of data events given the expectation from the template. The total acceptance for signal as a function of mass is propagated into the expectation. For each $Z^{\prime}$ pole mass, a uniform prior in the $Z^{\prime}$ cross section is used.

The normalization procedure described above makes this analysis insensitive to the uncertainty on the integrated luminosity as well as other mass-independent systematic uncertainties. Massdependent systematic uncertainties are incorporated as nuisance parameters whose variation is integrated over in the computation of the likelihood function [44]. The relevant systematic uncertainties are reconstruction efficiency, QCD and weak K-factors, PDF and resolution uncertainties. These uncertainties are correlated across all bins in the search region, and they are correlated between signal and background except for the weak K-factor which is only applied to the Drell-Yan background. In addition, there is an uncertainty on the QCD component of the background for the electron channel.

The uncertainties on the mass-dependent nuisance parameters are as follows: since the total background is normalized to the data in the region of the $Z \rightarrow \ell^{+} \ell^{-}$mass peak, the residual systematic uncertainties are small at low mass and grow at high mass. The dominant uncertainties are of a theoretical nature. The uncertainty on the cross sections due to PDF variation is $6 \%(8 \%)$ at 1 TeV for $Z^{\prime}$ $\left(Z^{*}\right)$ production, for both channels. The uncertainties on the QCD and weak K-factors are $3 \%$ and $4.5 \%$ respectively for both channels. The uncertainty in the weak K-factor includes the effects of neglecting real boson emission, the difference in the electroweak scheme definition between Pythia and horace, and higher-order electroweak and $\mathcal{O}\left(\alpha \alpha_{s}\right)$ corrections. Finally, an uncertainty of $5 \%$, due to the uncertainty on the $Z / \gamma^{*}$ cross section in the normalization region, as well as a $1 \%$ statistical error on the data in the normalization region, are applied.

On the experimental side, the systematic effects are as follows. In the electron channel, the calorimeter resolution is dominated at large transverse energy by a constant term which is $1.1 \%$ in the barrel and $1.8 \%$ in the endcaps with a small uncertainty. The simulation was adjusted to reproduce this resolution at high energy and the uncertainty on it has a negligible effect. The calorimeter energy calibration uncertainty is between $0.5 \%$ and $1.5 \%$ depending on transverse momentum and pseudorapidity. The non-linearity of the calorimeter response is negligible according to test beam data and Monte Carlo studies [46]. The uncertainty on the energy calibration has minimal impact on the sensitivity of the search,

Table 3
Summary of systematic uncertainties on the expected numbers of events at $m_{\ell^{+} \ell^{-}}=1 \mathrm{TeV}$. NA indicates that the uncertainty is not applicable, and "-" denotes a negligible entry.

| Source | Dielectrons |  |  | Dimuons |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
|  | $Z^{\prime}$ signal | background |  | $Z^{\prime}$ signal | background |
| Normalization | $5 \%$ | $5 \%$ |  | $5 \%$ | $5 \%$ |
| PDFs | $6 \%$ | $6 \%$ |  | $6 \%$ | $6 \%$ |
| QCD K-factor | $3 \%$ | $3 \%$ | $3 \%$ | $3 \%$ |  |
| Weak K-factor | NA | $4.5 \%$ |  | NA | $4.5 \%$ |
| Efficiency | - | - | $3 \%$ | $3 \%$ |  |
| Resolution | - | - | $3 \%$ | $3 \%$ |  |
| Total | $9.4 \%$ | $9.5 \%$ |  | $9.4 \%$ | $10.4 \%$ |

since its main effect is a shift of a potential peak in dilepton mass without change of the line-shape. No source of efficiency variation for electron reconstruction and identification at high $p_{\mathrm{T}}$ has been found.

For the muon channel, the combined uncertainty on the trigger and reconstruction efficiency is estimated to be $3 \%$ at 1 TeV . This uncertainty is dominated by the rate of muon bremsstrahlung in the calorimeter which may interfere with reconstruction in the muon spectrometer. The uncertainty on the resolution due to residual misalignments in the muon spectrometer propagates to a change in the observed width of $Z^{\prime} \mid Z^{*}$ line-shape, and affects the sensitivity by $3 \%$. The muon momentum scale is calibrated with a statistical precision of $0.2 \%$ using the $Z \rightarrow \ell^{+} \ell^{-}$mass peak. As with the electron channel, the momentum calibration uncertainty has negligible impact in the muon channel search. The systematic uncertainties are summarized in Table 3.

The limit on the number of $Z^{\prime}$ events produced is converted into a limit on cross section times branching ratio $\sigma B\left(Z^{\prime} \rightarrow \ell^{+} \ell^{-}\right)$ by scaling with the observed number of $Z$ boson events and the known value of $\sigma B\left(Z \rightarrow \ell^{+} \ell^{-}\right)$. The expected exclusion limits are determined using simulated pseudo-experiments containing only Standard Model processes by evaluating the $95 \%$ C.L. upper limits for each pseudo-experiment for each fixed value of $M_{Z^{\prime}}$. The median of the distribution of limits is chosen to represent the expected limit. The ensemble of limits is also used to find the $68 \%$ and $95 \%$ envelope of the expected limits as a function of $M_{Z^{\prime}}$.

Fig. 3 shows for the dielectron channel the 95\% C.L. observed and expected exclusion limits on $\sigma B$. It also shows the theoretical cross section times branching ratio for the $Z_{S S M}^{\prime}$ and for the lowest and highest $\sigma B$ of $E_{6}$-motivated $Z^{\prime}$ models. Similarly, Fig. 4 shows the same results in the case of the dimuon channel. Fig. 5 shows the $95 \%$ C.L. exclusion limit on $\sigma B$ for the combination of the electron and muon channels. The combination is performed by defining the likelihood function in terms of the total number of $Z^{\prime}$ events produced in both channels.

In the three cases (dielectron, dimuon and combined channels), the $95 \%$ C.L. $\sigma B$ limit is used to set mass limits for each of the considered models. Mass limits obtained for the $Z_{\text {SSM }}^{\prime}$ are displayed in Table 4 together with the corresponding $\sigma B$ limit. The combined mass limit for the $Z_{\text {SSM }}^{\prime}$ is 1.048 TeV (observed) and 1.088 TeV (expected). The combined mass limits on the $E_{6}$-motivated models are given in Table 5. The limits on the $E_{6}$-motivated $Z_{I}^{\prime}$ and $Z_{S}^{\prime}$ are 0.842 TeV and 0.871 TeV , more stringent than the previous highest limits [18].

Although the lepton decay angular distributions are not the same for $Z^{\prime}$ and $Z^{*}$ bosons, we found the difference in geometrical acceptance to be negligible for boson pole masses above 750 GeV . The same procedure as for the $Z^{\prime}$ is used to calculate a limit on $\sigma B\left(Z^{*} \rightarrow \ell^{+} \ell^{-}\right)$and on the $Z^{*}$ mass in each channel and for their combination. The results are displayed in Table 6. The combined

Fig. 3. Expected and observed $95 \%$ C.L. limits on $\sigma B$ and expected $\sigma B$ for $Z_{\mathrm{SSM}}^{\prime}$ production and the two $E_{6}$-motivated $Z^{\prime}$ models with lowest and highest $\sigma B$ for the dielectron channel. The thickness of the SSM theory curve represents the theoretical uncertainty and holds for the other theory curves.

Fig. 4. Expected and observed $95 \%$ C.L. limits on $\sigma B$ and expected $\sigma B$ for $Z_{S S M}^{\prime}$ production and the two $E_{6}$-motivated $Z^{\prime}$ models with lowest and highest $\sigma B$ for the dimuon channel. The thickness of the SSM theory curve represents the theoretical uncertainty and holds for the other theory curves.

Fig. 5. Expected and observed $95 \%$ C.L. limits on $\sigma B$ and expected $\sigma B$ for $Z_{\text {SSM }}^{\prime}$ production and the two $E_{6}$-motivated $Z^{\prime}$ models with lowest and highest $\sigma B$ for the combination of the electron and muon channels. The thickness of the $Z_{S S M}^{\prime}$ theory curve represents the theoretical uncertainty and holds for the other theory curves.

Table 4
$e^{+} e^{-}, \mu^{+} \mu^{-}$and combined $95 \%$ C.L. mass and $\sigma B$ limits on $Z_{\text {SSM }}^{\prime}$.

| $Z_{\text {SSM }}^{\prime} \rightarrow \ell^{+} \ell^{-}$ | 1.048 | 0.094 |  | 1.088 | 0.081 |

Table 5
Combined mass limits at $95 \%$ C.L. on the $E_{6}$-motivated $Z^{\prime}$ models.

| Model | $Z_{\psi}^{\prime}$ | $Z_{\mathrm{N}}^{\prime}$ | $Z_{\eta}^{\prime}$ | $Z_{I}^{\prime}$ | $Z_{\mathrm{S}}^{\prime}$ | $Z_{\chi}^{\prime}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Mass limit $[\mathrm{TeV}]$ | 0.738 | 0.763 | 0.771 | 0.842 | 0.871 | 0.900 |

## Table 6

$e^{+} e^{-}, \mu^{+} \mu^{-}$and combined $95 \%$ C.L. mass and $\sigma B$ limits on $Z^{*}$ production.

|  | Observed limit |  |  |  | Expected limit |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :---: |
|  | mass $[\mathrm{TeV}]$ | $\sigma B[\mathrm{pb}]$ |  | mass $[\mathrm{TeV}]$ | $\sigma B[\mathrm{pb}]$ |  |
| $Z^{*} \rightarrow e^{+} e^{-}$ | 1.058 | 0.149 |  | 1.062 | 0.143 |  |
| $Z^{*} \rightarrow \mu^{+} \mu^{-}$ | 0.946 | 0.265 |  | 0.995 | 0.199 |  |
| $Z^{*} \rightarrow \ell^{+} \ell^{-}$ | 1.152 | 0.089 |  | 1.185 | 0.080 |  |

mass limit for the $Z^{*}$ boson is 1.152 TeV (observed) and 1.185 TeV (expected). This is the first direct limit on this particle.

In conclusion, the ATLAS detector has been used to search for narrow resonances in the invariant mass spectrum above 110 GeV of $e^{+} e^{-}$and $\mu^{+} \mu^{-}$final states with $\sim 40 \mathrm{pb}^{-1}$ of proton-proton data. No evidence for such a resonance is found. Limits on the cross section times branching ratio $\sigma B\left(Z^{\prime} \rightarrow \ell^{+} \ell^{-}\right)$are calculated, as well as mass limits on the $Z_{\text {SSM }}^{\prime}(1.048 \mathrm{TeV})$, the $Z^{*}(1.152 \mathrm{TeV})$ and $E_{6}$-motivated $Z^{\prime}$ bosons (in the range $0.738-0.900 \mathrm{TeV}$ ). For certain $E_{6}$-motivated models, these limits are more stringent than the corresponding limits from the Tevatron.

## Acknowledgements

We wish to thank CERN for the efficient commissioning and operation of the LHC during this initial high-energy data-taking period as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

#### Abstract

A search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{\prime+} \ell^{\prime-}$, where $\ell=e, \mu$, is presented. Proton-proton collision data at $\sqrt{s}=7 \mathrm{TeV}$ recorded with the ATLAS detector and corresponding to an average integrated luminosity of $2.1 \mathrm{fb}^{-1}$ are compared to the Standard Model expectations. Upper limits on the production cross section of a Standard Model Higgs boson with a mass between 110 and 600 GeV are derived. The observed (expected) $95 \%$ confidence level upper limit on the production cross section for a Higgs boson with a mass of 194 GeV , the region with the best expected sensitivity for this search, is 0.99 (1.01) times the Standard Model prediction. The Standard Model Higgs boson is excluded at $95 \%$ confidence level in the mass ranges 191-197, 199-200 and 214-224 GeV.

## 1. Introduction

The search for the Standard Model (SM) Higgs boson [1-3] is a major goal of the Large Hadron Collider (LHC) programme. Direct searches at the CERN LEP $e^{+} e^{-}$collider led to a lower limit on the Higgs boson mass, $m_{H}$, of 114.4 GeV at $95 \%$ confidence level (CL) [4]. The searches at the Fermilab Tevatron $p \bar{p}$ collider have excluded at $95 \% \mathrm{CL}$ the region $156 \mathrm{GeV}<m_{H}<$ 177 GeV [5]. Results from the 2010 LHC run extended the search in the region $200 \mathrm{GeV}<m_{H}<600 \mathrm{GeV}$ by excluding a Higgs boson with cross section larger than 5-20 times the SM prediction [6,7].

This Letter presents a search for the SM Higgs boson in the mass range from 110 to 600 GeV in the channel $H \rightarrow$ $Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{\prime+} \ell^{\prime-}$, where $\ell, \ell^{\prime}=e, \mu$. Three distinct final states, $\mu \mu \mu \mu(4 \mu)$, ее $\mu \mu(2 e 2 \mu)$, and eeee ( $4 e$ ), are selected. The largest background to this search comes from continuum $Z Z^{(*)}$ production. For $m_{H}<180 \mathrm{GeV}$, contributions from $Z+$ jets and $t \bar{t}$ processes, where the additional charged leptons arise either from semi-leptonic decays of heavy flavour or from light flavour jets misidentified as leptons, are important. The $p p$ collision data were recorded with the ATLAS detector at the LHC at $\sqrt{s}=7 \mathrm{TeV}$ and correspond to an average integrated luminosity of $2.1 \mathrm{fb}^{-1}$ [8].

[^12]
## 2. The ATLAS detector

The ATLAS detector [9] is a multi-purpose particle physics apparatus with forward-backward symmetric cylindrical geometry. ${ }^{1}$ The inner tracking detector (ID) consists of a silicon pixel detector, a silicon microstrip detector, and a transition radiation tracker. The ID is surrounded by a thin superconducting solenoid providing a 2 T magnetic field. A high-granularity lead-liquid argon (LAr) sampling calorimeter measures the energy and the position of electromagnetic showers. An iron-scintillator tile calorimeter provides hadronic coverage in the central rapidity range. The end-cap and forward rapidity regions are instrumented with LAr calorimetry for both electromagnetic and hadronic measurements. The muon spectrometer (MS) surrounds the calorimeters and consists of three large superconducting toroids, each with eight coils, a system of precision tracking chambers, and detectors for triggering. A threelevel trigger system selects events to be recorded for offline analysis.

## 3. Data and simulation samples

The accumulated data are subjected to quality requirements ensuring that the relevant detector components were operating

[^13]Table 1
Higgs boson production cross sections for both gluon and vector-boson fusion processes in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$. The cross sections include the branching ratio of $H \rightarrow 4 \ell$, with $\ell=e, \mu$. The errors are the total theoretical systematic uncertainty.

normally. The resulting average integrated luminosity of $2.1 \mathrm{fb}^{-1}$ corresponds to $2.28 \mathrm{fb}^{-1}, 1.96 \mathrm{fb}^{-1}$ and $1.98 \mathrm{fb}^{-1}$ for the $4 \mu$, $2 e 2 \mu$ and $4 e$ final states, respectively.

The $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ signal is modelled using the powheg Monte Carlo (MC) event generator [10,11], which calculates separately the gluon and vector-boson fusion production mechanisms with matrix elements up to next-to-leading order (NLO). The Higgs boson transverse momentum, $p_{\mathrm{T}}$, spectrum is reweighted to the calculation of Ref. [12], providing QCD corrections up to next-to-leading order and QCD soft-gluon resummations up next-to-next-to-leading log (NNLL). powheg is interfaced to pythia [13] for showering and hadronization, which in turn is interfaced to рнотоs [14] for QED radiative corrections in the final state and to tauola [ 15,16 ] for the simulation of $\tau$ decays.

The cross sections for Higgs boson production, the corresponding branching fractions, as well as their uncertainties [17], are derived to next-to-next-to-leading order (NNLO) in QCD for the gluon fusion [18-23] and vector-boson fusion [24] processes. In addition, QCD soft-gluon resummations up to NNLL are available for the gluon fusion process [25], while the NLO electroweak (EW) corrections are applied to both the gluon fusion [26,27] and vectorboson fusion [28,29] processes. The Higgs boson decay branching ratio to the four-lepton final state is predicted by prophecy 4 F [30, 31], which includes the complete NLO QCD + EW corrections, interference effects between identical final state fermions and leading two-loop heavy Higgs boson corrections to the four-fermion width. Table 1 gives the production cross sections for the $H \rightarrow 4 \ell$ for several Higgs boson masses.

The $Z Z^{(*)}$ background is generated using PYTHIA, taking into account $Z-\gamma$ interference. For the inclusive total cross section and the shape of the $m_{Z Z^{(*)}}$ spectrum, the MCFM $[32,33]$ prediction is used, which includes both quark-antiquark annihilation at QCD NLO and gluon fusion. The inclusive $Z$ boson production, $Z+$ jets, is modelled using alpgen [34] and is divided into $Z+$ light flavour jets and $Z b \bar{b}$; overlaps between the two samples are removed. Specifically, $b \bar{b}$ pairs with separation $\Delta R=\sqrt{\Delta \phi^{2}+\Delta \eta^{2}} \geqslant 0.4$ between the $b$-jets are taken from the matrix-element calculation, whereas for $\Delta R<0.4$ the parton-shower jets are taken. PYTHIA is also used as a cross-check of the alpgen results. In this search the $Z+$ jets production is normalized from the data, but for comparisons the QCD NNLO FEWZ [35,36] and the MCFM $[32,33]$ cross section calculations are used for the inclusive $Z$ boson and the $Z b \bar{b}$ production, respectively. The $t \bar{t}$ background is modelled using mC@ NLO [37] and is normalized to the approximately NNLO cross section calculated using hathor [38]. Both Alpgen and mc@ NLo are interfaced to Herwig [39] for parton shower hadronization and to jimmy [40] for the underlying event simulations.

All generated events undergo a full detector simulation performed using GEANT4 [41,42].

The number of $p p$ interactions in the same bunch crossing (pileup) is included in the simulation. The MC samples are reweighted to reproduce the observed distribution in the data.

## 4. Physics object identification and event selection

The data considered in this analysis were selected using singlelepton triggers. For electrons the threshold on the transverse energy, $E_{T}$, was $20-22 \mathrm{GeV}$ depending on the LHC instantaneous luminosity and for muons the threshold on $p_{\mathrm{T}}$ was 18 GeV . Both triggers are more than $99.5 \%$ efficient for events passing the offline selection described below.

Electron candidates consist of clusters of energy deposited in the electromagnetic calorimeter associated to ID tracks. The electrons must satisfy the "medium" electron criteria [43], which require the shower profiles to be consistent with those expected for electromagnetic showers and a well reconstructed ID track pointing to the corresponding cluster. The electron transverse momentum is computed from the cluster energy and the track direction.

Muon candidates are reconstructed by matching ID tracks with either full or partial tracks in the MS [43]. For the former case, the two independent momentum measurements are combined, whereas for the latter case the momentum is measured using the ID information only, with the MS providing muon identification. To reject cosmic rays, tracks are required to be consistent with having originated from the primary vertex, defined as the reconstructed vertex with the highest $\sum p_{\mathrm{T}}^{2}$ of associated tracks.

Leptons from Higgs boson decays are expected to be isolated and to originate from a common vertex. Track and calorimeter isolation as well as transverse impact parameter significance requirements are therefore applied to further reduce the $Z+$ jets and $t \bar{t}$ contributions. The sum of $p_{\mathrm{T}}$ of tracks within $\Delta R<0.2$ of the lepton divided by the lepton $p_{\mathrm{T}}$ is required to be less than 0.15 , while the sum $E_{\mathrm{T}}$ of the calorimeter cells within $\Delta R<0.2$ around the lepton divided by the lepton $p_{T}$ is required to be less than 0.3 . In the case of electrons, the calorimeter cells corresponding to the electromagnetic shower are subtracted. The transverse impact parameter significance, defined as the transverse impact parameter of the lepton with respect to the primary vertex divided by its uncertainty, for the two lowest $p_{\mathrm{T}}$ leptons of the quadruplet in events with $m_{4 \ell}<190 \mathrm{GeV}$ is required to be less than 3.5 and 6 for muons and electrons respectively. The selection efficiency of the isolation and impact parameter requirements has been studied using data both for isolated leptons, with $Z \rightarrow \ell \ell$ decays and non-isolated leptons from semi-leptonic $b$ - and $c$-quark decays in a heavy-flavour enriched dijet sample. Good agreement is observed between data and simulation.

Higgs boson candidates are searched by selecting two sameflavour, opposite-sign isolated lepton pairs in an event. Each lepton must satisfy $p_{\mathrm{T}}>7 \mathrm{GeV}$ and be measured in the pseudorapidity range $|\eta|<2.47$ for electrons and $|\eta|<2.5$ for muons. The electron $p_{\mathrm{T}}$ threshold is increased to 15 GeV in the transition region between the barrel and end-cap calorimeters ( $1.37<|\eta|<1.52$ ). At least two leptons must have $p_{\mathrm{T}}>20 \mathrm{GeV}$. The leptons are required to be well separated from each other with $\Delta R>0.1$. The invariant mass of the lepton pair closest to the nominal $Z$ boson mass $\left(m_{Z}\right)$ is denoted by $m_{12}$ and it is required that $\left|m_{Z}-m_{12}\right|<$ 15 GeV . The invariant mass of the remaining lepton pair, $m_{34}$, is required to be lower than 115 GeV and greater than a threshold depending on the reconstructed four lepton mass, $m_{4 \ell}$, as summarized in Table 2. The final discriminating variable is $m_{4 \ell}$, where the Higgs boson production would appear as a clustering of events. The width of the reconstructed Higgs boson mass distribution is dominated by experimental resolution at low $m_{H}$ values,

Table 2
Thresholds applied to $m_{34}$ for reference values of $m_{4 \ell}$ (see text). For other $m_{4 \ell}$ values, the selection requirement is obtained via linear interpolation.

| $m_{4 \ell}(\mathrm{GeV})$ | $\leqslant 120$ | 130 | 140 | 150 | 160 | 165 | 180 | 190 | 200 |

with a full-width at half-maximum (FWHM) which varies according to decay mode and is between $4.5(4 \mu)$ and 6.5 ( $4 e) \mathrm{GeV}$ for $m_{H}=130 \mathrm{GeV}$. At high $m_{H}$ the reconstructed width is dominated by the natural width of the Higgs boson with a FWHM of approximately 35 GeV at $m_{H}=400 \mathrm{GeV}$.

## 5. Background estimation

The dominant $Z Z^{(*)}$ background is estimated using MC simulation. Generated events are required to pass the complete analysis selection and the final yield is normalized to the integrated luminosity.

The $t \bar{t}$ background is also estimated using MC simulation. Comparison of data to MC predictions, in a control sample of events with opposite sign electron-muon pairs consistent with the $Z$ boson mass and with one or two additional charged leptons, are used to verify that the $t \bar{t}$ background is small with respect to the dominant $Z Z^{(*)}$ process and in agreement with expectation.

The $Z+$ jets background is normalized using data. The control sample is formed by selecting events with a pair of sameflavour, opposite-sign isolated leptons consistent with the $Z$ boson mass, $\left|m_{Z}-m_{12}\right|<15 \mathrm{GeV}$, and a second same-flavour, oppositesign lepton pair where only kinematic, but no isolation or impact parameter, requirements are applied. At this stage, the dominant background source depends on the flavour of the second lepton pair: $Z+$ light flavour jets dominates the final states with a second electron pair, while $Z b \bar{b}$ production dominates the final states with a second muon pair after the contributions from $t \bar{t}, Z Z^{(*)}$, and muons from in-flight $\pi$ and $K$ decays which correspond to $44 \%$ of the event yield are subtracted. The observed background, which is found to be in good agreement with expectation, is extrapolated to the signal region by means of the MC simulation.

## 6. Systematic uncertainties

Uncertainties on lepton reconstruction and identification efficiency, and on the momentum resolution and momentum scale
are determined using samples of $W, Z$ and $J / \psi$ decays. The muon efficiency uncertainty results in an acceptance uncertainty on the signal and the irreducible background which is uniform over the mass range of interest and amounts to $1.7 \%$ (1.2\%) for the $4 \mu$ $(2 e 2 \mu)$ channel. The uncertainty on the electron efficiency results in an acceptance uncertainty of $3 \%(2 \%)$ for the $4 e(2 e 2 \mu)$ channel at $m_{4 \ell}=600 \mathrm{GeV}$ reaching $15 \%(6 \%)$ at $m_{4 \ell}=110 \mathrm{GeV}$.

A conservative theoretical uncertainty of $15 \%$ is assigned to the $Z Z^{(*)}$ background contribution [44]. The $Z+$ light flavour jets and $Z b \bar{b}$ backgrounds are evaluated using data. A systematic uncertainty between $20 \%$ and $40 \%$ is assigned on their normalization to account for the statistical uncertainty in the control sample and the MC-based extrapolation to the signal region. The uncertainty on the $t \bar{t}$ cross section is found to be $10 \%$ by adding linearly the contributions from variations of the renormalization and factorization scales to those of the parton distribution functions.

The theoretical uncertainties on the Higgs boson production cross section are $15-20 \%$ for the gluon fusion process and $3-9 \%$ for the vector-boson fusion process [17], depending on the Higgs boson mass. ${ }^{2}$ They include uncertainties on the QCD scale and on the parton distribution functions [46-49]. An additional $2 \%$ uncertainty is added to the signal selection efficiency due to the modelling of the signal kinematics. This is evaluated by comparing signal samples generated with PYTHIA and the default powheg samples.

The overall uncertainty on the total integrated luminosity is 3.7\% [8].

## 7. Results

The number of events observed in each final state, separately for $m_{4 \ell}<180 \mathrm{GeV}$ and $m_{4 \ell} \geqslant 180 \mathrm{GeV}$, are compared with the ex-

[^14]

Fig. 1. Invariant mass distributions (a) $m_{12}$, (b) $m_{34}$, and (c) $m_{4 \ell}$ for the selected candidates. The data (dots) are compared to the background expectations from the dominant $Z Z^{(*)}$ process and the sum of $t \bar{t}, Z b \bar{b}$ and $Z+$ light flavour jets processes. Error bars represent $68.3 \%$ central confidence intervals.

Fig. 2. $m_{4 \ell}$ distribution of the selected candidates, compared to the background expectation. Error bars represent $68.3 \%$ central confidence intervals. The signal expectation for three $m_{H}$ hypotheses is also shown.
pectations for background and signal for various $m_{H}$ hypotheses in Table 3. In total 27 candidate events are selected by the analysis: $124 \mu, 92 e 2 \mu$, and $64 e$ events, while in the same mass range $24 \pm 4$ events are expected from the background processes. The $m_{12}, m_{34}$, and $m_{4 \ell}$ mass spectra are shown in Fig. 1. The $m_{4 \ell}$ distribution for the total background and several signal hypotheses is compared to the data in Fig. 2. The selected events have been examined visually and no evidence for reconstruction problems was identified.

Upper limits are set on the Higgs boson cross section at 95\% CL, using the $C L_{s}$ modified frequentist formalism [50] with the profile likelihood test statistic [51]. The test statistic is evaluated with a maximum likelihood fit of signal and background models to the observed $m_{4 \ell}$ distribution. Fig. 3 shows the expected and observed $95 \%$ CL cross section upper limits as a function of $m_{H}$ and Table 4 summarizes the numerical values for selected $m_{H}$ points. The consistency with the background-only hypothesis is quantified using the $p$-value, the probability that a background-only experiment fluctuates more than the observation. The most significant deviation from the background-only hypothesis is observed for $m_{H}=242 \mathrm{GeV}$ with a $p$-value of $4.9 \%$. These results do not account for the so-called "look-elsewhere" effect [52]. The SM Higgs

Fig. 3. The expected (dashed) and observed (full line) $95 \%$ CL upper limits on the Higgs boson production cross section as a function of the Higgs boson mass, divided by the expected SM Higgs boson cross section. The green and yellow bands indicate the expected sensitivity with $\pm 1 \sigma$ and $\pm 2 \sigma$ fluctuations, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this Letter.)

Table 4
Median expected and observed 95\% CL upper limits on the Higgs boson production cross section for several Higgs boson masses, divided by the expected SM Higgs boson cross section.

| Mass $(\mathrm{GeV})$ | Expected | Observed |
| :--- | :--- | :---: |
| 130 | 3.29 | 4.11 |
| 150 | 1.39 | 1.47 |
| 200 | 1.03 | 0.96 |
| 240 | 1.28 | 2.03 |
| 300 | 1.51 | 1.54 |
| 400 | 1.91 | 1.77 |
| 600 | 8.40 | 12.34 |

boson is excluded at $95 \%$ CL in the mass ranges 191-197, 199-200 and $214-224 \mathrm{GeV}$.

## 8. Summary

A search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ based on $2.1 \mathrm{fb}^{-1}$ of data recorded by the

ATLAS detector at $\sqrt{s}=7 \mathrm{TeV}$ during the 2011 run, has been presented. No significant excess of candidates is observed in the mass range between 110 and 600 GeV with respect to the expected SM background. The observed (expected) 95\% CL upper limit on the Higgs boson production cross section, in units of the SM cross section, is 0.99 (1.01) for $m_{H}=194 \mathrm{GeV}$, the region with the best expected sensitivity for this search. The SM Higgs boson is excluded at $95 \%$ CL in the mass ranges 191-197, 199-200 and $214-224 \mathrm{GeV}$.

## Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

#### Abstract

A measurement of the differential cross-section for the inclusive production of isolated prompt photons in $p p$ collisions at a center-of-mass energy $\sqrt{s}=7 \mathrm{TeV}$ is presented. The measurement covers the pseudorapidity ranges $|\eta|<1.37$ and $1.52 \leqslant|\eta|<2.37$ in the transverse energy range $45 \leqslant E_{\mathrm{T}}<$ 400 GeV . The results are based on an integrated luminosity of $35 \mathrm{pb}^{-1}$, collected with the ATLAS detector at the LHC. The yields of the signal photons are measured using a data-driven technique, based on the observed distribution of the hadronic energy in a narrow cone around the photon candidate and the photon selection criteria. The results are compared with next-to-leading order perturbative QCD calculations and found to be in good agreement over four orders of magnitude in cross-section.

The production of prompt photons at hadron colliders provides means for testing perturbative QCD predictions [1], providing a colorless probe of the hard scattering process. The measurement of the inclusive production of prompt photons could be used to constrain the parton distribution functions; in particular it is sensitive to the gluon content of the proton [2] through the $q g \rightarrow q \gamma$ subprocess, which at leading order dominates the inclusive prompt photon cross-section at the LHC.

ATLAS has recently published a measurement of the inclusive photon cross-section in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ using an integrated luminosity of $880 \mathrm{nb}^{-1}$ [3]; a similar measurement has been performed by the CMS Collaboration [4] using an integrated luminosity of $2.9 \mathrm{pb}^{-1}$. Analogous measurements have been perfomed in $p \bar{p}$ collisions at a lower center of mass at the Tevatron [5,6], and in deep inelastic ep scattering at HERA [7,8]. This Letter presents the measurement of the differential production crosssection of isolated prompt photons with transverse energies $E_{\mathrm{T}}$ above 45 GeV using $34.6 \pm 1.2 \mathrm{pb}^{-1}$ of $p p$ collision data at $\sqrt{s}=$ 7 TeV collected in 2010. Isolated prompt photons in the pseudorapidity ranges $|\eta|<0.6,0.6 \leqslant|\eta|<1.37,1.52 \leqslant|\eta|<1.81$ and $1.81 \leqslant|\eta|<2.37$ are studied. ${ }^{1}$

[^15]In the following, all photons produced in $p p$ collisions and not coming from hadron decays are considered as prompt: they include both direct photons, which originate from the hard subprocess, and fragmentation photons, which are the result of the fragmentation of a colored high- $p_{\mathrm{T}}$ parton [9,10]. Isolated photons are considered: from a theoretical perspective, photons are isolated if the transverse energy $E_{\mathrm{T}}^{\text {iso }}$, within a cone of radius $R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}=0.4$ centered around the photon direction in the pseudorapidity $(\eta)$ and azimuthal angle $(\phi)$ plane, ${ }^{2}$ is smaller than $E_{\mathrm{T}}^{\text {cut }}$. In Jetphox [9], used for next-to-leading order (NLO) calculations, $E_{\mathrm{T}}^{\text {iso }}$ is calculated from all partons. Similarly, a corresponding isolation prescription is applied experimentally on the reconstructed objects, based on the energy reconstructed in an $R=0.4$ cone around the photon candidate, corrected for the effects associated with: the energy of the photon candidate itself, the underlying event and the collision pileup [3]. The main background to these isolated prompt photons is composed of photons from decays of light neutral mesons, such as the $\pi^{0}$ or $\eta$.

Photons are detected in ATLAS by a lead-liquid Argon sampling electromagnetic calorimeter (ECAL) with an accordion geometry, divided into a barrel section covering the pseudorapidity region $|\eta|<1.475$ and two endcap sections covering the pseudorapidity regions $1.375<|\eta|<3.2$. It consists of three longitudinal layers. The first layer has a high granularity along the $\eta$ direction (between 0.003 and 0.006 depending on $\eta$, with the exception of the regions $1.4<|\eta|<1.5$ and $|\eta|>2.4$ ), sufficient to provide an event-by-event discrimination between single photon showers and

[^16]showers coming from a $\pi^{0}$ decay. The second layer has a granularity of $0.025 \times 0.025$ in $\eta \times \phi$. A third layer is used to correct for the leakage beyond the electromagnetic calorimeter for highenergy showers, while in front of the accordion calorimeter a thin presampler layer, covering the pseudorapidity interval $|\eta|<1.8$, is used to correct for the energy absorbed before the calorimeter.

The ECAL energy resolution is parametrized as $\sigma(E) / E=$ $a / \sqrt{E(\mathrm{GeV})} \oplus c$ with the largest contribution coming from the sampling term $a$, corresponding to approximately $10 \%$ (20\%) in the barrel (endcap) region. For energies above 200 GeV the global constant term $c$, estimated to be $(1.2 \pm 0.6) \%((1.8 \pm 0.6) \%)$ in the barrel (endcap) for the 2010 data, starts to dominate [11]. In front of the electromagnetic calorimeter the inner detector allows the reconstruction of tracks from the primary $p p$ collision point and also from secondary vertices, permitting an efficient reconstruction of photon conversions in the beam pipe and inner detector up to a radius of $\sim 80 \mathrm{~cm}$. Further details of the inner detector, the electromagnetic calorimeter and the whole ATLAS detector are documented in Ref. [12].

Event samples simulated with Pythia 6.4.21 [13] are used to study the characteristics of signal and background events. To estimate systematic uncertainties related to the choice of the event generator and the parton shower model, alternative samples are generated with Herwig 6.5 [14]. Events used in this analysis are triggered using a single-photon trigger with a nominal transverse energy threshold of 40 GeV . The trigger efficiency, $\varepsilon^{\text {trig }}$, is measured using a bootstrap method to be $\left(99.4_{-0.2}^{+0.6}\right) \%$ for prompt photon candidates with $E_{\mathrm{T}}>45 \mathrm{GeV}$ passing the selection criteria presented below. The same trigger condition was used for the whole dataset, even though the mean number of events per collision rose from $<1$ to $\sim 3$ as the instantaneous luminosity increased during 2010. Collision candidates are selected by requiring a primary vertex with at least three associated charged particle tracks, consistent with the beam interaction region. The total number of selected events in data after these requirements is almost 1.7 million, with a negligible amount of non-collision background.

Photon candidates are formed from clusters of energy deposits reconstructed in the electromagnetic calorimeter [15]. Clusters without matching tracks are classified as unconverted photon candidates. The presence of one or two tracks coming from a conversion vertex is used to distinguish converted photons from electrons. Converted photon clusters are rebuilt with a wider size in $\phi$, to account for the opening angle between the conversion products due to the magnetic field. A specific energy calibration [15] is then applied separately for converted and unconverted photon candidates to account for energy loss in front of the ECAL and both lateral and longitudinal leakage. Photon clusters are removed if their barycenter lies in the transition between the barrel and endcap regions of the electromagnetic calorimeter, corresponding to $1.37<|\eta|<$ 1.52, where larger uncertainties related to the efficiency measurement are expected. Clusters containing cells overlapping with the small number of regions with problematic calorimeter readout or with very noisy cells are also removed. Over 0.8 million photon candidates with $E_{\mathrm{T}}>45 \mathrm{GeV}$ remain in the data sample.

A measurement of the transverse isolation energy $E_{\mathrm{T}}^{\text {iso }}$ is associated with each photon candidate, computed by summing the calorimeter energy in a cone of $R=0.4$ around the candidate, as detailed in Ref. [3]. Corrections to this isolation energy are derived from simulation to remove the energy of the photon itself that leaks into the isolation cone. An event-by-event correction [16,17] is applied to subtract the estimated contributions from the underlying event and in-time pileup (i.e. from additional proton-proton interactions). The correction to $E_{\mathrm{T}}^{\mathrm{iso}}$ is typically 900 MeV . After this subtraction, the remaining fluctuations are dominated by electronic noise from the calorimeter measurement. The effect of the out-
of-time pileup, associated with collisions taking place in previous bunch-crossings, is found to be minimal (i.e. shifts of 200 MeV at most, towards lower isolation energies). The corrections mentioned above allow $E_{\mathrm{T}}^{\text {iso }}$ to be directly compared to parton-level theoretical predictions.

All photon candidates having reconstructed isolation energy $<3 \mathrm{GeV}$ are considered as experimentally isolated. This definition is similar to applying a 4 GeV cut on the particle-level isolation, defined as the transverse energy of all stable particles in a cone of radius $R=0.4$ around the photon direction (with the underlying event removed as before). The small difference between the two, caused by noise and other detector effects, is taken into account in the uncertainties associated with the photon reconstruction efficiency $\varepsilon^{\text {reco }}$ discussed below. The particle-level isolation can in turn be related to the parton-level isolation in Jetphox that is used for the NLO predictions. The efficiency of the isolation criteria is found to be similar (i.e. within a few percent) at both the particle-level and the parton-level for simulated photons passing the selection described below.

As in Ref. [3], the reconstruction and preselection efficiency $\varepsilon^{\text {reco }}$ is computed from simulated prompt photons as a function of the true photon $E_{\mathrm{T}}$. It is defined as the ratio between the number of photons reconstructed in a given $|\eta|$ interval with reconstructed $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$, and the total number of true prompt photons with true pseudorapidity in the same $|\eta|$ interval, and with particlelevel transverse isolation energy $<4 \mathrm{GeV}$. The estimated $\varepsilon^{\text {reco }}$ for photons with $45<E_{\mathrm{T}}<400 \mathrm{GeV}$ is $\sim 85 \%$ (75\%) in the barrel (endcap) region. The main inefficiency $(\sim 10 \%)$ is due to the acceptance loss originating from a few inoperative optical links in the calorimeter readout. A similar reduction is caused by the isolation requirement in the pseudorapidity region $1.52 \leqslant|\eta|<1.81$ where the calorimetric isolation suffers from larger detector effects. The systematic uncertainty on $\varepsilon^{\text {reco }}$ associated with the experimental isolation requirement is evaluated from the prompt photon simulation by varying the value of the isolation criterion by the average difference $(\sim 500 \mathrm{MeV})$ observed for electrons from $W \rightarrow e v$ events in data and simulation. The estimated uncertainty varies between 3 and $4 \%$ depending on $\eta$. The uncertainty associated with the imperfect knowledge of the material in front of the ECAL is estimated by comparing the expected efficiencies in a sample simulated with the nominal ATLAS setup, and one with increased material. It varies between 1 and $2.5 \%$, depending on $\eta$.

Shape variables computed from the lateral and longitudinal energy profiles of the shower in the calorimeters are used to discriminate signal from background [15,18]. As detailed in Ref. [3], selection criteria on these variables, optimized independently for unconverted and converted photons, are applied to reconstructed photon candidates. The requirements on these variables are applied in stages resulting in tight candidates: firstly jets are removed whilst still keeping a high photon efficiency and then secondly wide or closely spaced showers (i.e. those consistent with jets or meson decays) are rejected. The selection criteria have been revised to minimize the systematics on the efficiency extraction, especially in the region $1.81 \leqslant|\eta|<2.37$. The photon identification efficiency $\varepsilon^{\mathrm{ID}}$ is computed from simulation as a function of transverse energy in each pseudorapidity region. It is defined as the efficiency for reconstructed (true) prompt photons, with measured $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$, to pass the identification criteria mentioned above.

Following the same method as in Ref. [3], the value of $\varepsilon^{\mathrm{ID}}$ is determined after correcting the simulated shower shapes for the observed average differences with respect to data. In the present analysis, however, the corrections are estimated for unconverted and converted photons separately. This helps to reduce the systematic uncertainties associated with the correction procedure. The

Fig. 1. Distributions of $E_{\mathrm{T}}^{\text {iso }}$ for photon candidates with $45<E_{\mathrm{T}}<55 \mathrm{GeV}$ in $|\eta|<$ 0.6 passing the tight (solid dots) and non-tight (open triangles) shower-shape-based selection criteria. The non-tight distribution is normalized to the tight distribution for $E_{\mathrm{T}}^{\text {iso }}>5 \mathrm{GeV}$ (non-isolated region), where the signal contamination is fairly small.
value of $\varepsilon^{\mathrm{ID}}$ varies from 90 to $97 \%$, depending on $\eta$ and increasing with $E_{\mathrm{T}}$. The systematic uncertainty on $\varepsilon^{\mathrm{ID}}$ is also $\eta$ dependent, ranging from 1.5 to $3 \%$, with contributions from: detector simulation; background contamination; (un)converted photon misclassification; direct/fragmentation photon fraction; the choice of different Monte Carlo generators (MC). These uncertainties affect the reconstruction and identification efficiencies in a correlated way, and are treated as such in their combination. After applying the isolation criterion and the tight selection on the shape variables, almost 173,000 photon candidates remain in the data sample.

As in Ref. [3], a two-dimensional-sideband method is used to estimate the background contribution from data and to measure the prompt photon signal yield. The two dimensions are the transverse isolation energy $E_{\mathrm{T}}^{\text {iso }}$ and the quality of the photon, defined by whether or not it passes the shower shape identification criteria. On the isolation axis, the signal region contains photon candidates with $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$, while the sideband region contains nonisolated photon candidates with $E_{\mathrm{T}}^{\text {iso }}>5 \mathrm{GeV}$. On the other axis, the signal photon candidates are required to pass the tight identification criteria (tight candidates). Those failing the tight criteria but passing a background-enriching subset of these criteria (non-tight candidates) are contained in the sideband. A typical distribution of $E_{\mathrm{T}}^{\text {iso }}$ for both tight and non-tight data is shown in Fig. 1 for photon candidates with $45<E_{\mathrm{T}}<55 \mathrm{GeV}$ in $|\eta|<0.6$. The non-tight distribution is normalized to the tight one above 5 GeV where a only small signal contamination is expected.

Corrections for the signal contamination in the background control regions are computed using prompt photon Monte Carlo samples. For the tight isolated signal leaking into the non-isolated region, these are as large as $17 \%$ at high $E_{\mathrm{T}}$. Smaller leakages of up to $6 \%$ are expected for the other two background control regions. The purity of isolated prompt photons measured with this method increases with $E_{\mathrm{T}}$ from $91 \%$ at $E_{\mathrm{T}}=45 \mathrm{GeV}$ to close to $100 \%$ at $E_{\mathrm{T}}>200 \mathrm{GeV}$.

The main contributions to the uncertainty on the yields come from the fragmentation fraction ( $\lesssim 8 \%$ ), estimated by conservatively varying the fraction from 0 to $100 \%$ in the signal sample, and pileup ( $5 \%$, with fluctuations up to $8 \%$ for $1.52 \leqslant|\eta|<1.81$ ), estimated by increasing the correction to $E_{\mathrm{T}}^{\text {iso }}$ by $50 \%$ both in data and simulation. This scaling of the correction minimizes the residual dependency of the isolation on the number of primary vertices
(i.e. pileup) in data. The other contributions to the uncertainty are: correlated background in the two-dimensional-sideband regions ( $\lesssim 5 \%$ barrel and $\lesssim 10 \%$ endcap, $E_{\mathrm{T}}$ dependent), definition of the two-dimensional-sideband regions ( $\lesssim 5 \%$ non-tight and $1 \%$ non-isolated), photon energy scale ( $2-8 \%, \eta$ dependent), slightly narrower showers in simulation than in data $\left(2-5 \%, \eta\right.$ and $E_{\mathrm{T}}$ dependent), isolation shower leakage corrections (1-5\%), Monte Carlo generator ( $2 \%$ ), material effects ( $<1 \%$ ), and prompt electron misidentification ( $\sim 0.5 \%$, varying with $E_{\mathrm{T}}$ ). Globally, the uncertainties on the photon signal yields are less than $10 \%$, and decrease with $E_{\mathrm{T}}$.

The average differential cross-section $\left\langle d \sigma_{j}^{k} / d E_{\mathrm{T}}^{\text {true }}\right\rangle$ for the production of isolated prompt photons in a bin $j$ of $E_{\mathrm{T}}^{\text {true }}$ (integrated over one true $|\eta|$ bin $k$ ) is related to the signal yield $N_{i}^{\gamma, \text { reco, } k}$ (in the $k$ th $|\eta|$ bin and $i$ th $E_{\mathrm{T}}$ bin) by the relationship:

$$
\begin{align*}
N_{i}^{\gamma, \text { reco }, k}= & \left(\int \mathcal{L} d t\right) \varepsilon^{\mathrm{trig}} \varepsilon_{i}^{\mathrm{ID}, k} \\
& \times \sum_{j} R_{i j}^{k} \varepsilon_{j}^{\mathrm{reco}, k} \Delta E_{\mathrm{T}, j}^{\mathrm{true}}\left\langle\frac{d \sigma_{j}^{k}}{d E_{\mathrm{T}}^{\mathrm{true}}}\right\rangle \tag{1}
\end{align*}
$$

where $\varepsilon_{i}^{\mathrm{ID}, k}$ is the average identification efficiency and $R_{i j}^{k}$ is the $E_{\mathrm{T}}$ response matrix. The elements of $R_{i j}^{k}$ are evaluated from the ratio of the true to reconstructed $E_{\mathrm{T}}$ distributions of photon candidates, using simulated samples of isolated prompt photons. The migration from one $E_{\mathrm{T}}$ bin to another is less than $10 \%$ in most $E_{\mathrm{T}}$ and $\eta$ regions. A larger migration of up to $18 \%$ is observed in the region $1.52 \leqslant|\eta|<1.81$, where more material is present in front of the electromagnetic calorimeter. Migrations between $\eta$ bins are neglected given the large bin size and the excellent ECAL $\eta$ resolution. A singular value decomposition (SVD) [19] is used to unfold the $E_{\mathrm{T}}$ distribution for detector effects. The regularization of the resulting unfolded distribution is tuned using simulated events and chosen to be very loose to avoid a potential bias toward the truth reference spectrum. The simulation model dependence is tested with pseudo-experiments, using Pythia and Herwig simulated samples. The difference of the unfolded crosssection obtained in both cases is found to be $<3 \%$. The uncertainty associated with the ECAL energy resolution is $\sim 1 \%$. The lower and upper $E_{\mathrm{T}}$ constraints have negligible effect on the unfolded spectrum.

The measured inclusive isolated prompt photon production cross-sections are shown in Fig. 2. They are presented as a function of the photon transverse energy, for each of the four considered pseudorapidity intervals. They are also presented in tabular form in Appendix A. The error bars on the data points represent the combination of the statistical and systematic uncertainties: systematic uncertainties dominate over the entire kinematic range considered. The contribution from the luminosity uncertainty (3.4\%) is shown separately as it represents a possible global change by a common multiplicative factor. The data agree with NLO pQCD calculations, obtained with JeTphox 1.2.2 [9] using the CTEQ 6.6 PDFs [20] and the BFG set II [21] fragmentation functions (FF). These predictions are negligibly affected when using BFG set I instead. The nominal renormalization, factorization and fragmentation scales are set to the $E_{\mathrm{T}}$ of the photon. Theoretical calculations using MSTW 2008 [22] and NNPDF2.0 [23] PDFs show a similarly good agreement to data. The central values obtained with the MSTW 2008 (NNPDF2.0) PDFs are 3 to 5\% ( 1 to $4 \%$ ) higher than those predicted using the CTEQ 6.6 PDFs. The total systematic uncertainties on the theoretical predictions are represented with a solid band. The scale uncertainty ( $\sim 10 \%$ ) is the leading theoretical systematic uncertainty. It is estimated from the enve-

Fig. 2. Measured (dots) and expected (shaded area) inclusive prompt photon production cross-sections, and their ratio, as a function of the photon $E_{T}$ and in the range (a) $|\eta|<0.6$, (b) $0.6 \leqslant|\eta|<1.37$, (c) $1.52 \leqslant|\eta|<1.81$ and (d) $1.81 \leqslant|\eta|<2.37$. The data error bars combine the statistical and systematic uncertainties, with the luminosity uncertainty shown separately (dotted bands).
lope of independent and coherent variations of the three scales, by a factor of two around the central value, with the renormalization scale (coherent variation) dominating this envelope at low (high) $E_{\mathrm{T}}$, while the fragmentation scale produces the smallest variation. The scale error is summed in quadrature with the contributions from the PDF uncertainty ( $5 \%$ at $68 \%$ C.L.) and the uncertainty associated with the choice of the parton-level isolation criterion (2\%). The same quantities are also shown in the bottom panels after having been normalized to the expected NLO pQCD cross-sections.

In conclusion, the inclusive isolated prompt photon production cross-section in $p p$ collisions at a center-of-mass energy $\sqrt{s}=$ 7 TeV has been measured using $35 \mathrm{pb}^{-1}$ of integrated luminosity collected by the ATLAS detector at the LHC. The differential crosssection has been measured as a function of the prompt photon transverse energy between 45 and 400 GeV , in the pseudorapidity ranges $0.0 \leqslant|\eta|<0.6,0.6 \leqslant|\eta|<1.37,1.52 \leqslant|\eta|<1.81$ and $1.81 \leqslant|\eta|<2.37$. In general, good agreement between the data and the NLO pQCD predictions is observed. This measurement improves the precision and significantly extends the kinematic
regime explored in the previous measurement [3] and is consistent in the region where the two measurements overlap.

Over most of this extended kinematic range the experimental errors are smaller than the theoretical ones. The large theoretical scale error limits the discrimination between PDFs. Future measurements of this process in finer pseudorapidity binning and those of the photon + jet system should provide more insight into the PDF differences.

## Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

## Appendix A. Cross-section measurements

Tables A.1-A. 4 list the values of the measured isolated prompt photon production cross-sections, for the $0.0 \leqslant|\eta|<0.6,0.6 \leqslant$ $|\eta|<1.37,1.52 \leqslant|\eta|<1.81$ and $1.81 \leqslant|\eta|<2.37$ regions, respectively. The various systematic uncertainties originating from the purity measurement, the photon selection and identification efficiency and the luminosity are shown. In addition, the correlated uncertainties between the efficiency and the purity determination
are propagated as such and included separately ( $\sigma_{\text {corr }}$ ). The total uncertainty is the combination of the statistical and systematic uncertainties (summed in quadrature), except for the uncertainty on the luminosity.

#### Abstract

This Letter presents a search for the Standard Model Higgs boson in the decay channel $H \rightarrow Z Z^{(*)} \rightarrow$ $\ell^{+} \ell^{-} \ell^{\prime+} \ell^{\prime-}$, where $\ell, \ell^{\prime}=e$ or $\mu$, using proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ recorded with the ATLAS detector and corresponding to an integrated luminosity of $4.8 \mathrm{fb}^{-1}$. The four-lepton invariant mass distribution is compared with Standard Model background expectations to derive upper limits on the cross section of a Standard Model Higgs boson with a mass between 110 GeV and 600 GeV . The mass ranges $134-156 \mathrm{GeV}, 182-233 \mathrm{GeV}, 256-265 \mathrm{GeV}$ and $268-415 \mathrm{GeV}$ are excluded at the $95 \%$ confidence level. The largest upward deviations from the background-only hypothesis are observed for Higgs boson masses of $125 \mathrm{GeV}, 244 \mathrm{GeV}$ and 500 GeV with local significances of 2.1, 2.2 and 2.1 standard deviations, respectively. Once the look-elsewhere effect is considered, none of these excesses are significant.

## 1. Introduction

The search for the Standard Model (SM) Higgs boson [1-3] is one of the most important aspects of the CERN Large Hadron Collider (LHC) physics program. Direct searches performed at the CERN Large Electron-Positron Collider (LEP) excluded at 95\% confidence level (CL) the production of a SM Higgs boson with mass, $m_{H}$, less than 114.4 GeV [4]. The searches at the Fermilab Tevatron $p \bar{p}$ collider have excluded at $95 \%$ CL the region $156<$ $m_{H}<177 \mathrm{GeV}$ [5]. At the LHC, results from data collected in 2010 extended the search in the region $200<m_{H}<600 \mathrm{GeV}$ by excluding a Higgs boson with cross section larger than 5-20 times the SM prediction [6,7]. In ATLAS these results were extended further using the first $1.04-2.28 \mathrm{fb}^{-1}$ of data recorded in 2011 [8-13]. In particular, the $H \rightarrow W W^{(*)} \rightarrow \ell^{+} \nu \ell^{-} \bar{v}$ search [13] excluded at $95 \%$ CL the region $145<m_{H}<206 \mathrm{GeV}$.

The search for the SM Higgs boson through the decay $H \rightarrow$ $Z Z^{(*)} \rightarrow \ell^{+} \ell^{-} \ell^{\prime+} \ell^{\prime-}$, where $\ell, \ell^{\prime}=e$ or $\mu$, provides good sensitivity over a wide mass range. Previous results from ATLAS in this channel [9] excluded three mass regions between 191 GeV and 224 GeV at $95 \% \mathrm{CL}$ with a $2.1 \mathrm{fb}^{-1}$ data sample. This Letter presents an update of this search in the mass range from 110 GeV to 600 GeV , superseding Ref. [9]. Three distinct final states, $\mu^{+} \mu^{-} \mu^{+} \mu^{-}(4 \mu), e^{+} e^{-} \mu^{+} \mu^{-}(2 e 2 \mu)$, and $e^{+} e^{-} e^{+} e^{-}$(4e), are selected. The largest background to this search comes from continuum $\left(Z^{(*)} / \gamma^{*}\right)\left(Z^{(*)} / \gamma^{*}\right)$ production, referred to as $Z Z^{(*)}$ hereafter.

[^17]For $m_{H}<180 \mathrm{GeV}$, there are also important background contributions from $Z+$ jets and $t \bar{t}$ production, where the additional charged lepton candidates arise either from decays of hadrons with $b$ - or $c$-quark content or from misidentification of jets.

The $\sqrt{s}=7 \mathrm{TeV} p p$ collision data were recorded during 2011 with the ATLAS detector at the LHC and correspond to an integrated luminosity of $4.8 \mathrm{fb}^{-1}$ [14,15]. This analysis is using more than twice the integrated luminosity of Ref. [9], including the data therein. The electron identification efficiency has been improved; furthermore the electron tracks have been refitted using a Gaussian-sum filter [16], which corrects for energy losses due to bremsstrahlung. The analysis also benefits from recent significant improvements in the alignment of the inner detector and the muon spectrometer.

## 2. The ATLAS detector

The ATLAS detector [17] is a multi-purpose particle physics detector with forward-backward symmetric cylindrical geometry. ${ }^{1}$ The inner tracking detector (ID) [18] covers $|\eta|<2.5$ and consists of a silicon pixel detector, a silicon microstrip detector, and a transition radiation tracker. The ID is surrounded by a thin superconducting solenoid providing a 2 T axial magnetic field. A high-granularity lead/liquid-argon (LAr) sampling

[^18]Table 1

 $m_{H}>300 \mathrm{GeV}$. The decay branching ratio for $H \rightarrow 4 \ell$, with $\ell=e$ or $\mu$, is reported in the last column [34].

calorimeter [19] measures the energy and the position of electromagnetic showers with $|\eta|<3.2$. LAr sampling calorimeters are also used to measure hadronic showers in the end-cap ( $1.5<|\eta|<3.2$ ) and forward ( $3.1<|\eta|<4.9$ ) regions, while an iron/scintillator tile calorimeter [20] measures hadronic showers in the central region ( $|\eta|<1.7$ ). The muon spectrometer (MS) [21] surrounds the calorimeters and consists of three large superconducting air-core toroids, each with eight coils, a system of precision tracking chambers ( $|\eta|<2.7$ ), and fast tracking chambers for triggering. A three-level trigger system [22] selects events to be recorded for offline analysis.

## 3. Data and simulation samples

The data are subjected to quality requirements: events recorded during periods when the relevant detector components were not operating normally are rejected. The resulting integrated luminosity is $4.8 \mathrm{fb}^{-1}, 4.8 \mathrm{fb}^{-1}$ and $4.9 \mathrm{fb}^{-1}$ for the $4 \mu, 2 e 2 \mu$ and $4 e$ final states, respectively.

The $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ signal is modelled using the powheg Monte Carlo (MC) event generator [23,24], which calculates separately the gluon-gluon and vector-boson fusion production mechanisms with matrix elements up to next-to-leading order (NLO). The Higgs boson transverse momentum $\left(p_{\mathrm{T}}\right)$ spectrum in the gluon fusion process is reweighted to match the calculation of Ref. [25], which includes quantum chromodynamics (QCD) corrections up to NLO and QCD soft-gluon resummations up to next-to-next-toleading logarithm (NNLL). pOWHEG is interfaced to PYTHIA [26] for showering and hadronization, which in turn is interfaced to рнотоs [27] for quantum electrodynamics (QED) radiative corrections in the final state and to tauola $[28,29]$ for the simulation of $\tau$ lepton decays. pythia is used to simulate the production of a Higgs boson in association with a $W$ or a $Z$ boson.

The Higgs boson production cross sections and decay branching ratios [30-33], as well as their uncertainties, are taken from Refs. [34,35]. The cross sections for the gluon fusion process have been calculated at next-to-leading order (NLO) in QCD [36-38], and then at next-to-next-to-leading order (NNLO) [39-41]. In addition, QCD soft-gluon resummations up to NNLL are applied for the gluon fusion process [42]. The NLO electroweak (EW) corrections are applied $[43,44]$. These results are compiled in Refs. [45-47] assuming factorization between QCD and EW corrections. The cross sections for the vector-boson fusion process are calculated with full NLO QCD and EW corrections [48-50], and approximate NNLO QCD corrections are available [51]. The associated productions with a $W$ or $Z$ boson are calculated at NLO [52] and at NNLO [53] in QCD, and NLO EW radiative corrections [54] are applied. The uncertainty in the production cross section due to the choice of QCD scale is ${ }_{-8}^{+12} \%$ for the gluon fusion process, and $\pm 1 \%$ for the vector-boson fusion, associated WH production, and associated ZH production processes [34]. The uncertainty in the production cross section due to the parton distribution function (PDF) and $\alpha_{s}$ is $\pm 8 \%$ for gluoninitiated process and $\pm 4 \%$ for quark-initiated processes [55-59].

The Higgs boson decay branching ratio to the four-lepton final state is predicted by prophecy 4 F [31,32], which includes the complete NLO QCD + EW corrections, interference effects between identical final-state fermions, and leading two-loop heavy Higgs boson corrections to the four-fermion width. Table 1 gives the production cross sections and branching ratios for $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ for several Higgs boson masses.

The cross section calculations do not take into account the width of the Higgs boson, which is implemented through a relativistic Breit-Wigner line shape applied at the event-generator level. It has been suggested [35,60-62] that effects related to off-shell Higgs boson production and interference with other SM processes may become sizeable for the highest masses ( $m_{H}>$ 400 GeV ) considered in this search. In the absence of a full calculation, a conservative estimate of the possible size of such effects is included as a signal normalization systematic uncertainty following a parameterization as a function of $m_{H}: 150 \% \times m_{H}^{3}[\mathrm{TeV}]$, for $m_{H} \geqslant 300 \mathrm{GeV}$ [35].

The $Z Z^{(*)}$ continuum background is modelled using pythia. The mCFM [63,64] prediction, including both quark-antiquark annihilation and gluon fusion at QCD NLO, is used for the inclusive total cross section and the shape of the invariant mass of the $Z Z^{(*)}$ system $\left(m_{Z Z^{(*)}}\right)$. The QCD scale uncertainty has a $\pm 5 \%$ effect on the expected $Z Z^{(*)}$ background, and the effect due to the PDF and $\alpha_{s}$ uncertainties is $\pm 4 \%$ ( $\pm 8 \%$ ) for quark-initiated (gluoninitiated) processes. An additional theoretical uncertainty of $\pm 10 \%$ on the inclusive $Z Z^{(*)}$ cross section is conservatively included due to the missing higher-order QCD corrections for the gluoninitiated process, and a correlated uncertainty on the predicted $m_{Z Z^{(*)}}$ spectrum is estimated by varying the gluon-initiated contribution by $100 \%$ [65].

The $Z+$ jets production is modelled using alpgen [66] and is divided into two sources: $Z+$ light jets - which includes $Z c \bar{c}$ in the massless $c$-quark approximation and $Z b \bar{b}$ from parton showers - and $Z b \bar{b}$ using matrix-element calculations that take into account the $b$-quark mass. The MLM [67] matching scheme is used to remove any double counting of identical jets produced via the matrix-element calculation and the parton shower, but this scheme is not implemented for $b$-jets. Therefore, $b \bar{b}$ pairs with separation $\Delta R=\sqrt{(\Delta \phi)^{2}+(\Delta \eta)^{2}}>0.4$ between the $b$-quarks are taken from the matrix-element calculation, whereas for $\Delta R<0.4$ the partonshower $b \bar{b}$ pairs are used. In this search the $Z+$ jets background is normalized using control samples from data. For comparisons with simulation, the QCD NNLO FEWZ $[68,69]$ and MCFM cross section calculations are used for inclusive $Z$ boson and $Z b \bar{b}$ production, respectively. The $t \bar{t}$ background is modelled using mc@nlo [70] and is normalized to the approximate NNLO cross section calculated using hathor [71]. The effect of the QCD scale uncertainty on the cross section is ${ }_{-9}^{+4} \%$, while the effect of PDF and $\alpha_{s}$ uncertainties is $\pm 7 \%$. Both ALPGEN and mc@nlo are interfaced to HERWIG [72] for parton shower hadronization and to JIMMY [73] for the underlying event simulation.

Table 2
Lower thresholds applied to $m_{34}$ for reference values of $m_{4 \ell}$. For $m_{4 \ell}$ values between these reference values the selection requirement is obtained via linear interpolation.

| $m_{4 \ell}(\mathrm{GeV})$ | $\leqslant 120$ | 130 | 140 | 150 | 160 | 165 | 180 | 190 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| $m_{34}$ threshold $(\mathrm{GeV})$ | 15 | 20 | 25 | 30 | 30 | 35 | 40 | 50 |

Generated events are fully simulated using the ATLAS detector simulation [74] within the GEANT4 framework [75]. Additional $p p$ interactions in the same and nearby bunch crossings (pile-up) are included in the simulation. The MC samples are reweighted to reproduce the observed distribution of the mean number of interactions per bunch crossing in the data.

## 4. Lepton identification and event selection

The data considered in this analysis are selected using singlelepton or di-lepton triggers. For the single-muon trigger the $p_{T}$ threshold is 18 GeV , while for the single-electron trigger the transverse energy, $E_{\mathrm{T}}$, threshold is $20-22 \mathrm{GeV}$ depending on the LHC instantaneous luminosity. For the di-muon and di-electron triggers the thresholds are $p_{\mathrm{T}}=10 \mathrm{GeV}$ for each of the muons, and $E_{\mathrm{T}}=12 \mathrm{GeV}$ for each of the electrons, respectively.

Electron candidates consist of clusters of energy deposited in the electromagnetic calorimeter that are associated to ID tracks. Electron tracks have been refitted using a Gaussian-sum filter. The electron candidates must satisfy a set of identification criteria [76] that require the shower profiles to be consistent with those expected for electromagnetic showers and a well-reconstructed ID track pointing to the corresponding cluster. The electron transverse momentum is computed from the cluster energy and the track direction at the interaction point.

Muon candidates are reconstructed by matching ID tracks with either complete or partial tracks reconstructed in the MS [77]. If a complete track is present, the two independent momentum measurements are combined; otherwise the momentum is measured using the ID information only. To reject cosmic rays, muon tracks are required to have a transverse impact parameter, defined as the impact parameter in the transverse plane with respect to the primary vertex, of less than 1 mm . The primary vertex is defined as the reconstructed vertex with the highest $\sum p_{\mathrm{T}}^{2}$ of associated tracks among the reconstructed vertices with at least three associated tracks.

This analysis searches for Higgs boson candidates by selecting two same-flavour, opposite-sign lepton pairs in an event. The impact parameter of the leptons along the beam axis is required to be within 10 mm of the primary vertex. Each lepton must satisfy $p_{\mathrm{T}}>7 \mathrm{GeV}$ and be measured in the pseudorapidity range $|\eta|<2.47$ for electrons and $|\eta|<2.7$ for muons. At least two leptons in the quadruplet must have $p_{\mathrm{T}}>20 \mathrm{GeV}$. The leptons are required to be separated from each other by $\Delta R>0.1$. The invariant mass of the same-flavour and opposite-sign lepton pair closest to the $Z$ boson mass $\left(m_{Z}\right)$ is denoted by $m_{12}$ and $\left|m_{Z}-m_{12}\right|<$ 15 GeV is required. The invariant mass of the remaining sameflavour and opposite-sign lepton pair, $m_{34}$, is required to be in the range $m_{\min }<m_{34}<115 \mathrm{GeV}$, where $m_{\text {min }}$ depends on the reconstructed four-lepton invariant mass, $m_{4 \ell}$, as shown in Table 2.

The $Z+$ jets and $t \bar{t}$ background contributions are further reduced by applying track- and calorimeter-based isolation and impact parameter requirements on the leptons. For a lepton to be isolated, the sum of the $p_{\mathrm{T}}$ of tracks within $\Delta R<0.2$ of the lepton divided by the lepton $p_{\mathrm{T}}$ is required to be less than 0.15 , while the sum of the $E_{\mathrm{T}}$ of the calorimeter cells with $\Delta R<0.2$ around the lepton divided by the lepton $p_{\mathrm{T}}$ is required to be less than 0.3 . The lepton track and the energies of calorimeter cells associated to it are excluded from the sum. Any contributions arising from other
leptons of the quadruplet are subtracted. To reduce the impact of event pile-up, the tracks included in the $p_{\mathrm{T}}$ sum for track isolation must be associated with the primary vertex, and the transverse energy included in the $E_{T}$ sum for calorimeter isolation is corrected by subtracting a small amount of energy that depends on the number of reconstructed vertices in the event. In events with four-lepton invariant mass ( $m_{4 \ell}$ ) below 190 GeV , the transverse impact parameter significance, defined as the transverse impact parameter divided by the corresponding uncertainty, for the two lowest $p_{\text {T }}$ leptons in the quadruplet is required to be less than 3.5 (6) for muons (electrons).

The combined signal reconstruction and selection efficiencies for $m_{H}=130 \mathrm{GeV}\left(m_{H}=360 \mathrm{GeV}\right)$ are $27 \%(60 \%)$ for the $4 \mu$ channel, $18 \%$ ( $52 \%$ ) for the $2 e 2 \mu$ channel and $14 \%$ ( $45 \%$ ) for the $4 e$ channel. The final discriminating variable is $m_{4 \ell}$, for which Higgs boson production would appear as a clustering of events. In Fig. 1, the invariant mass distributions for the $4 \mu$ and $4 e$ channels are presented for a simulated signal sample with $m_{H}=130 \mathrm{GeV}$. The width of the reconstructed Higgs boson mass distribution is dominated by experimental resolution for $m_{H}<350 \mathrm{GeV}$, while for higher $m_{H}$ the reconstructed width is dominated by the natural width of the Higgs boson; the predicted full-width at halfmaximum is approximately 35 GeV at $m_{H}=400 \mathrm{GeV}$.

## 5. Background estimation

The expected background yield and its composition is estimated using MC simulation normalized to the theoretical cross section for $Z Z^{(*)}$ production and by data-driven methods for the $Z+$ jets and $t \bar{t}$ processes.

A control sample consisting of $Z \rightarrow \ell^{+} \ell^{-}$candidates with an additional loosely selected - no isolation or impact parameter requirements - same-flavour lepton pair is used to study the contributions of $Z b \bar{b}$ and $Z+$ light jets. The $Z b \bar{b}$ background dominates the $Z+\mu \mu$ sample, and the $Z+$ light jets background dominates in the $Z+e e$ sample. The heavy flavour contribution in the $Z+\mu \mu$ control sample is estimated by subtracting from the data the light jet component. The latter is obtained in a data-driven manner by using measurements of the rate at which other particles are misidentified as muons. The $Z+$ light jets contribution in the $Z+e e$ final state is estimated by extrapolation, using MC simulation, from a background-dominated region defined by inverting the electron identification requirement on the transverse shower shape of the electromagnetic energy deposit. These data-driven backgrounds are extrapolated to the signal region by applying the efficiencies found in MC simulation, and verified using data, for the isolation and impact parameter significance requirements.

The normalization of the $t \bar{t}$ background, which also contributes substantially in the $Z+\mu \mu$ final state, is verified using a control region of events containing an opposite-sign electron-muon pair consistent with the $Z$ boson mass and two additional same-flavour leptons.

Fig. 2 displays the invariant masses of lepton pairs in events with a $Z$ boson candidate and an additional same-flavour lepton pair, selected by following the kinematic requirements of the analysis, and by applying isolation requirements to the first lepton pair only. The events are divided according to the flavour of the additional lepton pair into $Z+\mu \mu$ and $Z+e e$ samples, where $Z \rightarrow \mu^{+} \mu^{-} / e^{+} e^{-}$. In Figs. 2(a) and 2(c) the $m_{12}$ and $m_{34}$ distribu-

Fig. 1. Invariant mass distributions for simulated (a) $H \rightarrow Z Z^{(*)} \rightarrow 4 \mu$ and (b) $H \rightarrow Z Z^{(*)} \rightarrow 4 e$ events for $m_{H}=130 \mathrm{GeV}$. The fitted range for the Gaussian is chosen to be: $-2 \sigma$ to $2 \sigma(-1.5 \sigma$ to $2.5 \sigma)$ for the $4 \mu(4 e)$ channel. The reduced mean value of the reconstructed invariant mass in the $4 e$ channel arises from energy losses due to bremsstrahlung [76]. The fraction of events outside the $\pm 2 \sigma$ region is found to be $15 \%$ for $4 \mu$ and $18 \%$ for $4 e$.
tions are presented for $Z+\mu \mu$ events, while in Figs. 2(b) and 2(d) the corresponding distributions are presented for $Z+e e$ events. The shapes and normalizations of the backgrounds discussed earlier are in good agreement with data; this is observed both for large values of $m_{34}$, where the $Z Z^{(*)}$ background dominates, and for low $m_{34}$ values.

## 6. Systematic uncertainties

Uncertainties in lepton reconstruction and identification efficiency, and on the momentum resolution and scale, are determined using samples of $W, Z$ and $J / \psi$ decays. The muon efficiency uncertainty results in a relative acceptance uncertainty in the signal and the $Z Z^{(*)}$ background which is uniform over the mass range of interest, and amounts to $0.22 \%(0.16 \%)$ for the $4 \mu(2 e 2 \mu)$ channel. The uncertainty in the electron efficiency results in a relative acceptance uncertainty of $2.3 \%$ (1.6\%) for the $4 e(2 e 2 \mu)$ channel at $m_{4 \ell}=600 \mathrm{GeV}$ and reaches $8.0 \%$ (4.1\%) at $m_{4 \ell}=110 \mathrm{GeV}$. The effects of muon momentum resolution and scale uncertainties are found to be negligible. The energy resolution uncertainty for electrons is negligible, while the electron energy scale uncertainty results in an uncertainty of less than $0.6 \%(0.3 \%)$ on the mass scale of the $m_{4 \ell}$ distribution for the $4 e(2 e 2 \mu)$ channel.

The selection efficiencies of the isolation and impact parameter requirements are studied using data for both isolated and non-isolated leptons. Isolated leptons are obtained from $Z \rightarrow \ell \ell$ decays, while additional leptons reconstructed in events with $Z \rightarrow \ell \ell$ decays constitute the sample of non-isolated leptons. Additional checks are performed with non-isolated leptons from semileptonic $b$ - and $c$-quark decays in a heavy-flavour enriched di-jet sample. Good agreement is observed between data and simulation and the systematic uncertainty is, in general, estimated to be small with respect to the other systematic uncertainties. An exception is found in the case of isolated electrons with $E_{\mathrm{T}}<15 \mathrm{GeV}$, where due to the small number of $Z \rightarrow e^{+} e^{-}$events and the substantial QCD backgrounds an additional uncertainty of $5 \%$ is added.

An additional uncertainty in the signal selection efficiency is added due to the modelling of the signal kinematics. This is evaluated by varying the Higgs boson $p_{\mathrm{T}}$ spectrum in the gluon fusion process according to the PDF and QCD scale uncertainties.

The $Z+$ light jets and $Z b \bar{b}$ backgrounds are evaluated using data. Systematic uncertainties of $45 \%$ and $40 \%$, respectively, are assigned to their normalization to account for the statistical uncertainty in the yield of the control sample, the uncertainty in the composition of the control sample, and the uncertainty in the MC-based extrapolation to the signal region.

The overall uncertainty in the integrated luminosity for the complete 2011 dataset is $3.9 \%$, based on the calibration described in Refs. [14,15] including an additional uncertainty for the extrapolation to the later data-taking period with higher instantaneous luminosity.

## 7. Results

In total, 71 candidate events are selected by the analysis: $244 \mu, 302 e 2 \mu$, and $174 e$ events. From the background processes, $62 \pm 9$ events are expected: $18.6 \pm 2.84 \mu, 29.7 \pm 4.52 e 2 \mu$ and $13.4 \pm 2.04 e$. In Table 3, the number of events observed in each final state is summarized and compared to the expected backgrounds, separately for $m_{4 \ell}<180 \mathrm{GeV}$ and $m_{4 \ell} \geqslant 180 \mathrm{GeV}$, and to the expected signal for various $m_{H}$ hypotheses. The $m_{12}$ and $m_{34}$ mass spectra are shown in Fig. 3. The expected $m_{4 \ell}$ distributions for the total background and several signal hypotheses are compared to the data in Fig. 4.

Upper limits are set on the Higgs boson production cross section at $95 \% \mathrm{CL}$, using the $C L_{s}$ modified frequentist formalism [78] with the profile likelihood ratio test statistic [79]. The test statistic is evaluated with a binned maximum-likelihood fit of signal and background models to the observed $m_{4 \ell}$ distribution. Fig. 5 shows the observed and expected $95 \%$ CL cross section upper limits, calculated using ensembles of simulated pseudo-experiments, as a function of $m_{H}$. The SM Higgs boson is excluded at $95 \% \mathrm{CL}$ in the mass ranges $134-156 \mathrm{GeV}, 182-233 \mathrm{GeV}, 256-265 \mathrm{GeV}$ and $268-415 \mathrm{GeV}$. The expected exclusion ranges are $136-157 \mathrm{GeV}$ and $184-400 \mathrm{GeV}$.

The significance of an excess is given by the probability, $p_{0}$, that a background-only experiment is more signal-like than that observed. In Fig. 6 the $p_{0}$-values, calculated using an ensemble of simulated pseudo-experiments, are given as a function of $m_{H}$ for the full mass range of the analysis. The most significant upward deviations from the background-only hypothesis are observed for

Fig. 2. Invariant mass distributions of the lepton pairs in the control sample defined by a $Z$ boson candidate and an additional same-flavour lepton pair. The sample is divided according to the flavour of the additional lepton pair. In (a) the $m_{12}$ and in (c) the $m_{34}$ distributions are presented for $Z\left(\rightarrow \mu^{+} \mu^{-} / e^{+} e^{-}\right)+\mu \mu$ events. In (b) the $m_{12}$ and in (d) the $m_{34}$ distributions are presented for $Z\left(\rightarrow \mu^{+} \mu^{-} / e^{+} e^{-}\right)+e e$ events. The kinematic selections of the analysis are applied. Isolation requirements are applied to the first lepton pair only.

Table 3
The expected numbers of background events, with their systematic uncertainty, separated into "Low- $m_{4 \ell}$ " ( $m_{4 \ell}<180 \mathrm{GeV}$ ) and "High- $m_{4 \ell}$ " ( $m_{4 \ell} \geqslant 180 \mathrm{GeV}$ ) regions, compared to the observed numbers of events. The expectations for a Higgs boson signal for five different $m_{H}$ values are also given.

$m_{H}=125 \mathrm{GeV}$ with a local $p_{0}$ of $1.6 \%$ (2.1 standard deviations), $m_{H}=244 \mathrm{GeV}$ with a local $p_{0}$ of $1.3 \%$ (2.2 standard deviations) and $m_{H}=500 \mathrm{GeV}$ with a local $p_{0}$ of $1.8 \%$ (2.1 standard deviations). The median expected local $p_{0}$ in the presence of a SM Higgs boson are $10.6 \%$ ( 1.3 standard deviations), $0.14 \%$ ( 3.0 stan-
dard deviations) and $7.1 \%$ ( 1.5 standard deviations) for $m_{H}=$ $125 \mathrm{GeV}, 244 \mathrm{GeV}$ and 500 GeV , respectively. An alternative calculation, using the asymptotic approximation of Ref. [79], yielded compatible results - within 0.2 standard deviations - in the entire mass range.

Fig. 3. Invariant mass distributions (a) $m_{12}$ and (b) $m_{34}$ for the selected candidates. The data (dots) are compared to the background expectations from the dominant $Z Z(*)$ process and the sum of $t \bar{t}, Z b \bar{b}$ and $Z+$ light jets processes. Error bars represent $68.3 \%$ central confidence intervals.

 dominated by detector resolution at low $m_{H}$ values and by the Higgs boson width at high $m_{H}$.

The quoted values do not account for the so-called lookelsewhere effect, which takes into account that such an excess (or a larger one) can appear anywhere in the search range as a result of an upward fluctuation of the background. When considering the complete mass range of this search, using the method of Ref. [80], the global $p_{0}$-value for each of the three excesses becomes of $O(50 \%)$. Thus, once the look-elsewhere effect is considered, none of the observed local excesses are significant.

## 8. Summary

A search for the SM Higgs boson in the decay channel $H \rightarrow$ $Z Z^{(*)} \rightarrow 4 \ell$ based on $4.8 \mathrm{fb}^{-1}$ of data recorded by the ATLAS detector at $\sqrt{s}=7 \mathrm{TeV}$ during the 2011 run has been presented. The SM Higgs boson is excluded at $95 \% \mathrm{CL}$ in the mass ranges $134-156 \mathrm{GeV}, 182-233 \mathrm{GeV}, 256-265 \mathrm{GeV}$ and $268-415 \mathrm{GeV}$. The largest upward deviations from the background-only hypothesis are observed for $m_{H}=125 \mathrm{GeV}, 244 \mathrm{GeV}$ and 500 GeV with local
significances of 2.1, 2.2 and 2.1 standard deviations, respectively. Once the look-elsewhere effect is considered, none of these excesses are significant.

## Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN,

Fig. 5. The expected (dashed) and observed (full line) 95\% CL upper limits on the Standard Model Higgs boson production cross section as a function of $m_{H}$, divided by the expected SM Higgs boson cross section. The dark (green) and light (yellow) bands indicate the expected limits with $\pm 1 \sigma$ and $\pm 2 \sigma$ fluctuations, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this Letter.)

Fig. 6. The observed local $p_{0}$, the probability that the background fluctuates to the observed number of events or higher, is shown as the solid line. The dashed curve shows the expected median local $p_{0}$ for the signal hypothesis when tested at $m_{H}$. The two horizontal dashed lines indicate the $p_{0}$ values corresponding to local significances of $2 \sigma$ and $3 \sigma$.

Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF
(Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

#### Abstract

Using data recorded in 2011 with the ATLAS detector at the Large Hadron Collider, a search for evidence of extra spatial dimensions has been performed through an analysis of the diphoton final state. The analysis uses data corresponding to an integrated luminosity of $2.12 \mathrm{fb}^{-1}$ of $\sqrt{s}=7 \mathrm{TeV}$ protonproton collisions. The diphoton invariant mass ( $m_{\gamma \gamma}$ ) spectrum is observed to be in good agreement with the expected Standard Model background. In the large extra dimension scenario of Arkani-Hamed, Dimopoulos and Dvali, the results provide $95 \%$ CL lower limits on the fundamental Planck scale between 2.27 and 3.53 TeV , depending on the number of extra dimensions and the theoretical formalism used. The results also set $95 \%$ CL lower limits on the lightest Randall-Sundrum graviton mass of between 0.79 and 1.85 TeV , for values of the dimensionless coupling $k / \bar{M}_{P l}$ varying from 0.01 to 0.1 . Combining with previously published ATLAS results from the dielectron and dimuon final states, the 95\% CL lower limit on the Randall-Sundrum graviton mass for $k / \bar{M}_{P l}=0.01$ (0.1) is 0.80 (1.95) TeV. © 2012 CERN. ## 1. Introduction

The enormous difference between the Planck scale and the electroweak scale is known as the hierarchy problem. A prominent class of new physics models addresses the hierarchy problem through the existence of extra spatial dimensions. In this Letter, we search for evidence of extra dimensions within the context of the models of Arkani-Hamed, Dimopoulos, and Dvali (ADD) [1] and of Randall and Sundrum (RS) [2]. In these models, gravity can propagate in the higher-dimensional bulk, giving rise to a socalled Kaluza-Klein (KK) tower of massive spin-2 graviton excitations (KK gravitons, $G$ ). Due to their couplings to Standard Model (SM) particle-antiparticle pairs, KK gravitons can be investigated in proton-proton ( $p p$ ) collisions at the Large Hadron Collider (LHC) via a variety of processes, including virtual graviton exchange as well as direct graviton production through gluon-gluon fusion or quark-antiquark annihilation.

The ADD model [1] postulates the existence of $n$ flat additional spatial dimensions compactified with radius $R$, in which only gravity propagates. The fundamental Planck scale in the $(4+n)$ dimensional spacetime, $M_{D}$, is related to the apparent scale $M_{P l}$ by Gauss' law: $\bar{M}_{P l}^{2}=M_{D}^{n+2} R^{n}$, where $\bar{M}_{P l}=M_{P l} / \sqrt{8 \pi}$ is the reduced Planck scale. The mass splitting between subsequent KK states is of order $1 / R$. In the ADD model, resolving the hierarchy problem requires typically small values of $1 / R$, giving rise to an almost continuous spectrum of KK graviton states.

[^20]While processes involving direct graviton emission depend on $M_{D}$, effects involving virtual gravitons depend on the ultraviolet cutoff of the KK spectrum, denoted $M_{S}$. The effects of the extra dimensions are typically parametrized by $\eta_{G}=\mathcal{F} / M_{S}^{4}$, where $\eta_{G}$ describes the strength of gravity in the presence of the extra dimensions and $\mathcal{F}$ is a dimensionless parameter of order unity reflecting the dependence of virtual KK graviton exchange on the number of extra dimensions. Several theoretical formalisms exist in the literature, using different definitions of $\mathcal{F}$ and, consequently, of $M_{S}$ :
$\mathcal{F}=1 \quad(\mathrm{GRW})[3] ;$
$\mathcal{F}=\left\{\begin{array}{ll}\log \left(\frac{M_{S}^{2}}{\hat{s}}\right) & n=2, \\ \frac{2}{n-2} & n>2\end{array} \quad(\operatorname{HLZ})[4] ;\right.$
$\mathcal{F}= \pm \frac{2}{\pi} \quad$ (Hewett) [5];
where $\sqrt{\hat{\hat{S}}}$ is the center-of-mass energy of the parton-parton collision. Effects due to ADD graviton exchange would be evidenced by a non-resonant deviation from the SM background expectation. Collider searches for ADD virtual graviton effects have been performed at HERA [6], LEP [7], the Tevatron [8], and the LHC [9,10]. Recent diphoton results from CMS are the most restrictive so far, setting limits on $M_{S}$ in the range of $2.3-3.8 \mathrm{TeV}$ [10].

The RS model [2] posits the existence of a fifth dimension with "warped" geometry, bounded by two $(3+1)$-dimensional branes, with the SM fields localized on the so-called TeV brane and gravity originating on the other, dubbed the Planck brane, but capable
of propagating in the bulk. Mass scales on the TeV brane, such as the Planck mass describing the observed strength of gravity, correspond to mass scales on the Planck brane as given by $M_{D}=$ $M_{P l} e^{-k \pi r_{c}}$, where $k$ and $r_{c}$ are the curvature scale and compactification radius of the extra dimension, respectively. The observed hierarchy of scales can therefore be naturally reproduced in this model, if $k r_{c} \approx 12$ [11]. KK gravitons in this model would have a mass splitting of order 1 TeV and would appear as new resonances. The phenomenology can be described in terms of the mass of the lightest KK graviton excitation $\left(m_{G}\right)$ and the dimensionless coupling to the SM fields, $k / \bar{M}_{P l}$. It is theoretically preferred [11] for $k / \bar{M}_{P l}$ to have a value in the range from 0.01 to 0.1 . The most stringent experimental limits on RS gravitons are from the LHC. For $k / \bar{M}_{P l}=0.1, \sim 1 \mathrm{fb}^{-1}$ ATLAS results from $G \rightarrow e e / \mu \mu$ exclude gravitons below 1.63 TeV [12], assuming leading order (LO) cross section predictions, and a recent $2.2 \mathrm{fb}^{-1} G \rightarrow \gamma \gamma$ result from CMS excludes gravitons below 1.84 TeV [10], using next-to-leading order (NLO) cross section values. These results have surpassed the limits from searches at the Tevatron [13] and earlier searches at the LHC [14].

The diphoton final state provides a sensitive channel for this search due to the clean experimental signature, excellent diphoton mass resolution, and modest backgrounds, as well as a branching ratio for graviton decay to diphotons that is twice the value of that for graviton decay to any individual charged-lepton pair. In this Letter, we report on a search in the diphoton final state for evidence of extra dimensions, using a data sample corresponding to an integrated luminosity of $2.12 \mathrm{fb}^{-1}$ of $\sqrt{s}=7 \mathrm{TeV} p p$ collisions, recorded during 2011 with the ATLAS detector at the LHC. The measurement of the diphoton invariant mass spectrum is interpreted in both the ADD and RS scenarios.

## 2. The ATLAS detector

The ATLAS detector [15] is a multipurpose particle physics instrument with a forward-backward symmetric cylindrical geometry and near $4 \pi$ solid angle coverage. ${ }^{1}$ Closest to the beamline are tracking detectors to measure the trajectories of charged particles, including layers of silicon-based detectors as well as a transition radiation tracker using straw-tube technology. The tracker is surrounded by a thin solenoid that provides a 2 T magnetic field for momentum measurements. The solenoid is surrounded by a hermetic calorimeter system, which is particularly important for this analysis. A system of liquid-argon (LAr) sampling calorimeters is divided into a central barrel calorimeter and two endcap calorimeters, each housed in a separate cryostat. Fine-grained LAr electromagnetic (EM) calorimeters, segmented in three longitudinal layers, are used to precisely measure the energies of electrons, positrons and photons for $|\eta|<3.2$. Most of the EM shower energy is collected in the second layer, which has a granularity of $\Delta \eta \times \Delta \phi=0.025 \times 0.025$. The first layer is segmented into eight strips per middle-layer cell in the $\eta$ direction, extending over four middle-layer cells in $\phi$, designed to separate photons from $\pi^{0}$ mesons. A presampler, covering $|\eta|<1.81$, is used to correct for energy lost upstream of the calorimeter. The regions spanning $1.5<|\eta|<4.9$ are instrumented with LAr calorimetry also for hadronic measurements, while an iron-scintillator tile calorimeter provides hadronic coverage in the range $|\eta|<1.7$. A muon spectrometer consisting of three superconducting toroidal magnet

[^21]systems, tracking chambers, and detectors for triggering lies outside the calorimeter system.

## 3. Trigger and data selection

The analysis uses data collected between March and September 2011 during stable beam periods of $7 \mathrm{TeV} p p$ collisions. Selected events had to satisfy a trigger requiring at least two photon candidates with transverse energy $E_{\mathrm{T}}^{\gamma}>20 \mathrm{GeV}$ and satisfying a set of requirements, referred to as the "loose" photon definition [16], which includes requirements on the leakage of energy into the hadronic calorimeter as well as on variables that require the transverse width of the shower, measured in the second EM calorimeter layer, be consistent with the narrow width expected for an EM shower. The loose definition is designed to have high photon efficiency, albeit with reduced background rejection. The trigger was essentially fully efficient for high mass diphoton events passing the final selection requirements.

Events were required to have at least one primary collision vertex, with at least three reconstructed tracks. Selected events had to have at least two photon candidates, each with $E_{\mathrm{T}}^{\gamma}>25 \mathrm{GeV}$ and pseudorapidity $\left|\eta^{\gamma}\right|<2.37$, with the exclusion of $1.37<$ $\left|\eta^{\gamma}\right|<1.52$, the transition region between the barrel and endcap calorimeters. As described in more detail in Ref. [16], photon candidates included those classified as unconverted photons, with no associated track, or photons which converted to electron-positron pairs, with one or two associated tracks. The two photons were required to satisfy several quality criteria and to lie outside detector regions where their energy was not measured in an optimal way. The two photon candidates each had to satisfy a set of stricter requirements, referred to as the "tight" photon definition [16], which included a more stringent selection on the shower width in the second EM layer and additional requirements on the energy distribution in the first EM calorimeter layer. The tight photon definition was designed to increase the purity of the photon selection sample by rejecting most of the remaining jet background, including jets with a leading neutral hadron (mostly $\pi^{0}$ mesons) that decay to a pair of collimated photons.

The isolation transverse energy $E_{\mathrm{T}}^{i s o}$ for each photon was calculated [16] by summing over the cells of both the EM and hadronic calorimeters that surround the photon candidate within an angular cone of radius $\Delta R=\sqrt{\left(\eta-\eta^{\gamma}\right)^{2}+\left(\phi-\phi^{\gamma}\right)^{2}}<0.4$, after removing a central core that contains most of the energy of the photon. To reduce the jet background further, an isolation requirement was applied, requiring that each of the two leading photons satisfied $E_{\mathrm{T}}^{i \text { is }}<5 \mathrm{GeV}$. An out-of-core energy correction was applied, to make $E_{\mathrm{T}}^{\text {iso }}$ essentially independent of $E_{\mathrm{T}}^{\gamma}$. An ambient energy correction, based on the measurement of low transverse momentum jets [17], was also applied, on an event-by-event basis, to remove the contributions from the underlying event and from "pileup", which results from the presence of multiple $p p$ collisions within the same or nearby bunch crossings.

For events with more than two photon candidates passing all the selection requirements, the two photons with the highest $E_{\mathrm{T}}^{\gamma}$ values were considered. The diphoton invariant mass had to exceed 140 GeV . A total of 6846 events were selected.

## 4. Monte Carlo simulation studies

Monte Carlo (MC) simulations were performed to study the detector response for various possible signal models, as well as to perform some SM background studies. All MC events were simulated [18] with the ATLAS detector simulation based on geant 4 [19] and using ATLAS parameter tunes [20], and were processed through the same reconstruction software chain as used
for the data. The MC events were reweighted to mimic the pileup conditions observed in the data.

SM diphoton production was simulated with PYTHIA [21] version 6.424 and MRST2007LOMOD [22] parton distribution functions (PDFs). The PYTHIA events were reweighted as a function of diphoton invariant mass to the differential cross section predicted by the NLO calculation of DIPHOX [23] version 1.3.2. The reweighting factor varied from $\approx 1.6$ for a diphoton mass of 140 GeV , decreasing smoothly to unity for large masses. For the DIPHOX calculation, the renormalization scale and the initial and final factorization scales of the model were all set to the diphoton mass. The various scales were varied by a factor of two both up and down, compared to this central value, to evaluate systematic uncertainties. The PDFs were chosen following the recommendations of the PDF4LHC working group [24], with MSTW2008 NLO PDFs [25] used for the NLO predictions, and CTEQ6.6 [26] and MRST2007LOMOD [22] used for systematic comparisons.

SHERPA [27] version 1.2.3 was used with CTEQ6L [26] PDFs to simulate the various ADD scenarios for a variety of $M_{S}$ values. Due to the interference between the SM and gravity-mediated contributions, it is necessary to simulate events according to the full differential cross section as a function of the diphoton mass. A generator-level cut was applied to restrict the signal simulation to diphoton masses above 200 GeV . The ADD MC samples were used to determine the signal acceptance ( $A$ ) and selection efficiency $(\epsilon)$. The acceptance, defined as the percentage of diphoton signal events with the two highest $E_{\mathrm{T}}$ photons passing the applied $E_{\mathrm{T}}^{\gamma}$ and $\eta^{\gamma}$ cuts, varied somewhat for the various ADD implementations and fell from typical values of $\approx 20 \%$ for $M_{S}=1.5 \mathrm{TeV}$ down to $\approx 15 \%$ for $M_{S}=3 \mathrm{TeV}$, due mostly to the variations in the $\eta^{\gamma}$ distributions. The selection efficiency, for events within the detector acceptance, was found to be $\approx 70 \%$.

RS model MC signal samples were produced using the implementation of the RS model in PYTHIA [21] version 6.424, which is fully specified by providing the values of $m_{G}$ and $k / \bar{M}_{P l}$. MC signal samples were produced for a range of $m_{G}$ and $k / \bar{M}_{P l}$ values, using the MRST2007LOMOD [22] PDFs. The products of $A \times \epsilon$ for the RS signal models were in the range $\approx(53-60) \%$, slowly rising with increasing graviton mass. The reconstructed shape of the graviton resonance was modeled by convolving the graviton BreitWigner lineshape with a double-sided Crystal Ball (CB) function to describe the detector response. The natural width of the BreitWigner was fixed according to the expected theoretical value, which varies as the square of $k / \bar{M}_{P l}$. The values of the width increase, for $k / \bar{M}_{P l}=0.1$, from $\approx 8 \mathrm{GeV}$ up to $\approx 30 \mathrm{GeV}$ for $m_{G}$ values from 800 GeV to 2200 GeV , respectively. The parameters of the CB function, which includes a Gaussian core to model the detector resolution matched to exponential functions on both sides to model the modest non-Gaussian tails, were determined by fitting to the reconstructed MC signals. The fitted values of $\sigma$ of the Gaussian core approached a value of $\approx 1 \%$ for high $m_{G}$ values, as expected given the current value of the constant term in the EM calorimeter energy resolution, and were found to be independent of $k / \bar{M}_{P l}$. The EM energy resolution has been verified in data using $Z \rightarrow e e$ decays [28], and MC used to describe the modest differences between the response to photons versus electrons. The fitted values of the CB parameters varied smoothly with $m_{G}$. Fitting this mass dependence provided a signal parametrization that was used to describe signals with any values of $m_{G}$ and $k / \bar{M}_{P l}$.

## 5. Background evaluation

The largest background for this analysis is the irreducible background due to SM $\gamma \gamma$ production. The shape of the diphoton invariant mass spectrum from this background was estimated using

MC, reweighting the PYTHIA samples to the differential cross section predictions of DIPHOX.

Another significant background component is the reducible background that includes events in which one or both of the reconstructed photon candidates result from a different physics object being misidentified as a photon. This background is dominated by $\gamma+$ jet $(j)$ and $j j$ events, with one or two jets faking photons, respectively. Backgrounds with electrons faking photons, such as the Drell-Yan production of electron-positron pairs as well as $W / Z+\gamma$ and $t \bar{t}$ processes, were verified using MC to be small after the event selection and were neglected. Several backgroundenriched control samples were defined in order to determine the shape of the reducible background using data-driven techniques. In all control samples, the two photon candidates were required to pass the same isolation cut as for the signal selection, since removing the isolation requirement was seen to modify the diphoton mass spectrum. The first control sample contained those events where one of the photon candidates passed the tight requirement applied for the signal selection. However, the other photon candidate was required to fail the tight photon identification definition, but to pass the loose requirement; the latter restriction was applied to avoid any trigger bias, as the trigger required two loose photons. This sample is enriched in $\gamma+j$ events, where the photon passed the tight requirement and a jet passed the loose one, and also in $j j$ events where both photon candidates were due to jets. A second control sample, dominated by $j j$ events, was similarly defined, but both photon candidates were required to fail the tight photon identification while passing the loose definition.

The diphoton invariant mass distributions were compared for these control samples. To check for any kinematic bias, the control sample with one tight and one loose photon candidate was further divided, with the $\gamma j(j \gamma)$ subsample being defined as the case with the tight photon being the photon candidate with the highest (second highest) transverse energy. The diphoton invariant mass distributions of all three control subsamples were found to be consistent with each other, within statistical uncertainties. The sum of the control samples was used to provide the best estimate of the reducible background shape. Variations among the subsamples were taken into account as a source of systematic uncertainty in the reducible background prediction.

The data control samples have relatively few events in the high diphoton mass signal region. It was therefore necessary to extrapolate the reducible background shape to higher masses, which was done by fitting with a smooth function of the form $f(x)=$ $p_{1} \times x^{p_{2}+p_{3} \log x}$, where $x=m_{\gamma \gamma}$ and $p_{i}$ are the fit parameters. This functional form has been used in previous ATLAS resonance searches [12,29], and describes well the shape of the control data samples.

The total background, calculated as the sum of the irreducible and reducible components, was normalized to the number of data events in a low mass control region with diphoton masses between 140 and 400 GeV , in which possible ADD and RS signals have been excluded by previous searches. The fraction of the total background in this region that is due to the irreducible background is defined as the purity of the sample. The purity $(p)$ was determined by three complementary methods. The most precise measurement resulted from a method previously used in Refs. $[30,31]$ that examines the $E_{\mathrm{T}}^{\text {iso }}$ values of the two photon candidates. Templates for the $E_{\mathrm{T}}^{\text {iso }}$ distributions of true photons and of fake photons from jets were both determined from the data. The shape for fake photons was found using a sample of photon candidates that failed at least one of a subset of several of the selection requirements used for the tight photon definition. The shape for photons was found from the tight photon sample, after subtracting the fake photon shape normalized to match the number of candidates with large
values (greater than 10 GeV ) of $E_{\mathrm{T}}^{\text {iso }}$. In addition, for $j j$ events, due to the observed significant ( $\approx 20 \%$ ) correlation between the $E_{\mathrm{T}}^{\text {iso }}$ values of the two photon candidates, a two-dimensional template was formed using events in which both photon candidates failed the tight identification. An extended maximum likelihood fit to the two-dimensional distribution formed from the $E_{\mathrm{T}}^{\text {iso }}$ values of the two photon candidates was performed in order to extract the contributions from $\gamma \gamma, \gamma j, j \gamma$, and $j j$ events. The fit was performed using the photon and fake photon $E_{\mathrm{T}}^{i s o}$ templates, as well as the two-dimensional $j j$ template. The resultant value of the purity in the low mass control region was $p=71_{-9}^{+5} \%$. The uncertainty was determined by varying the subset of tight selection criteria failed by fake photon candidates, and then repeating the purity determination. Cross checks using either the DIPHOX prediction for the absolute normalization of the irreducible component, or fitting the shapes of the irreducible and reducible backgrounds to the data in the low mass control region, yielded consistent, but less precise results. The result from the isolation method was therefore used as the best estimate of the purity, and the total SM background prediction was set equal to the sum of the irreducible and reducible components, weighted appropriately by this purity value and normalized to data in the low mass control region.

## 6. Systematic uncertainties

Systematic uncertainties in the DIPHOX prediction for the shape of the irreducible background were obtained by varying the scales of the model and the PDFs, while keeping the overall normalization fixed in the low mass control region in which the total background prediction was normalized to the data. The resultant systematic uncertainties range from a few percent at low masses, up to $\approx 15 \%$ for diphoton masses of $\approx 2 \mathrm{TeV}$. Systematic uncertainties in the reducible background shape were obtained by comparing the results of the extrapolation fit for the various control data subsamples, in each case maintaining the overall normalization to the data in the low mass control region. The resultant uncertainties increase from $\approx 5 \%$ for low masses to $\approx 100 \%$ at a mass of $\approx 2 \mathrm{TeV}$.

The systematic uncertainty on the shape of the total background was obtained by adding in quadrature the uncertainties on the shapes of the irreducible and reducible background components, weighted appropriately to account for the purity. In addition, there is a contribution, which is roughly constant with a value of $\approx 10 \%$ for diphoton masses above 800 GeV , introduced by varying the purity value within its uncertainty. An additional overall uncertainty of $\approx 2 \%$ was included due to the finite statistics of the data sample in the low mass control region.

The total background systematic uncertainty starts at $\approx 2 \%$ for $m_{\gamma \gamma}=140 \mathrm{GeV}$, rises to $\approx 15 \%$ by 700 GeV and then increases slowly up to almost $20 \%$ for the highest $m_{\gamma \gamma}$ values, above 2 TeV.

Systematic uncertainties on the signal yields were evaluated separately for the ADD and RS models. Since the differences were small, for simplicity the higher value was taken and applied to both models. The systematic uncertainties considered for the signal yield include the $3.7 \%$ uncertainty on the integrated luminosity [32], and a $1 \%$ uncertainty to account for the limited signal MC statistics. A value of $1 \%$ for the uncertainty on the bunch crossing identification (BCID) efficiency accounts for the ability of the Level 1 trigger hardware to pick the correct BCID when signal pulse saturation occurs in the trigger digitization. In addition, a value of $2 \%$ was applied for the uncertainty on the efficiency of the diphoton trigger. An uncertainty of $2.5 \%$ was applied due to the influence of pileup on the signal efficiency. Finally, a value of
4.3\% was taken to account for the uncertainty in the selection and identification of the pair of photons, including uncertainties due to the photon isolation cut, the description of the detector material, the tight photon identification requirements, and extrapolation to the high photon $E_{\mathrm{T}}$ values typical of the signal models. Uncertainties due to the current knowledge of the EM energy scale and resolution were verified to have a negligible impact. Adding all effects in quadrature, the total systematic uncertainty on the signal yields was 6.7\%.

Uncertainties in the theoretical signal cross sections due to PDFs and due to the NLO approximation were considered. The uncertainties due to PDFs range from $\approx 10-15 \%$ for ADD models and from $\approx 5-10 \%$ for RS models. The authors of Refs. [33,34] have privately updated their calculations of the NLO signal cross sections for 14 TeV , and provided k-factors to the LHC experiments to scale from LO to NLO cross section values for the case of 7 TeV $p p$ collisions. The NLO k-factor values, evaluated in our case for $\left|\eta^{\gamma}\right|<2.5$, have some modest dependence on the diphoton mass as well as on $M_{S}$ for the ADD model, and on the $k / \bar{M}_{P l}$ value for the RS model. However, the variations are within the theoretical uncertainty. For simplicity, therefore, constant values of 1.70 and 1.75 were assumed for the ADD and RS models, respectively, and an uncertainty in the $k$-factor value of $\pm 0.1$ was assigned to account for the variations.

## 7. Results and interpretation

Fig. 1 shows the observed invariant mass distribution of diphoton events, with the predicted SM background superimposed as well as ADD and RS signals for certain choices of the model parameters. The reducible background component is shown separately, in addition to the total background expectation, which sums the reducible and irreducible contributions. The shaded bands around each contribution indicate the corresponding uncertainty. The bottom plot of Fig. 1 shows the statistical significance, measured in standard deviations and based on Poisson distributions, of the difference between the data and the expected background in each bin. The significance was calculated and displayed as detailed in Ref. [35], and plotted as positive (negative) where there was an excess (deficit) in the data in a given bin. Table 1 lists, in bins of diphoton mass, the expected numbers of events for the irreducible and reducible background components, as well as for the total background, and also the numbers of observed data events. Both Fig. 1 and Table 1 demonstrate that there is agreement between the observed mass distribution and the expectation from the SM backgrounds over the entire diphoton mass range; no evidence is seen for either resonant or non-resonant deviations which would indicate the presence of a signal due to new physics. An analysis using the BUMPHUNTER [36] tool found that the probability, given the background-only hypothesis, of observing discrepancies at least as large as observed in the data was 0.28 , indicating quantitatively the good agreement between the data and the expected SM background.

Given the absence of evidence for a signal, 95\% CL upper limits were determined on the ADD and RS signal cross sections, using a Bayesian approach [37] with a flat prior on the signal cross section. The systematic uncertainties were incorporated as Gaussian-distributed nuisance parameters and integrated over.

To set limits on the ADD model, the number of observed events with diphoton invariant mass in a high mass signal region was compared with the expected total SM background. To optimise the expected limit, the ADD signal search region was chosen as $m_{\gamma \gamma}>1.1 \mathrm{TeV}$. There are 2 observed events in this signal region, with a background expectation of $1.33 \pm 0.26$ events,

Fig. 1. The observed invariant mass distribution of diphoton events, superimposed with the predicted SM background and expected signals for ADD and RS models with certain choices of parameters. The bin width is constant in $\log \left(m_{\gamma \gamma}\right)$. The bin-by-bin significance of the difference between data and background is shown in the lower panel.

Table 1
The expected numbers of events for the irreducible and reducible background components and for the total background, as well as the numbers of observed data events, in different diphoton mass bins. The first row, with masses from 140 to 400 GeV , corresponds to the control region in which the total background was normalized to the corresponding number of observed events. The errors include both statistical and systematic uncertainties. The errors on the irreducible and reducible background components do not include the contribution, which is anti-correlated between the two background components, from the uncertainty on the purity. However, this contribution is included in the errors listed for the total background.

| Mass range <br> $(\mathrm{GeV})$ | Background expectation |  | Observed <br> events |  |
| :--- | :---: | ---: | ---: | :---: |
|  | Irreducible | Reducible |  |  |
| $[140,400]$ | $4738 \pm 180$ | $1935 \pm 97$ | 6674 | 6674 |
| $[400,500]$ | $90.0 \pm 8.5$ | $19.9 \pm 1.8$ | $109.9 \pm 9.2$ | 102 |
| $[500,600]$ | $31.1 \pm 4.0$ | $5.8 \pm 0.8$ | $37.0 \pm 4.2$ | 36 |
| $[600,700]$ | $13.7 \pm 2.3$ | $2.0 \pm 0.4$ | $15.7 \pm 2.4$ | 16 |
| $[700,800]$ | $6.2 \pm 1.2$ | $0.8 \pm 0.2$ | $6.9 \pm 1.3$ | 9 |

where the uncertainty includes both statistical and systematic errors. The observed (expected) 95\% CL upper limit is 2.49 (1.94) fb for the product of the cross section due to new physics multiplied by the acceptance and efficiency. The cross section result can be translated into limits on $\eta_{G}$ and, subsequently, on the parameter $M_{S}$ of the ADD model. As summarized in Table 2, assuming a k-factor of 1.70 , the $95 \%$ CL lower limits on $M_{S}$ range between 2.27 and 3.53 TeV , depending on the number of extra dimensions assumed and the ADD model implementation. LO results are also included in Table 2, for reference.

To determine the limits on the RS model, the observed invariant mass distribution was compared to templates of the expected backgrounds and varying amounts of signal for various graviton masses and $k / \bar{M}_{P l}$ values. A likelihood function was defined as the product of the Poisson probabilities over all mass bins in the

Table 2
95\% CL limits on the value of $M_{S}$ (in TeV) for various implementations of the ADD model, using both LO $(\mathrm{k}$-factor $=1)$ and NLO ( k -factor $=1.70$ ) theory cross section calculations.

| k-Factor value | GRW | Hewett |  | HLZ |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Pos | Neg | $n=3$ | $n=4$ | $n=5$ | $n=6$ | $n=7$ |
| 1 | 2.73 | 2.44 | 2.16 | 3.25 | 2.73 | 2.47 | 2.30 | 2.17 |
| 1.70 | 2.97 | 2.66 | 2.27 | 3.53 | 2.97 | 2.69 | 2.50 | 2.36 |

Table 3
95\% CL lower limits on the mass ( GeV ) of the lightest RS graviton, for various values of $k / \bar{M}_{P I}$. The results are shown for the diphoton channel alone and for the combination of the diphoton channel with the dilepton results of Ref. [12], using both LO ( $k$-factor $=1$ ) and NLO ( $k$-factor $=1.75$ ) theory cross section calculations.

| k-Factor value | Channel(s) used | $95 \%$ CL limit $[\mathrm{TeV}]$ |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
|  |  |  | $k / \bar{M}_{P l}$ value |  |  |
|  |  | 0.01 | 0.03 | 0.05 | 0.1 |
| 1 | $G \rightarrow \gamma \gamma$ | 0.74 | 1.26 | 1.41 | 1.79 |
| 1.75 | $G \rightarrow \gamma \gamma / e e / \mu \mu$ | 0.76 | 1.32 | 1.47 | 1.90 |
|  |  |  |  |  |  |
|  | $G \rightarrow \gamma \gamma$ | 0.79 | 1.30 | 1.45 | 1.85 |
|  | $G \rightarrow \gamma \gamma / e e / \mu \mu$ | 0.80 | 1.37 | 1.55 | 1.95 |

search region, defined as $m_{\gamma \gamma}>500 \mathrm{GeV}$, where the Poisson probability in each bin was evaluated for the observed number of data events given the expectation from the template. The total signal acceptance as a function of mass was propagated into the expectation. The theory uncertainties were not included in the limit calculation, but are indicated by showing the theory prediction as a band with a width equal to the combined theory uncertainty when plotting the results. The resultant limits are summarized in Table 3. Using a constant k-factor value of 1.75 , the $95 \%$ CL lower limits from the diphoton channel are $m_{G}>0.79$ (1.85) TeV for $k / \bar{M}_{P l}=0.01$ (0.1).

The RS model results can be combined with the previously published ATLAS results [12] from the dilepton final state, where, assuming LO cross sections and $k / \bar{M}_{P l}=0.1$, RS gravitons with masses below 1.51 (1.45) TeV were excluded at $95 \% \mathrm{CL}$ using data samples of $1.08(1.21) \mathrm{fb}^{-1}$ to search for $G \rightarrow e e(G \rightarrow \mu \mu)$. To ensure their statistical independence, the selection cuts of the diphoton analysis included a veto of any events which were also selected by the $1.08 \mathrm{fb}^{-1} G \rightarrow e e$ analysis. In performing the combination, correlations were considered between the systematic uncertainties in the $\gamma \gamma$ and ee channels. In the ee analysis [12], the background prediction was normalized such that the expected and observed numbers of events in the region of the $Z$ peak agreed, eliminating the dependence of the ee result on the measured integrated luminosity. Therefore, the $\gamma \gamma$ and ee signal predictions were treated as uncorrelated, since there should be no correlation in the luminosity and efficiency uncertainties. The systematic uncertainty on the QCD dijet background was treated as being correlated; however, this background was quite small so the effect was minor. The PDF and scale uncertainties were treated as correlated across all three channels, and affect the irreducible background in the $\gamma \gamma$ channel as well as the Drell-Yan background in the ee/ $\mu \mu$ channels. The left plot of Fig. 2 shows the combined 95\% CL upper limit on the product of the graviton production cross section times the branching ratio for $G \rightarrow \gamma \gamma / e e / \mu \mu$, obtained using the same k -factor value of 1.75 for all three channels. As summarized in Table 3, the combined 95\% CL lower limit is $m_{G}>0.80$ (1.95) TeV for $k / \bar{M}_{P l}=0.01$ (0.1). As shown in the right plot of Fig. 2, the results can be translated into a $95 \%$ CL exclusion in the plane of $k / \bar{M}_{P l}$ versus graviton mass.

Fig. 2. (Left) Expected and observed $95 \%$ CL limits from the combination of $G \rightarrow \gamma \gamma / e e / \mu \mu$ channels on $\sigma B$, the product of the RS graviton production cross section and the branching ratio for graviton decay via $G \rightarrow \gamma \gamma / e e / \mu \mu$, as a function of the graviton mass. The theory curves are drawn assuming a k-factor of 1.75 . The thickness of the theory curve for $k / \bar{M}_{P l}=0.1$ illustrates the theoretical uncertainties. (Right) The RS results interpreted in the plane of $k / \bar{M}_{P l}$ versus graviton mass, and including recent results from other experiments [13,10]. The region above the curve is excluded at $95 \% \mathrm{CL}$. In both figures, linear interpolations are performed between the discrete set of mass points for which the dilepton limits were calculated in Ref. [12].

## 8. Summary

Using a dataset corresponding to $2.12 \mathrm{fb}^{-1}$, an analysis of the diphoton final state was used to set $95 \%$ CL lower limits of between 2.27 and 3.53 TeV on the parameter $M_{S}$ of the ADD large extra dimension scenario, depending on the number of extra dimensions and the theoretical formalism used. The diphoton results also exclude at $95 \%$ CL RS graviton masses below 0.79 (1.85) TeV for the dimensionless RS coupling $k / \bar{M}_{P l}=0.01$ (0.1). Combining with the previous ATLAS dilepton analyses further tightens these limits to exclude at $95 \%$ CL RS graviton masses below 0.80 (1.95) TeV for $k / \bar{M}_{P l}=0.01$ (0.1).

## Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NLT1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

#### Abstract

A search for the Standard Model Higgs boson in proton-proton collisions with the ATLAS detector at the LHC is presented. The datasets used correspond to integrated luminosities of approximately $4.8 \mathrm{fb}^{-1}$ collected at $\sqrt{s}=7 \mathrm{TeV}$ in 2011 and $5.8 \mathrm{fb}^{-1}$ at $\sqrt{s}=8 \mathrm{TeV}$ in 2012. Individual searches in the channels $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow \gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ in the 8 TeV data are combined with previously published results of searches for $H \rightarrow Z Z^{(*)}, W W^{(*)}, b \bar{b}$ and $\tau^{+} \tau^{-}$in the 7 TeV data and results from improved analyses of the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$ channels in the 7 TeV data. Clear evidence for the production of a neutral boson with a measured mass of $126.0 \pm 0.4$ (stat) $\pm 0.4$ (sys) GeV is presented. This observation, which has a significance of 5.9 standard deviations, corresponding to a background fluctuation probability of $1.7 \times 10^{-9}$, is compatible with the production and decay of the Standard Model Higgs boson.

## 1. Introduction

The Standard Model (SM) of particle physics [1-4] has been tested by many experiments over the last four decades and has been shown to successfully describe high energy particle interactions. However, the mechanism that breaks electroweak symmetry in the SM has not been verified experimentally. This mechanism [5-10], which gives mass to massive elementary particles, implies the existence of a scalar particle, the SM Higgs boson. The search for the Higgs boson, the only elementary particle in the SM that has not yet been observed, is one of the highlights of the Large Hadron Collider [11] (LHC) physics programme.

Indirect limits on the SM Higgs boson mass of $m_{H}<158 \mathrm{GeV}$ at $95 \%$ confidence level (CL) have been set using global fits to precision electroweak results [12]. Direct searches at LEP [13], the Tevatron [14-16] and the LHC [17,18] have previously excluded, at $95 \%$ CL, a SM Higgs boson with mass below 600 GeV , apart from some mass regions between 116 GeV and 127 GeV .

Both the ATLAS and CMS Collaborations reported excesses of events in their 2011 datasets of proton-proton ( $p p$ ) collisions at centre-of-mass energy $\sqrt{s}=7 \mathrm{TeV}$ at the LHC, which were compatible with SM Higgs boson production and decay in the mass region $124-126 \mathrm{GeV}$, with significances of 2.9 and 3.1 standard deviations $(\sigma)$, respectively $[17,18]$. The CDF and $\mathrm{D} \varnothing$ experiments at the Tevatron have also recently reported a broad excess in the mass region

120-135 GeV; using the existing LHC constraints, the observed local significances for $m_{H}=125 \mathrm{GeV}$ are $2.7 \sigma$ for CDF [14], 1.1 $\sigma$ for $\mathrm{D} \emptyset$ [15] and $2.8 \sigma$ for their combination [16].

The previous ATLAS searches in $4.6-4.8 \mathrm{fb}^{-1}$ of data at $\sqrt{s}=$ 7 TeV are combined here with new searches for $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell,{ }^{1}$ $H \rightarrow \gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ in the $5.8-5.9 \mathrm{fb}^{-1}$ of $p p$ collision data taken at $\sqrt{s}=8 \mathrm{TeV}$ between April and June 2012.

The data were recorded with instantaneous luminosities up to $6.8 \times 10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$; they are therefore affected by multiple $p p$ collisions occurring in the same or neighbouring bunch crossings (pile-up). In the 7 TeV data, the average number of interactions per bunch crossing was approximately 10 ; the average increased to approximately 20 in the 8 TeV data. The reconstruction, identification and isolation criteria used for electrons and photons in the 8 TeV data are improved, making the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$ searches more robust against the increased pile-up. These analyses were re-optimised with simulation and frozen before looking at the 8 TeV data.

In the $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channel, the increased pile-up deteriorates the event missing transverse momentum, $E_{\mathrm{T}}^{\text {miss }}$, resolution, which results in significantly larger Drell-Yan background in the same-flavour final states. Since the $e \mu$ channel provides most of the sensitivity of the search, only this final state is used in the analysis of the 8 TeV data. The kinematic region in which a SM Higgs boson with a mass between 110 GeV and 140 GeV is

[^22][^23]searched for was kept blinded during the analysis optimisation, until satisfactory agreement was found between the observed and predicted numbers of events in control samples dominated by the principal backgrounds.

This Letter is organised as follows. The ATLAS detector is briefly described in Section 2. The simulation samples and the signal predictions are presented in Section 3. The analyses of the $H \rightarrow$ $Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow \gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ channels are described in Sections 4-6, respectively. The statistical procedure used to analyse the results is summarised in Section 7. The systematic uncertainties which are correlated between datasets and search channels are described in Section 8. The results of the combination of all channels are reported in Section 9, while Section 10 provides the conclusions.

## 2. The ATLAS detector

The ATLAS detector [19-21] is a multipurpose particle physics apparatus with forward-backward symmetric cylindrical geometry. The inner tracking detector (ID) consists of a silicon pixel detector, a silicon microstrip detector (SCT), and a straw-tube transition radiation tracker (TRT). The ID is surrounded by a thin superconducting solenoid which provides a 2 T magnetic field, and by highgranularity liquid-argon (LAr) sampling electromagnetic calorimetry. The electromagnetic calorimeter is divided into a central barrel (pseudorapidity ${ }^{2}|\eta|<1.475$ ) and end-cap regions on either end of the detector ( $1.375<|\eta|<2.5$ for the outer wheel and $2.5<|\eta|<3.2$ for the inner wheel). In the region matched to the ID $(|\eta|<2.5)$, it is radially segmented into three layers. The first layer has a fine segmentation in $\eta$ to facilitate $e / \gamma$ separation from $\pi^{0}$ and to improve the resolution of the shower position and direction measurements. In the region $|\eta|<1.8$, the electromagnetic calorimeter is preceded by a presampler detector to correct for upstream energy losses. An iron-scintillator/tile calorimeter gives hadronic coverage in the central rapidity range ( $|\eta|<1.7$ ), while a LAr hadronic end-cap calorimeter provides coverage over $1.5<$ $|\eta|<3.2$. The forward regions ( $3.2<|\eta|<4.9$ ) are instrumented with LAr calorimeters for both electromagnetic and hadronic measurements. The muon spectrometer (MS) surrounds the calorimeters and consists of three large air-core superconducting magnets providing a toroidal field, each with eight coils, a system of precision tracking chambers, and fast detectors for triggering. The combination of all these systems provides charged particle measurements together with efficient and precise lepton and photon measurements in the pseudorapidity range $|\eta|<2.5$. Jets and $E_{\mathrm{T}}^{\text {miss }}$ are reconstructed using energy deposits over the full coverage of the calorimeters, $|\eta|<4.9$.

## 3. Signal and background simulation samples

The SM Higgs boson production processes considered in this analysis are the dominant gluon fusion ( $g g \rightarrow H$, denoted ggF ), vector-boson fusion ( $q q^{\prime} \rightarrow q q^{\prime} H$, denoted VBF) and Higgs-strahlung ( $q q^{\prime} \rightarrow W H, Z H$, denoted $W H / Z H$ ). The small contribution from the associated production with a $t \bar{t}$ pair ( $q \bar{q} / g g \rightarrow t \bar{t} H$, denoted $t \bar{t} H$ ) is taken into account only in the $H \rightarrow \gamma \gamma$ analysis.

For the ggF process, the signal cross section is computed at up to next-to-next-to-leading order (NNLO) in QCD [22-28]. Next-to-

[^24]Table 1
Event generators used to model the signal and background processes. "PYTHIA" indicates that PYTHIA6 and PYTHIA8 are used for simulations of $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data, respectively.

| Process | Generator |
| :--- | :--- |
| ggF, VBF | POWHEG [57,58] + PYTHIA |
| $W H, Z H, t \bar{t} H$ | PYTHIA |
| $W+$ jets, $Z / \gamma^{*}+$ jets | ALPGEN [59] + HERWIG |
| $t \bar{t}, t W, t b$ | MC@NLO [60] + HERWIG |
| $t q b$ | AcerMC [61] + PYTHIA |
| $q \bar{q} \rightarrow W W$ | MC@NLO + HERWIG |
| $g g \rightarrow W W$ | gg2WW [62] + HERWIG |
| $q \bar{q} \rightarrow Z Z$ | POWHEG [63] + PYTHIA |
| $g g \rightarrow Z Z$ | gg2ZZ [64] + HERWIG |
| $W Z$ | MadGraph + PYTHIA, HERWIG |
| $W \gamma+$ jets | ALPGEN + HERWIG |
| $W \gamma^{*}[65]$ | MadGraph + PYTHIA |
| $q \bar{q} / g g \rightarrow \gamma \gamma$ | SHERPA |

leading order (NLO) electroweak (EW) corrections are applied [29, 30], as well as QCD soft-gluon re-summations at up to next-to-next-to-leading logarithm (NNLL) [31]. These calculations, which are described in Refs. [32-35], assume factorisation between QCD and EW corrections. The transverse momentum, $p_{\mathrm{T}}$, spectrum of the Higgs boson in the ggF process follows the HqT calculation [36], which includes QCD corrections at NLO and QCD soft-gluon re-summations up to NNLL; the effects of finite quark masses are also taken into account [37].

For the VBF process, full QCD and EW corrections up to NLO [38-41] and approximate NNLO QCD corrections [42] are used to calculate the cross section. Cross sections of the associated $W H / Z H$ processes $(\mathrm{VH})$ are calculated including QCD corrections up to NNLO [43-45] and EW corrections up to NLO [46]. The cross sections for the $t \bar{t} H$ process are estimated up to NLO QCD [47-51].

The total cross sections for SM Higgs boson production at the LHC with $m_{H}=125 \mathrm{GeV}$ are predicted to be 17.5 pb for $\sqrt{s}=$ 7 TeV and 22.3 pb for $\sqrt{s}=8 \mathrm{TeV}[52,53]$.

The branching ratios of the SM Higgs boson as a function of $m_{H}$, as well as their uncertainties, are calculated using the HDECAY [54] and PROPHECY4F [55,56] programs and are taken from Refs. [52,53]. The interference in the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ final states with identical leptons is taken into account [55,56,53].

The event generators used to model signal and background processes in samples of Monte Carlo (MC) simulated events are listed in Table 1. The normalisations of the generated samples are obtained from the state of the art calculations described above. Several different programs are used to generate the hard-scattering processes. To generate parton showers and their hadronisation, and to simulate the underlying event [66-68], PYTHIA6 [69] (for 7 TeV samples and 8 TeV samples produced with MadGraph [70,71] or AcerMC) or PYTHIA8 [72] (for other 8 TeV samples) are used. Alternatively, HERWIG [73] or SHERPA [74] are used to generate and hadronise parton showers, with the HERWIG underlying event simulation performed using JIMMY [75]. When PYTHIA6 or HERWIG are used, TAUOLA [76] and PHOTOS [77] are employed to describe tau lepton decays and additional photon radiation from charged leptons, respectively.

The following parton distribution function (PDF) sets are used: CT10 [78] for the POWHEG, MC@NLO, gg2WW and gg2ZZ samples; CTEQ6L1 [79] for the PYTHIA8, ALPGEN, AcerMC, MadGraph, HERWIG and SHERPA samples; and MRSTMCal [80] for the PYTHIA6 samples.

Acceptances and efficiencies are obtained mostly from full simulations of the ATLAS detector [81] using Geant4 [82]. These simulations include a realistic modelling of the pile-up conditions observed in the data. Corrections obtained from measurements in
data are applied to account for small differences between data and simulation (e.g. large samples of $W, Z$ and $J / \psi$ decays are used to derive scale factors for lepton reconstruction and identification efficiencies).

## 4. $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ channel

The search for the SM Higgs boson through the decay $H \rightarrow$ $Z Z^{(*)} \rightarrow 4 \ell$, where $\ell=e$ or $\mu$, provides good sensitivity over a wide mass range ( $110-600 \mathrm{GeV}$ ), largely due to the excellent momentum resolution of the ATLAS detector. This analysis searches for Higgs boson candidates by selecting two pairs of isolated leptons, each of which is comprised of two leptons with the same flavour and opposite charge. The expected cross section times branching ratio for the process $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ with $m_{H}=125 \mathrm{GeV}$ is 2.2 fb for $\sqrt{s}=7 \mathrm{TeV}$ and 2.8 fb for $\sqrt{s}=8 \mathrm{TeV}$.

The largest background comes from continuum $\left(Z^{(*)} / \gamma^{*}\right)\left(Z^{(*)} /\right.$ $\gamma^{*}$ ) production, referred to hereafter as $Z Z^{(*)}$. For low masses there are also important background contributions from $Z+$ jets and $t \bar{t}$ production, where charged lepton candidates arise either from decays of hadrons with $b$ - or $c$-quark content or from misidentification of jets.

The 7 TeV data have been re-analysed and combined with the 8 TeV data. The analysis is improved in several aspects with respect to Ref. [83] to enhance the sensitivity to a low-mass Higgs boson. In particular, the kinematic selections are revised, and the 8 TeV data analysis benefits from improvements in the electron reconstruction and identification. The expected signal significances for a Higgs boson with $m_{H}=125 \mathrm{GeV}$ are $1.6 \sigma$ for the 7 TeV data (to be compared with $1.25 \sigma$ in Ref. [83]) and $2.1 \sigma$ for the 8 TeV data.

### 4.1. Event selection

The data are selected using single-lepton or dilepton triggers. For the single-muon trigger, the $p_{\mathrm{T}}$ threshold is 18 GeV for the 7 TeV data and 24 GeV for the 8 TeV data, while for the singleelectron trigger the transverse energy, $E_{\mathrm{T}}$, threshold varies from 20 GeV to 22 GeV for the 7 TeV data and is 24 GeV for the 8 TeV data. For the dielectron triggers, the thresholds are 12 GeV for both electrons. For the dimuon triggers, the thresholds for the 7 TeV data are 10 GeV for each muon, while for the 8 TeV data the thresholds are 13 GeV . An additional asymmetric dimuon trigger is used in the 8 TeV data with thresholds 18 GeV and 8 GeV for the leading and sub-leading muon, respectively.

Muon candidates are formed by matching reconstructed ID tracks with either a complete track or a track-segment reconstructed in the MS [84]. The muon acceptance is extended with respect to Ref. [83] using tracks reconstructed in the forward region of the MS $(2.5<|\eta|<2.7)$, which is outside the ID coverage. If both an ID and a complete MS track are present, the two independent momentum measurements are combined; otherwise the information of the ID or the MS is used alone. Electron candidates must have a well-reconstructed ID track pointing to an electromagnetic calorimeter cluster and the cluster should satisfy a set of identification criteria [85] that require the longitudinal and transverse shower profiles to be consistent with those expected for electromagnetic showers. Tracks associated with electromagnetic clusters are fitted using a Gaussian-Sum Filter [86], which allows for bremsstrahlung energy losses to be taken into account.

Each electron (muon) must satisfy $p_{\mathrm{T}}>7 \mathrm{GeV}\left(p_{\mathrm{T}}>6 \mathrm{GeV}\right)$ and be measured in the pseudorapidity range $|\eta|<2.47$ ( $|\eta|<2.7$ ). All possible quadruplet combinations with same-flavour oppositecharge lepton pairs are then formed. The most energetic lepton in the quadruplet must satisfy $p_{\mathrm{T}}>20 \mathrm{GeV}$, and the second (third)
lepton in $p_{\mathrm{T}}$ order must satisfy $p_{\mathrm{T}}>15 \mathrm{GeV}\left(p_{\mathrm{T}}>10 \mathrm{GeV}\right)$. At least one of the leptons must satisfy the single-lepton trigger or one pair must satisfy the dilepton trigger requirements. The leptons are required to be separated from each other by $\Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}>0.1$ if they are of the same flavour and by $\Delta R>0.2$ otherwise. The longitudinal impact parameters of the leptons along the beam axis are required to be within 10 mm of the reconstructed primary vertex. The primary vertex used for the event is defined as the reconstructed vertex with the highest $\sum p_{\mathrm{T}}^{2}$ of associated tracks and is required to have at least three tracks with $p_{\mathrm{T}}>0.4 \mathrm{GeV}$. To reject cosmic rays, muon tracks are required to have a transverse impact parameter, defined as the distance of closest approach to the primary vertex in the transverse plane, of less than 1 mm .

The same-flavour and opposite-charge lepton pair with an invariant mass closest to the $Z$ boson mass ( $m_{Z}$ ) in the quadruplet is referred to as the leading lepton pair. Its invariant mass, denoted by $m_{12}$, is required to be between 50 GeV and 106 GeV . The remaining same-flavour, opposite-charge lepton pair is the subleading lepton pair. Its invariant mass, $m_{34}$, is required to be in the range $m_{\min }<m_{34}<115 \mathrm{GeV}$, where the value of $m_{\min }$ depends on the reconstructed four-lepton invariant mass, $m_{4 \ell}$. The value of $m_{\min }$ varies monotonically from 17.5 GeV at $m_{4 \ell}=120 \mathrm{GeV}$ to 50 GeV at $m_{4 \ell}=190 \mathrm{GeV}$ [87] and is constant above this value. All possible lepton pairs in the quadruplet that have the same flavour and opposite charge must satisfy $m_{\ell \ell}>5 \mathrm{GeV}$ in order to reject backgrounds involving the production and decay of $J / \psi$ mesons. If two or more quadruplets satisfy the above selection, the one with the highest value of $m_{34}$ is selected. Four different analysis sub-channels, $4 e, 2 e 2 \mu, 2 \mu 2 e$ and $4 \mu$, arranged by the flavour of the leading lepton pair, are defined.

Non-prompt leptons from heavy flavour decays, electrons from photon conversions and jets mis-identified as electrons have broader transverse impact parameter distributions than prompt leptons from $Z$ boson decays and/or are non-isolated. Thus, the $Z+$ jets and $t \bar{t}$ background contributions are reduced by applying a cut on the transverse impact parameter significance, defined as the transverse impact parameter divided by its uncertainty, $d_{0} / \sigma_{d_{0}}$. This is required to be less than 3.5 (6.5) for muons (electrons). The electron impact parameter is affected by bremsstrahlung and thus has a broader distribution.

In addition, leptons must satisfy isolation requirements based on tracking and calorimetric information. The normalised track isolation discriminant is defined as the sum of the transverse momenta of tracks inside a cone of size $\Delta R=0.2$ around the lepton direction, excluding the lepton track, divided by the lepton $p_{\mathrm{T}}$. The tracks considered in the sum are those compatible with the lepton vertex and have $p_{\mathrm{T}}>0.4 \mathrm{GeV}\left(p_{\mathrm{T}}>1 \mathrm{GeV}\right)$ in the case of electron (muon) candidates. Each lepton is required to have a normalised track isolation smaller than 0.15 . The normalised calorimetric isolation for electrons is computed as the sum of the $E_{T}$ of positive-energy topological clusters [88] with a reconstructed barycentre falling within a cone of size $\Delta R=0.2$ around the candidate electron cluster, divided by the electron $E_{\mathrm{T}}$. The algorithm for topological clustering suppresses noise by keeping cells with a significant energy deposit and their neighbours. The summed energy of the cells assigned to the electron cluster is excluded, while a correction is applied to account for the electron energy deposited outside the cluster. The ambient energy deposition in the event from pile-up and the underlying event is accounted for using a calculation of the median transverse energy density from low$p_{\mathrm{T}}$ jets [89,90]. The normalised calorimetric isolation for electrons is required to be less than 0.20 . The normalised calorimetric isolation discriminant for muons is defined by the ratio to the $p_{\mathrm{T}}$ of the muon of the $E_{\mathrm{T}}$ sum of the calorimeter cells inside a cone of size
$\Delta R=0.2$ around the muon direction minus the energy deposited by the muon. Muons are required to have a normalised calorimetric isolation less than 0.30 ( 0.15 for muons without an associated ID track). For both the track- and calorimeter-based isolation, any contributions arising from other leptons of the quadruplet are subtracted.

The combined signal reconstruction and selection efficiencies for a SM Higgs with $m_{H}=125 \mathrm{GeV}$ for the $7 \mathrm{TeV}(8 \mathrm{TeV})$ data are $37 \%$ ( $36 \%$ ) for the $4 \mu$ channel, $20 \%$ ( $22 \%$ ) for the $2 e 2 \mu / 2 \mu 2 e$ channels and $15 \%$ ( $20 \%$ ) for the $4 e$ channel.

The $4 \ell$ invariant mass resolution is improved by applying a Z-mass constrained kinematic fit to the leading lepton pair for $m_{4 \ell}<190 \mathrm{GeV}$ and to both lepton pairs for higher masses. The expected width of the reconstructed mass distribution is dominated by the experimental resolution for $m_{H}<350 \mathrm{GeV}$, and by the natural width of the Higgs boson for higher masses ( 30 GeV at $m_{H}=400 \mathrm{GeV}$ ). The typical mass resolutions for $m_{H}=125 \mathrm{GeV}$ are $1.7 \mathrm{GeV}, 1.7 \mathrm{GeV} / 2.2 \mathrm{GeV}$ and 2.3 GeV for the $4 \mu, 2 e 2 \mu / 2 \mu 2 e$ and $4 e$ sub-channels, respectively.

### 4.2. Background estimation

The expected background yield and composition are estimated using the MC simulation normalised to the theoretical cross section for $Z Z^{(*)}$ production and by methods using control regions from data for the $Z+$ jets and $t \bar{t}$ processes. Since the background composition depends on the flavour of the sub-leading lepton pair, different approaches are taken for the $\ell \ell+\mu \mu$ and the $\ell \ell+e e$ final states. The transfer factors needed to extrapolate the background yields from the control regions defined below to the signal region are obtained from the MC simulation. The MC description of the selection efficiencies for the different background components has been verified with data.

The reducible $\ell \ell+\mu \mu$ background is dominated by $t \bar{t}$ and $Z+$ jets (mostly $Z b \bar{b}$ ) events. A control region is defined by removing the isolation requirement on the leptons in the sub-leading pair, and by requiring that at least one of the sub-leading muons fails the transverse impact parameter significance selection. These modifications remove $Z Z^{(*)}$ contributions, and allow both the $t \bar{t}$ and $Z+$ jets backgrounds to be estimated simultaneously using a fit to the $m_{12}$ distribution. The $t \bar{t}$ background contribution is cross-checked by selecting a control sample of events with an opposite charge $e \mu$ pair with an invariant mass between 50 GeV and 106 GeV , accompanied by an opposite-charge muon pair. Events with a $Z$ candidate decaying to a pair of electrons or muons in the aforementioned mass range are excluded. Isolation and transverse impact parameter significance requirements are applied only to the leptons of the $e \mu$ pair.

In order to estimate the reducible $\ell \ell+e e$ background, a control region is formed by relaxing the selection criteria for the electrons of the sub-leading pair. The different sources of electron background are then separated into categories consisting of nonprompt leptons from heavy flavour decays, electrons from photon conversions and jets mis-identified as electrons, using appropriate discriminating variables [91]. This method allows the sum of the $Z+$ jets and $t \bar{t}$ background contributions to be estimated. As a cross-check, the same method is also applied to a similar control region containing same-charge sub-leading electron pairs. An additional cross-check of the $\ell \ell+e e$ background estimation is performed by using a control region with same-charge sub-leading electron pairs, where the three highest $p_{\mathrm{T}}$ leptons satisfy all the analysis criteria whereas the selection cuts are relaxed for the remaining electrons. All the cross-checks yield consistent results.

The data-driven background estimates are summarised in Table 2 . The distribution of $m_{34}$, for events selected by the analysis

Table 2
Summary of the estimated numbers of $Z+$ jets and $t \bar{t}$ background events, for the $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data in the entire phase-space of the analysis after the kinematic selections described in the text. The backgrounds are combined for the $2 \mu 2 e$ and $4 e$ channels, as discussed in the text. The first uncertainty is statistical, while the second is systematic.

| Background | Estimated numbers of events |  |
| :--- | :--- | :--- |
|  | $\sqrt{s}=7 \mathrm{TeV}$ | $\sqrt{s}=8 \mathrm{TeV}$ |
| $4 \mu$ | $0.3 \pm 0.1 \pm 0.1$ | $0.5 \pm 0.1 \pm 0.2$ |
| $Z+$ jets | $0.02 \pm 0.02 \pm 0.01$ | $0.04 \pm 0.02 \pm 0.02$ |
| $t \bar{t}$ |  |  |
| $2 e 2 \mu$ | $0.2 \pm 0.1 \pm 0.1$ | $0.4 \pm 0.1 \pm 0.1$ |
| $Z+$ jets | $0.02 \pm 0.01 \pm 0.01$ | $0.04 \pm 0.01 \pm 0.01$ |
| $t \bar{t}$ |  | $4.9 \pm 0.8 \pm 0.7$ |
| $2 \mu 2 e$ | $2.6 \pm 0.4 \pm 0.4$ |  |
| $Z+$ jets, $t \bar{t}$ | $3.1 \pm 0.6 \pm 0.5$ |  |
| $4 e$ |  | $3.9 \pm 0.7 \pm 0.8$ |
| $Z+$ jets, $t \bar{t}$ |  |  |

Fig. 1. Invariant mass distribution of the sub-leading lepton pair ( $m_{34}$ ) for a sample defined by the presence of a $Z$ boson candidate and an additional same-flavour electron or muon pair, for the combination of $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data in the entire phase-space of the analysis after the kinematic selections described in the text. Isolation and transverse impact parameter significance requirements are applied to the leading lepton pair only. The MC is normalised to the data-driven background estimations. The relatively small contribution of a SM Higgs with $m_{H}=$ 125 GeV in this sample is also shown.
except that the isolation and transverse impact parameter requirements for the sub-leading lepton pair are removed, is presented in Fig. 1.

### 4.3. Systematic uncertainties

The uncertainties on the integrated luminosities are determined to be $1.8 \%$ for the 7 TeV data and $3.6 \%$ for the 8 TeV data using the techniques described in Ref. [92].

The uncertainties on the lepton reconstruction and identification efficiencies and on the momentum scale and resolution are determined using samples of $W, Z$ and $J / \psi$ decays [85, 84]. The relative uncertainty on the signal acceptance due to the uncertainty on the muon reconstruction and identification efficiency is $\pm 0.7 \%$ ( $\pm 0.5 \% / \pm 0.5 \%$ ) for the $4 \mu$ ( $2 e 2 \mu / 2 \mu 2 e$ ) channel for $m_{4 \ell}=600 \mathrm{GeV}$ and increases to $\pm 0.9 \%( \pm 0.8 \% / \pm 0.5 \%)$ for $m_{4 \ell}=115 \mathrm{GeV}$. Similarly, the relative uncertainty on the signal acceptance due to the uncertainty on the electron reconstruction and identification efficiency is $\pm 2.6 \%( \pm 1.7 \% / \pm 1.8 \%)$ for the $4 e(2 e 2 \mu / 2 \mu 2 e)$ channel for $m_{4 \ell}=600 \mathrm{GeV}$ and reaches $\pm 8.0 \%$

Fig. 2. The distribution of the four-lepton invariant mass, $m_{4 \ell}$, for the selected candidates, compared to the background expectation in the $80-250 \mathrm{GeV}$ mass range, for the combination of the $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data. The signal expectation for a SM Higgs with $m_{H}=125 \mathrm{GeV}$ is also shown.

Table 3
The numbers of expected signal ( $m_{H}=125 \mathrm{GeV}$ ) and background events, together with the numbers of observed events in the data, in a window of size $\pm 5 \mathrm{GeV}$ around 125 GeV , for the combined $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data.

|  | Signal | $Z Z^{(*)}$ | $Z+$ jets, $t \bar{t}$ | Observed |
| :--- | :--- | :--- | :--- | :--- |
| $4 \mu$ | $2.09 \pm 0.30$ | $1.12 \pm 0.05$ | $0.13 \pm 0.04$ | 6 |
| $2 e 2 \mu / 2 \mu 2 e$ | $2.29 \pm 0.33$ | $0.80 \pm 0.05$ | $1.27 \pm 0.19$ | 5 |
| $4 e$ | $0.90 \pm 0.14$ | $0.44 \pm 0.04$ | $1.09 \pm 0.20$ | 2 |

$( \pm 2.3 \% / \pm 7.6 \%)$ for $m_{4 \ell}=115 \mathrm{GeV}$. The uncertainty on the electron energy scale results in an uncertainty of $\pm 0.7 \%( \pm 0.5 \% / \pm 0.2 \%)$ on the mass scale of the $m_{4 \ell}$ distribution for the $4 e(2 e 2 \mu / 2 \mu 2 e)$ channel. The impact of the uncertainties on the electron energy resolution and on the muon momentum resolution and scale are found to be negligible.

The theoretical uncertainties associated with the signal are described in detail in Section 8. For the SM $Z Z^{(*)}$ background, which is estimated from MC simulation, the uncertainty on the total yield due to the QCD scale uncertainty is $\pm 5 \%$, while the effect of the PDF and $\alpha_{s}$ uncertainties is $\pm 4 \%( \pm 8 \%)$ for processes initiated by quarks (gluons) [53]. In addition, the dependence of these uncertainties on the four-lepton invariant mass spectrum has been taken into account as discussed in Ref. [53]. Though a small excess of events is observed for $m_{4 l}>160 \mathrm{GeV}$, the measured $Z Z^{(*)} \rightarrow 4 \ell$ cross section [93] is consistent with the SM theoretical prediction. The impact of not using the theoretical constraints on the $Z Z^{(*)}$ yield on the search for a Higgs boson with $m_{H}<2 m_{Z}$ has been studied in Ref. [87] and has been found to be negligible. The impact of the interference between a Higgs signal and the nonresonant $g g \rightarrow Z Z^{(*)}$ background is small and becomes negligible for $m_{H}<2 m_{Z}$ [94].

### 4.4. Results

The expected distributions of $m_{4 \ell}$ for the background and for a Higgs boson signal with $m_{H}=125 \mathrm{GeV}$ are compared to the data in Fig. 2. The numbers of observed and expected events in a window of $\pm 5 \mathrm{GeV}$ around $m_{H}=125 \mathrm{GeV}$ are presented for the combined 7 TeV and 8 TeV data in Table 3. The distribution of the $m_{34}$ versus $m_{12}$ invariant mass is shown in Fig. 3. The statistical interpretation of the excess of events near $m_{4 \ell}=125 \mathrm{GeV}$ in Fig. 2 is presented in Section 9.

Fig. 3. Distribution of the $m_{34}$ versus the $m_{12}$ invariant mass, before the application of the $Z$-mass constrained kinematic fit, for the selected candidates in the $m_{4 \ell}$ range $120-130 \mathrm{GeV}$. The expected distributions for a SM Higgs with $m_{H}=125 \mathrm{GeV}$ (the sizes of the boxes indicate the relative density) and for the total background (the intensity of the shading indicates the relative density) are also shown.

## 5. $H \rightarrow \gamma \gamma$ channel

The search for the SM Higgs boson through the decay $H \rightarrow \gamma \gamma$ is performed in the mass range between 110 GeV and 150 GeV . The dominant background is SM diphoton production $(\gamma \gamma)$; contributions also come from $\gamma+$ jet and jet + jet production with one or two jets mis-identified as photons ( $\gamma j$ and $j j$ ) and from the Drell-Yan process. The 7 TeV data have been re-analysed and the results combined with those from the 8 TeV data. Among other changes to the analysis, a new category of events with two jets is introduced, which enhances the sensitivity to the VBF process. Higgs boson events produced by the VBF process have two forward jets, originating from the two scattered quarks, and tend to be devoid of jets in the central region. Overall, the sensitivity of the analysis has been improved by about $20 \%$ with respect to that described in Ref. [95].

### 5.1. Event selection

The data used in this channel are selected using a diphoton trigger [96], which requires two clusters formed from energy depositions in the electromagnetic calorimeter. An $E_{\mathrm{T}}$ threshold of 20 GeV is applied to each cluster for the 7 TeV data, while for the 8 TeV data the thresholds are increased to 35 GeV on the leading (the highest $E_{\mathrm{T}}$ ) cluster and to 25 GeV on the sub-leading (the next-highest $E_{T}$ ) cluster. In addition, loose criteria are applied to the shapes of the clusters to match the expectations for electromagnetic showers initiated by photons. The efficiency of the trigger is greater than $99 \%$ for events passing the final event selection.

Events are required to contain at least one reconstructed vertex with at least two associated tracks with $p_{\mathrm{T}}>0.4 \mathrm{GeV}$, as well as two photon candidates. Photon candidates are reconstructed in the fiducial region $|\eta|<2.37$, excluding the calorimeter barrel/endcap transition region $1.37 \leqslant|\eta|<1.52$. Photons that convert to electron-positron pairs in the ID material can have one or two reconstructed tracks matched to the clusters in the calorimeter. The photon reconstruction efficiency is about $97 \%$ for $E_{\mathrm{T}}>30 \mathrm{GeV}$.

In order to account for energy losses upstream of the calorimeter and energy leakage outside of the cluster, MC simulation results are used to calibrate the energies of the photon candidates; there are separate calibrations for unconverted and converted
candidates. The calibration is refined by applying $\eta$-dependent correction factors, which are of the order of $\pm 1 \%$, determined from measured $Z \rightarrow e^{+} e^{-}$events. The leading (sub-leading) photon candidate is required to have $E_{\mathrm{T}}>40 \mathrm{GeV}(30 \mathrm{GeV})$.

Photon candidates are required to pass identification criteria based on shower shapes in the electromagnetic calorimeter and on energy leakage into the hadronic calorimeter [97]. For the 7 TeV data, this information is combined in a neural network, tuned to achieve a similar jet rejection as the cut-based selection described in Ref. [95], but with higher photon efficiency. For the 8 TeV data, cut-based criteria are used to ensure reliable photon performance for recently-recorded data. This cut-based selection has been tuned to be robust against pile-up by relaxing requirements on shower shape criteria more susceptible to pile-up, and tightening others. The photon identification efficiencies, averaged over $\eta$, range from $85 \%$ to above $95 \%$ for the $E_{\mathrm{T}}$ range under consideration.

To further suppress the jet background, an isolation requirement is applied. The isolation transverse energy is defined as the sum of the transverse energy of positive-energy topological clusters, as described in Section 4, within a cone of size $\Delta R=0.4$ around the photon candidate, excluding the region within $0.125 \times$ 0.175 in $\Delta \eta \times \Delta \phi$ around the photon barycentre. The distributions of the isolation transverse energy in data and simulation have been found to be in good agreement using electrons from $Z \rightarrow e^{+} e^{-}$ events and photons from $Z \rightarrow \ell^{+} \ell^{-} \gamma$ events. Remaining small differences are taken into account as a systematic uncertainty. Photon candidates are required to have an isolation transverse energy of less than 4 GeV .

### 5.2. Invariant mass reconstruction

The invariant mass of the two photons is evaluated using the photon energies measured in the calorimeter, the azimuthal angle $\phi$ between the photons as determined from the positions of the photons in the calorimeter, and the values of $\eta$ calculated from the position of the identified primary vertex and the impact points of the photons in the calorimeter.

The primary vertex of the hard interaction is identified by combining the following information in a global likelihood: the directions of flight of the photons as determined using the longitudinal segmentation of the electromagnetic calorimeter (calorimeter pointing), the parameters of the beam spot, and the $\sum p_{\mathrm{T}}^{2}$ of the tracks associated with each reconstructed vertex. In addition, for the 7 TeV data analysis, the reconstructed conversion vertex is used in the likelihood for converted photons with tracks containing hits in the silicon layers of the ID. The calorimeter pointing is sufficient to ensure that the contribution of the opening angle between the photons to the mass resolution is negligible. Using the calorimeter pointing alone, the resolution of the vertex $z$ coordinate is $\sim 15 \mathrm{~mm}$, improving to $\sim 6 \mathrm{~mm}$ for events with two reconstructed converted photons. The tracking information from the ID improves the identification of the vertex of the hard interaction, which is needed for the jet selection in the 2-jet category.

With the selection described in Section 5.1, in the diphoton invariant mass range between 100 GeV and $160 \mathrm{GeV}, 23788$ and 35251 diphoton candidates are observed in the 7 TeV and 8 TeV data samples, respectively.

Data-driven techniques [98] are used to estimate the numbers of $\gamma \gamma, \gamma j$ and $j j$ events in the selected sample. The contribution from the Drell-Yan background is determined from a sample of $Z \rightarrow e^{+} e^{-}$decays in data where either one or both electrons pass the photon selection. The measured composition of the selected sample is approximately $74 \%, 22 \%, 3 \%$ and $1 \%$ for the $\gamma \gamma, \gamma j$, $j j$ and Drell-Yan processes, respectively, demonstrating the dominance of the irreducible diphoton production. This decomposition
is not directly used in the signal search; however, it is used to study the parameterisation of the background modelling.

### 5.3. Event categorisation

To increase the sensitivity to a Higgs boson signal, the events are separated into ten mutually exclusive categories having different mass resolutions and signal-to-background ratios. An exclusive category of events containing two jets improves the sensitivity to VBF. The other nine categories are defined by the presence or not of converted photons, $\eta$ of the selected photons, and $p_{\mathrm{Tt}}$, the component ${ }^{3}$ of the diphoton $p_{\mathrm{T}}$ that is orthogonal to the axis defined by the difference between the two photon momenta [99,100].

Jets are reconstructed [101] using the anti- $k_{t}$ algorithm [102] with radius parameter $R=0.4$. At least two jets with $|\eta|<4.5$ and $p_{\mathrm{T}}>25 \mathrm{GeV}$ are required in the 2 -jet selection. In the analysis of the 8 TeV data, the $p_{\mathrm{T}}$ threshold is raised to 30 GeV for jets with $2.5<|\eta|<4.5$. For jets in the ID acceptance ( $|\eta|<2.5$ ), the fraction of the sum of the $p_{\mathrm{T}}$ of tracks, associated with the jet and matched to the selected primary vertex, with respect to the sum of the $p_{\text {T }}$ of tracks associated with the jet (jet vertex fraction, JVF) is required to be at least 0.75 . This requirement on the JVF reduces the number of jets from proton-proton interactions not associated with the primary vertex. Motivated by the VBF topology, three additional cuts are applied in the 2-jet selection: the difference of the pseudorapidity between the leading and sub-leading jets (tag jets) is required to be larger than 2.8 , the invariant mass of the tag jets has to be larger than 400 GeV , and the azimuthal angle difference between the diphoton system and the system of the tag jets has to be larger than 2.6 . About $70 \%$ of the signal events in the 2-jet category come from the VBF process.

The other nine categories are defined as follows: events with two unconverted photons are separated into unconverted central ( $|\eta|<0.75$ for both candidates) and unconverted rest (all other events), events with at least one converted photon are separated into converted central ( $|\eta|<0.75$ for both candidates), converted transition (at least one photon with $1.3<|\eta|<1.75$ ) and converted rest (all other events). Except for the converted transition category, each category is further divided by a cut at $p_{\mathrm{Tt}}=60 \mathrm{GeV}$ into two categories, low $p_{\text {Tt }}$ and high $p_{\text {Tt }}$. MC studies show that signal events, particularly those produced via VBF or associated production ( $W H / Z H$ and $t \bar{t} H$ ), have on average larger $p_{\mathrm{Tt}}$ than background events. The number of data events in each category, as well as the sum of all the categories, which is denoted inclusive, are given in Table 4.

### 5.4. Signal modelling

The description of the Higgs boson signal is obtained from MC, as described in Section 3. The cross sections multiplied by the branching ratio into two photons are given in Table 4 for $m_{H}=126.5 \mathrm{GeV}$. The number of signal events produced via the ggF process is rescaled to take into account the expected destructive interference between the $g g \rightarrow \gamma \gamma$ continuum background and $\operatorname{ggF}$ [103], leading to a reduction of the production rate by $2-5 \%$ depending on $m_{H}$ and the event category. For both the 7 TeV and 8 TeV MC samples, the fractions of ggF, VBF, $W H, Z H$ and $t \bar{t} H$ production are approximately $88 \%, 7 \%, 3 \%, 2 \%$ and $0.5 \%$, respectively, for $m_{H}=126.5 \mathrm{GeV}$.

In the simulation, the shower shape distributions are shifted slightly to improve the agreement with the data [97], and the

[^25]Table 4
Number of events in the data ( $N_{\mathrm{D}}$ ) and expected number of signal events ( $N_{\mathrm{S}}$ ) for $m_{H}=126.5 \mathrm{GeV}$ from the $H \rightarrow \gamma \gamma$ analysis, for each category in the mass range $100-160 \mathrm{GeV}$. The mass resolution FWHM (see text) is also given for the 8 TeV data. The Higgs boson production cross section multiplied by the branching ratio into two photons $(\sigma \times B(H \rightarrow \gamma \gamma))$ is listed for $m_{H}=126.5 \mathrm{GeV}$. The statistical uncertainties on $N_{\mathrm{S}}$ and FWHM are less than $1 \%$.

| $\sqrt{s}$ | 7 TeV |  | 8 TeV |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $\sigma \times B(H \rightarrow \gamma \gamma)[\mathrm{fb}]$ | 39 |  | 50 |  | FWHM [GeV] |
| Category | $N_{\text {D }}$ | $N_{\text {S }}$ | $N_{\text {D }}$ | $N_{\text {S }}$ |  |
| Unconv. central, low $p_{\text {Tt }}$ | 2054 | 10.5 | 2945 | 14.2 | 3.4 |
| Unconv. central, high $p_{\mathrm{Tt}}$ | 97 | 1.5 | 173 | 2.5 | 3.2 |
| Unconv. rest, low $p_{\text {Tt }}$ | 7129 | 21.6 | 12136 | 30.9 | 3.7 |

| All categories (inclusive) | 23788 | 79.6 | 35251 | 110.5 | 3.9 |

photon energy resolution is broadened (by approximately $1 \%$ in the barrel calorimeter and $1.2-2.1 \%$ in the end-cap regions) to account for small differences observed between $Z \rightarrow e^{+} e^{-}$data and MC events. The signal yields expected for the 7 TeV and 8 TeV data samples are given in Table 4. The overall selection efficiency is about $40 \%$.

The shape of the invariant mass of the signal in each category is modelled by the sum of a Crystal Ball function [104], describing the core of the distribution with a width $\sigma_{C B}$, and a Gaussian contribution describing the tails (amounting to $<10 \%$ ) of the mass distribution. The expected full-width-at-half-maximum (FWHM) is 3.9 GeV and $\sigma_{C B}$ is 1.6 GeV for the inclusive sample. The resolution varies with event category (see Table 4); the FWHM is typically a factor 2.3 larger than $\sigma_{C B}$.

### 5.5. Background modelling

The background in each category is estimated from data by fitting the diphoton mass spectrum in the mass range $100-160 \mathrm{GeV}$ with a selected model with free parameters of shape and normalisation. Different models are chosen for the different categories to achieve a good compromise between limiting the size of a potential bias while retaining good statistical power. A fourth-order Bernstein polynomial function [105] is used for the unconverted rest (low $p_{\mathrm{Tt}}$ ), converted rest (low $p_{\mathrm{Tt}}$ ) and inclusive categories, an exponential function of a second-order polynomial for the unconverted central (low $p_{\mathrm{Tt}}$ ), converted central (low $p_{\mathrm{Tt}}$ ) and converted transition categories, and an exponential function for all others.

Studies to determine the potential bias have been performed using large samples of simulated background events complemented by data-driven estimates. The background shapes in the simulation have been cross-checked using data from control regions. The potential bias for a given model is estimated, separately for each category, by performing a maximum likelihood fit to large samples of simulated background events in the mass range 100160 GeV , of the sum of a signal plus the given background model. The signal shape is taken to follow the expectation for a SM Higgs boson; the signal yield is a free parameter of the fit. The potential bias is defined by the largest absolute signal yield obtained from the likelihood fit to the simulated background samples for hypothesised Higgs boson masses in the range $110-150 \mathrm{GeV}$. A pre-selection of background parameterisations is made by requiring that the potential bias, as defined above, is less than $20 \%$ of the statistical uncertainty on the fitted signal yield. The pre-
selected parameterisation in each category with the best expected sensitivity for $m_{H}=125 \mathrm{GeV}$ is selected as the background model.

The largest absolute signal yield as defined above is taken as the systematic uncertainty on the background model. It amounts to $\pm(0.2-4.6)$ and $\pm(0.3-6.8)$ events, depending on the category for the 7 TeV and 8 TeV data samples, respectively. In the final fit to the data (see Section 5.7) a signal-like term is included in the likelihood function for each category. This term incorporates the estimated potential bias, thus providing a conservative estimate of the uncertainty due to the background modelling.

### 5.6. Systematic uncertainties

Hereafter, in cases where two uncertainties are quoted, they refer to the 7 TeV and 8 TeV data, respectively. The dominant experimental uncertainty on the signal yield ( $\pm 8 \%, \pm 11 \%$ ) comes from the photon reconstruction and identification efficiency, which is estimated with data using electrons from $Z$ decays and photons from $Z \rightarrow \ell^{+} \ell^{-} \gamma$ events. Pile-up modelling also affects the expected yields and contributes to the uncertainty ( $\pm 4 \%$ ). Further uncertainties on the signal yield are related to the trigger $( \pm 1 \%)$, photon isolation ( $\pm 0.4 \%, \pm 0.5 \%$ ) and luminosity ( $\pm 1.8 \%, \pm 3.6 \%$ ). Uncertainties due to the modelling of the underlying event are $\pm 6 \%$ for VBF and $\pm 30 \%$ for other production processes in the 2-jet category. Uncertainties on the predicted cross sections and branching ratio are summarised in Section 8.

The uncertainty on the expected fractions of signal events in each category is described in the following. The uncertainty on the knowledge of the material in front of the calorimeter is used to derive the amount of possible event migration between the converted and unconverted categories ( $\pm 4 \%$ ). The uncertainty from pile-up on the population of the converted and unconverted categories is $\pm 2 \%$. The uncertainty from the jet energy scale (JES) amounts to up to $\pm 19 \%$ for the 2-jet category, and up to $\pm 4 \%$ for the other categories. Uncertainties from the JVF modelling are $\pm 12 \%$ (for the 8 TeV data) for the 2-jet category, estimated from $Z+2$-jets events by comparing data and MC. Different PDFs and scale variations in the HqT calculations are used to derive possible event migration among categories $( \pm 9 \%)$ due to the modelling of the Higgs boson kinematics.

The total uncertainty on the mass resolution is $\pm 14 \%$. The dominant contribution ( $\pm 12 \%$ ) comes from the uncertainty on the energy resolution of the calorimeter, which is determined from $Z \rightarrow e^{+} e^{-}$events. Smaller contributions come from the imperfect knowledge of the material in front of the calorimeter, which affects the extrapolation of the calibration from electrons to photons ( $\pm 6 \%$ ), and from pile-up ( $\pm 4 \%$ ).

### 5.7. Results

The distributions of the invariant mass, $m_{\gamma \gamma}$, of the diphoton events, summed over all categories, are shown in Fig. 4(a) and (b). The result of a fit including a signal component fixed to $m_{H}=$ 126.5 GeV and a background component described by a fourthorder Bernstein polynomial is superimposed.

The statistical analysis of the data employs an unbinned likelihood function constructed from those of the ten categories of the 7 TeV and 8 TeV data samples. To demonstrate the sensitivity of this likelihood analysis, Figs. 4(c) and (d) also show the mass spectrum obtained after weighting events with categorydependent factors reflecting the signal-to-background ratios. The weight $w_{i}$ for events in category $i \in[1,10]$ for the 7 TeV and 8 TeV data samples is defined to be $\ln \left(1+S_{i} / B_{i}\right)$, where $S_{i}$ is $90 \%$ of the expected signal for $m_{H}=126.5 \mathrm{GeV}$, and $B_{i}$ is the integral, in

Fig. 4. The distributions of the invariant mass of diphoton candidates after all selections for the combined 7 TeV and 8 TeV data sample. The inclusive sample is shown in (a) and a weighted version of the same sample in (c); the weights are explained in the text. The result of a fit to the data of the sum of a signal component fixed to $m_{H}=126.5 \mathrm{GeV}$ and a background component described by a fourth-order Bernstein polynomial is superimposed. The residuals of the data and weighted data with respect to the respective fitted background component are displayed in (b) and (d).
a window containing $S_{i}$, of a background-only fit to the data. The values $S_{i} / B_{i}$ have only a mild dependence on $m_{H}$.

The statistical interpretation of the excess of events near $m_{\gamma \gamma}=$ 126.5 GeV in Fig. 4 is presented in Section 9.

## 6. $H \rightarrow W W^{(*)} \rightarrow e v \mu \nu$ channel

The signature for this channel is two opposite-charge leptons with large transverse momentum and a large momentum imbalance in the event due to the escaping neutrinos. The dominant backgrounds are non-resonant $W W, t \bar{t}$, and $W t$ production, all of which have real $W$ pairs in the final state. Other important backgrounds include Drell-Yan events ( $p p \rightarrow Z / \gamma^{(*)} \rightarrow \ell \ell$ ) with $E_{\mathrm{T}}^{\text {miss }}$ that may arise from mismeasurement, $W+$ jets events in which a jet produces an object reconstructed as the second electron or muon, and $W \gamma$ events in which the photon undergoes a conversion. Boson pair production ( $W \gamma^{*} / W Z^{(*)}$ and $Z Z^{(*)}$ ) can also produce opposite-charge lepton pairs with additional leptons that are not detected.

The analysis of the 8 TeV data presented here is focused on the mass range $110<m_{H}<200 \mathrm{GeV}$. It follows the procedure used for the 7 TeV data, described in Ref. [106], except that more stringent criteria are applied to reduce the $W+$ jets background and some selections have been modified to mitigate the impact of the higher instantaneous luminosity at the LHC in 2012. In particular, the higher luminosity results in a larger Drell-Yan background to the same-flavour final states, due to the deterioration of the missing transverse momentum resolution. For this reason, and the fact that the $e \mu$ final state provides more than $85 \%$ of the sensitivity of
the search, the same-flavour final states have not been used in the analysis described here.

### 6.1. Event selection

For the $8 \mathrm{TeV} H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ search, the data are selected using inclusive single-muon and single-electron triggers. Both triggers require an isolated lepton with $p_{\mathrm{T}}>24 \mathrm{GeV}$. Quality criteria are applied to suppress non-collision backgrounds such as cosmic-ray muons, beam-related backgrounds, and noise in the calorimeters. The primary vertex selection follows that described in Section 4. Candidates for the $H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ search are pre-selected by requiring exactly two opposite-charge leptons of different flavours, with $p_{\mathrm{T}}$ thresholds of 25 GeV for the leading lepton and 15 GeV for the sub-leading lepton. Events are classified into two exclusive lepton channels depending on the flavour of the leading lepton, where $e \mu(\mu e)$ refers to events with a leading electron (muon). The dilepton invariant mass is required to be greater than 10 GeV .

The lepton selection and isolation have more stringent requirements than those used for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ analysis (see Section 4), to reduce the larger background from non-prompt leptons in the $\ell \nu \ell \nu$ final state. Electron candidates are selected using a combination of tracking and calorimetric information [85]; the criteria are optimised for background rejection, at the expense of some reduced efficiency. Muon candidates are restricted to those with matching MS and ID tracks [84], and therefore are reconstructed over $|\eta|<2.5$. The isolation criteria require the scalar sums of the $p_{\mathrm{T}}$ of charged particles and of calorimeter topological clusters within $\Delta R=0.3$ of the lepton direction (excluding the lepton itself) each to be less than $0.12-0.20$ times the lepton $p_{\mathrm{T}}$. The exact value differs between the criteria for tracks and calorimeter clusters, for both electrons and muons, and depends on the lepton $p_{\mathrm{T}}$. Jet selections follow those described in Section 5.3, except that the JVF is required to be greater than 0.5 .

Since two neutrinos are present in the signal final state, events are required to have large $E_{\mathrm{T}}^{\text {miss }}$. $\mathbf{E}_{\mathrm{T}}^{\text {miss }}$ is the negative vector sum of the transverse momenta of the reconstructed objects, including muons, electrons, photons, jets, and clusters of calorimeter cells not associated with these objects. The quantity $E_{T, \text { rel }}^{\text {miss }}$ used in this analysis is required to be greater than 25 GeV and is defined as: $E_{\mathrm{T}, \text { rel }}^{\text {miss }}=E_{\mathrm{T}}^{\mathrm{miss}} \sin \Delta \phi_{\min }$, where $\Delta \phi_{\min }$ is $\min \left(\Delta \phi, \frac{\pi}{2}\right)$, and $E_{\mathrm{T}}^{\text {miss }}$ is the magnitude of the vector $\mathbf{E}_{\mathrm{T}}^{\text {miss }}$. Here, $\Delta \phi$ is the angle between $\mathbf{E}_{\mathrm{T}}^{\text {miss }}$ and the transverse momentum of the nearest lepton or jet with $p_{\mathrm{T}}>25 \mathrm{GeV}$. Compared to $E_{\mathrm{T}}^{\text {miss }}, E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ has increased rejection power for events in which the $E_{\mathrm{T}}^{\text {miss }}$ is generated by a neutrino in a jet or the mismeasurement of an object, since in those events the $\mathbf{E}_{\mathrm{T}}^{\text {miss }}$ tends to point in the direction of the object. After the lepton isolation and $E_{\mathrm{T}, \mathrm{rel}}^{\text {miss }}$ requirements that define the pre-selected sample, the multijet background is negligible and the Drell-Yan background is much reduced. The Drell-Yan contribution becomes very small after the topological selections, described below, are applied.

The background rate and composition depend significantly on the jet multiplicity, as does the signal topology. Without accompanying jets, the signal originates almost entirely from the ggF process and the background is dominated by $W W$ events. In contrast, when produced in association with two or more jets, the signal contains a much larger contribution from the VBF process compared to the ggF process, and the background is dominated by $t \bar{t}$ production. Therefore, to maximise the sensitivity to SM Higgs events, further selection criteria depending on the jet multiplicity are applied to the pre-selected sample. The data are subdivided into 0 -jet, 1 -jet and 2 -jet search channels according to the number
of jets in the final state, with the 2-jet channel also including higher jet multiplicities.

Owing to spin correlations in the $W W^{(*)}$ system arising from the spin-0 nature of the SM Higgs boson and the V-A structure of the $W$ boson decay vertex, the charged leptons tend to emerge from the primary vertex pointing in the same direction [107]. This kinematic feature is exploited for all jet multiplicities by requiring that $\left|\Delta \phi_{\ell \ell}\right|<1.8$, and the dilepton invariant mass, $m_{\ell \ell}$, be less than 50 GeV for the 0 -jet and 1 -jet channels. For the 2 -jet channel, the $m_{\ell \ell}$ upper bound is increased to 80 GeV .

In the 0 -jet channel, the magnitude $p_{\mathrm{T}}^{\ell \ell}$ of the transverse momentum of the dilepton system, $\mathbf{p}_{\mathrm{T}}^{\ell \ell}=\mathbf{p}_{\mathrm{T}}^{\ell 1}+\mathbf{p}_{\mathrm{T}}^{\ell 2}$, is required to be greater than 30 GeV . This improves the rejection of the Drell-Yan background.

In the 1-jet channel, backgrounds from top quark production are suppressed by rejecting events containing a $b$-tagged jet, as determined using a $b$-tagging algorithm that uses a neural network and exploits the topology of weak decays of $b$ - and $c$-hadrons [108]. The total transverse momentum, $p_{\mathrm{T}}^{\text {tot }}$, defined as the magnitude of the vector sum $\mathbf{p}_{\mathrm{T}}^{\text {tot }}=\mathbf{p}_{\mathrm{T}}^{\ell 1}+\mathbf{p}_{\mathrm{T}}^{\ell 2}+\mathbf{p}_{\mathrm{T}}^{j}+\mathbf{E}_{\mathrm{T}}^{\text {miss }}$, is required to be smaller than 30 GeV to suppress top background events that have jets with $p_{\mathrm{T}}$ below the threshold defined for jet counting. In order to reject the background from $Z \rightarrow \tau \tau$, the $\tau \tau$ invariant mass, $m_{\tau \tau}$, is computed under the assumptions that the reconstructed leptons are $\tau$ lepton decay products. In addition the neutrinos produced in these decays are assumed to be the only source of $E_{\mathrm{T}}^{\text {miss }}$ and to be collinear with the leptons [109]. Events with $\left|m_{\tau \tau}-m_{Z}\right|<25 \mathrm{GeV}$ are rejected if the collinear approximation yields a physical solution.

The 2 -jet selection follows the 1 -jet selection described above, with the $p_{\mathrm{T}}^{\text {tot }}$ definition modified to include all selected jets. Motivated by the VBF topology, several additional criteria are applied to the tag jets, defined as the two highest $-p_{\mathrm{T}}$ jets in the event. These are required to be separated in rapidity by a distance $\left|\Delta y_{j j}\right|>3.8$ and to have an invariant mass, $m_{j j}$, larger than 500 GeV . Events with an additional jet with $p_{\mathrm{T}}>20 \mathrm{GeV}$ between the tag jets ( $y_{j 1}<y<y_{j 2}$ ) are rejected.

A transverse mass variable, $m_{\mathrm{T}}$ [110], is used to test for the presence of a signal for all jet multiplicities. This variable is defined as:
$m_{\mathrm{T}}=\sqrt{\left(E_{\mathrm{T}}^{\ell \ell}+E_{\mathrm{T}}^{\text {miss }}\right)^{2}-\left|\mathbf{p}_{\mathrm{T}}^{\ell \ell}+\mathbf{E}_{\mathrm{T}}^{\text {miss }}\right|^{2}}$,
where $E_{\mathrm{T}}^{\ell \ell}=\sqrt{\left|\mathbf{p}_{\mathrm{T}}^{\ell \ell}\right|^{2}+m_{\ell \ell}^{2}}$. The statistical analysis of the data uses a fit to the $m_{\mathrm{T}}$ distribution in the signal region after the $\Delta \phi_{\ell \ell}$ requirement (see Section 6.4), which results in increased sensitivity compared to the analysis described in Ref. [111].

For a SM Higgs boson with $m_{H}=125 \mathrm{GeV}$, the cross section times branching ratio to the $e \nu \mu \nu$ final state is 88 fb for $\sqrt{s}=7 \mathrm{TeV}$, increasing to 112 fb at $\sqrt{s}=8 \mathrm{TeV}$. The combined acceptance times efficiency of the 8 TeV 0 -jet and 1 -jet selection relative to the ggF production cross section times branching ratio is about $7.4 \%$. The acceptance times efficiency of the 8 TeV 2-jet selection relative to the VBF production cross section times branching ratio is about $14 \%$. Both of these figures are based on the number of events selected before the final $m_{\mathrm{T}}$ criterion is applied (as described in Section 6.4).

### 6.2. Background normalisation and control samples

The leading backgrounds from SM processes producing two isolated high- $p_{\mathrm{T}}$ leptons are $W W$ and top (in this section, "top" background always includes both $t \bar{t}$ and single top, unless otherwise noted). These are estimated using partially data-driven techniques
based on normalising the MC predictions to the data in control regions dominated by the relevant background source. The $W+$ jets background is estimated from data for all jet multiplicities. Only the small backgrounds from Drell-Yan and diboson processes other than $W W$, as well as the $W W$ background for the 2-jet analysis, are estimated using MC simulation.

The control and validation regions are defined by selections similar to those used for the signal region but with some criteria reversed or modified to obtain signal-depleted samples enriched in a particular background. The term "validation region" distinguishes these regions from the control regions that are used to directly normalise the backgrounds. Some control regions have significant contributions from backgrounds other than the targeted one, which introduces dependencies among the background estimates. These correlations are fully incorporated in the fit to the $m_{\mathrm{T}}$ distribution. In the following sections, each background estimate is described after any others on which it depends. Hence, the largest background $(W W)$ is described last.

### 6.2.1. $W+$ jets background estimation

The $W+$ jets background contribution is estimated using a control sample of events where one of the two leptons satisfies the identification and isolation criteria described in Section 6.1, and the other lepton fails these criteria but satisfies a loosened selection (denoted "anti-identified"). Otherwise, events in this sample are required to pass all the signal selections. The dominant contribution to this sample comes from $W+$ jets events in which a jet produces an object that is reconstructed as a lepton. This object may be either a true electron or muon from the decay of a heavy quark, or else a product of the fragmentation identified as a lepton candidate.

The contamination in the signal region is obtained by scaling the number of events in the data control sample by a transfer factor. The transfer factor is defined here as the ratio of the number of identified lepton candidates passing all selections to the number of anti-identified leptons. It is calculated as a function of the anti-identified lepton $p_{\text {T }}$ using a data sample dominated by QCD jet production (dijet sample) after subtracting the residual contributions from leptons produced by leptonic $W$ and $Z$ decays, as estimated from data. The small remaining lepton contamination, which includes $W \gamma^{(*)} / W Z^{(*)}$ events, is subtracted using MC simulation.

The processes producing the majority of same-charge dilepton events, $W+$ jets, $W \gamma^{(*)} / W Z^{(*)}$ and $Z^{(*)} Z^{(*)}$, are all backgrounds in the opposite-charge signal region. $W+$ jets and $W \gamma^{(*)}$ backgrounds are particularly important in a search optimised for a low Higgs boson mass hypothesis. Therefore, the normalisation and kinematic features of same-charge dilepton events are used to validate the predictions of these backgrounds. The predicted number of same-charge events after the $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ and zero-jet requirements is $216 \pm 7$ (stat) $\pm 42$ (syst), while 182 events are observed in the data. Satisfactory agreement between data and simulation is observed in various kinematic distributions, including those of $\Delta \phi_{\ell \ell}$ (see Fig. 5(a)) and the transverse mass.

### 6.2.2. Top control sample

In the 0 -jet channel, the top quark background prediction is first normalised using events satisfying the pre-selection criteria described in Section 6.1. This sample is selected without jet multiplicity or $b$-tagging requirements, and the majority of events contain top quarks. Non-top contributions are subtracted using predictions from simulation, except for $W+$ jets, which is estimated using data. After this normalisation is performed, the fraction of events with zero jets that pass all selections is evaluated. This fraction is small (about 3\%), since the top quark decay $t \rightarrow W b$

Fig. 5. Validation and control distributions for the $H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ analysis. (a) $\Delta \phi_{\ell \ell}$ distribution in the same-charge validation region after the $E_{\mathrm{T}, \text { rel }}^{\text {miss }}$ and zerojet requirements. (b) $m_{\mathrm{T}}$ distribution in the $W W$ control region for the 0 -jet channel. The $e \mu$ and $\mu e$ final states are combined. The hashed area indicates the total uncertainty on the background prediction. The expected signal for $m_{H}=125 \mathrm{GeV}$ is negligible and therefore not visible.
has a branching ratio of nearly 1 . Predictions of this fraction from MC simulation are sensitive to theoretical uncertainties such as the modelling of initial- and final-state radiation, as well as experimental uncertainties, especially that on the jet energy scale. To reduce the impact of these uncertainties, the top quark background determination uses data from a $b$-tagged control region in which the one-to-two jet ratio is compared to the MC simulation [112]. The resulting correction factor to a purely MC-based background estimate after all selections amounts to $1.11 \pm 0.06$ (stat).

In the 1 -jet and 2 -jet analyses, the top quark background predictions are normalised to the data using control samples defined by reversing the $b$-jet veto and removing the requirements on $\Delta \phi_{\ell \ell}$ and $m_{\ell \ell}$. The $\left|\Delta y_{\mathrm{jj}}\right|$ and $m_{\mathrm{jj}}$ requirements are included in the definition of the 2 -jet control region. The resulting samples are dominated by top quark events. The small contributions from other sources are taken into account using MC simulation and the data-driven $W+$ jets estimate. Good agreement between data and MC simulation is observed for the total numbers of events and the shapes of the $m_{\mathrm{T}}$ distributions. The resulting normalisation factors are $1.11 \pm 0.05$ for the 1 -jet control region and $1.01 \pm 0.26$ for the 2 -jet control region. Only the statistical uncertainties are quoted.

### 6.2.3. WW control sample

The MC predictions of the $W W$ background in the 0 -jet and 1-jet analyses, summed over lepton flavours, are normalised using control regions defined with the same selections as for the signal
region except that the $\Delta \phi_{\ell \ell}$ requirement is removed and the upper bound on $m_{\ell \ell}$ is replaced with a lower bound: $m_{\ell \ell}>80 \mathrm{GeV}$. The numbers of events and the shape of the $m_{\mathrm{T}}$ distribution in the control regions are in good agreement between data and MC, as shown in Fig. 5(b). WW production contributes about $70 \%$ of the events in the 0 -jet control region and about $45 \%$ in the 1 -jet region. Contaminations from sources other than $W W$ are derived as for the signal region, including the data-driven $W+$ jets and top estimates. The resulting normalisation factors with their associated statistical uncertainties are $1.06 \pm 0.06$ for the 0 -jet control region and $0.99 \pm 0.15$ for the 1 -jet control region.

### 6.3. Systematic uncertainties

The systematic uncertainties that have the largest impact on the sensitivity of the search are the theoretical uncertainties associated with the signal. These are described in Section 9. The main experimental uncertainties are associated with the JES, the jet energy resolution (JER), pile-up, $E_{\mathrm{T}}^{\text {miss }}$, the $b$-tagging efficiency, the $W+$ jets transfer factor, and the integrated luminosity. The largest uncertainties on the backgrounds include $W W$ normalisation and modelling, top normalisation, and $W \gamma^{(*)}$ normalisation. The 2-jet systematic uncertainties are dominated by the statistical uncertainties in the data and the MC simulation, and are therefore not discussed further.

Variations of the jet energy scale within the systematic uncertainties can cause events to migrate between the jet bins. The uncertainty on the JES varies from $\pm 2 \%$ to $\pm 9 \%$ as a function of jet $p_{\mathrm{T}}$ and $\eta$ for jets with $p_{\mathrm{T}}>25 \mathrm{GeV}$ and $|\eta|<4.5$ [101]. The largest impact of this uncertainty on the total signal (background) yield amounts to $7 \%(4 \%)$ in the 0 -jet (1-jet) bin. The uncertainty on the JER is estimated from in situ measurements and it impacts mostly the 1-jet channel, where its effect on the total signal and background yields is $4 \%$ and $2 \%$, respectively. An additional contribution to the JES uncertainty arises from pile-up, and is estimated to vary between $\pm 1 \%$ and $\pm 5 \%$ for multiple $p p$ collisions in the same bunch crossing and up to $\pm 10 \%$ for neighbouring bunch crossings. This uncertainty affects mainly the 1 -jet channel, where its impact on the signal and background yields is $4 \%$ and $2 \%$, respectively. JES and lepton momentum scale uncertainties are propagated to the $E_{\mathrm{T}}^{\text {miss }}$ measurement. Additional contributions to the $E_{\mathrm{T}}^{\text {miss }}$ uncertainties arise from jets with $p_{\mathrm{T}}<20 \mathrm{GeV}$ and from low-energy calorimeter deposits not associated with reconstructed physics objects [113]. The impact of the $E_{\mathrm{T}}^{\text {miss }}$ uncertainty on the total signal and background yields is $\sim 3 \%$. The efficiency of the $b$-tagging algorithm is calibrated using samples containing muons reconstructed in the vicinity of jets [114]. The uncertainty on the $b$-jet tagging efficiency varies between $\pm 5 \%$ and $\pm 18 \%$ as a function of the jet $p_{\mathrm{T}}$, and its impact on the total background yield is $10 \%$ for the 1 -jet channel. The uncertainty in the $W+$ jets transfer factor is dominated by differences in jet properties between dijet and $W+$ jets events as observed in MC simulations. The total uncertainty on this background is approximately $\pm 40 \%$, resulting in an uncertainty on the total background yield of $5 \%$. The uncertainty on the integrated luminosity is $\pm 3.6 \%$.

A fit to the distribution of $m_{\mathrm{T}}$ is performed in order to obtain the signal yield for each mass hypothesis (see Section 6.4). Most theoretical and experimental uncertainties do not produce statistically significant changes to the $m_{\mathrm{T}}$ distribution. The uncertainties that do produce significant changes of the distribution of $m_{\mathrm{T}}$ have no appreciable effect on the final results, with the exception of those associated with the $W W$ background. In this case, an uncertainty is included to take into account differences in the distribution of $m_{\mathrm{T}}$ and normalisation observed between the MCFM [115], MC@NLO + HERWIG and POWHEG + PYTHIA

Table 5
The expected numbers of signal ( $m_{H}=125 \mathrm{GeV}$ ) and background events after all selections, including a cut on the transverse mass of $0.75 m_{H}<m_{\mathrm{T}}<m_{H}$ for $m_{H}=$ 125 GeV . The observed numbers of events in data are also displayed. The $e \mu$ and $\mu e$ channels are combined. The uncertainties shown are the combination of the statistical and all systematic uncertainties, taking into account the constraints from control samples. For the 2 -jet analysis, backgrounds with fewer than 0.01 expected events are marked with '-'.

|  | 0 -jet | 1-jet | 2-jet |
| :--- | :--- | :--- | :--- |
| Signal | $20 \pm 4$ | $5 \pm 2$ | $0.34 \pm 0.07$ |
| $W W$ | $101 \pm 13$ | $12 \pm 5$ | $0.10 \pm 0.14$ |
| $W Z^{(*)} / Z Z / W \gamma^{(*)}$ | $12 \pm 3$ | $1.9 \pm 1.1$ | $0.10 \pm 0.10$ |
| $t \bar{t}$ | $8 \pm 2$ | $6 \pm 2$ | $0.15 \pm 0.10$ |
| $t W / t b / t q b$ | $3.4 \pm 1.5$ | $3.7 \pm 1.6$ | - |
| $Z / \gamma^{*}+$ jets | $1.9 \pm 1.3$ | $0.10 \pm 0.10$ | - |
| $W+$ jets | $15 \pm 7$ | $2 \pm 1$ | - |
| Total background | $142 \pm 16$ | $26 \pm 6$ | $0.35 \pm 0.18$ |
| Observed | 185 | 38 | 0 |

generators. The potential impact of interference between resonant (Higgs-mediated) and non-resonant $g g \rightarrow W W$ diagrams [116] for $m_{\mathrm{T}}>m_{H}$ was investigated and found to be negligible. The effect of the $W W$ normalisation, modelling, and shape systematics on the total background yield is $9 \%$ for the 0 -jet channel and $19 \%$ for the 1 -jet channel. The uncertainty on the shape of the total background is dominated by the uncertainties on the normalisations of the individual backgrounds. The main uncertainties on the top background in the 0 -jet analysis include those associated with interference effects between $t \bar{t}$ and single top, initial state an final state radiation, $b$-tagging, and JER. The impact on the total background yield in the 0 -jet bin is $3 \%$. For the 1 -jet analysis, the impact of the top background on the total yield is $14 \%$. Theoretical uncertainties on the $W \gamma$ background normalisation are evaluated for each jet bin using the procedure described in Ref. [117]. They are $\pm 11 \%$ for the 0 -jet bin and $\pm 50 \%$ for the 1 -jet bin. For $W \gamma^{*}$ with $m_{\ell \ell}<7 \mathrm{GeV}$, a $k$-factor of $1.3 \pm 0.3$ is applied to the MadGraph LO prediction based on the comparison with the MCFM NLO calculation. The $k$-factor for $W \gamma^{*} / W Z^{(*)}$ with $m_{\ell \ell}>7 \mathrm{GeV}$ is $1.5 \pm 0.5$. These uncertainties affect mostly the 1-jet channel, where their impact on the total background yield is approximately 4\%.

### 6.4. Results

Table 5 shows the numbers of events expected from a SM Higgs boson with $m_{H}=125 \mathrm{GeV}$ and from the backgrounds, as well as the numbers of candidates observed in data, after application of all selection criteria plus an additional cut on $m_{\mathrm{T}}$ of $0.75 m_{H}<m_{\mathrm{T}}<m_{H}$. The uncertainties shown in Table 5 include the systematic uncertainties discussed in Section 6.3, constrained by the use of the control regions discussed in Section 6.2. An excess of events relative to the background expectation is observed in the data.

Fig. 6 shows the distribution of the transverse mass after all selection criteria in the 0 -jet and 1 -jet channels combined, and for both lepton channels together.

The statistical analysis of the data employs a binned likelihood function constructed as the product of Poisson probability terms for the $e \mu$ channel and the $\mu e$ channel. The mass-dependent cuts on $m_{\mathrm{T}}$ described above are not used. Instead, the 0 -jet (1-jet) signal regions are subdivided into five (three) $m_{\mathrm{T}}$ bins. For the 2-jet signal region, only the results integrated over $m_{\mathrm{T}}$ are used, due to the small number of events in the final sample. The statistical interpretation of the observed excess of events is presented in Section 9.

Fig. 6. Distribution of the transverse mass, $m_{\mathrm{T}}$, in the 0 -jet and 1 -jet analyses with both $e \mu$ and $\mu e$ channels combined, for events satisfying all selection criteria. The expected signal for $m_{H}=125 \mathrm{GeV}$ is shown stacked on top of the background prediction. The $W+$ jets background is estimated from data, and $W W$ and top background MC predictions are normalised to the data using control regions. The hashed area indicates the total uncertainty on the background prediction.

## 7. Statistical procedure

The statistical procedure used to interpret the data is described in Refs. [17,118-121]. The parameter of interest is the global signal strength factor $\mu$, which acts as a scale factor on the total number of events predicted by the Standard Model for the Higgs boson signal. This factor is defined such that $\mu=0$ corresponds to the background-only hypothesis and $\mu=1$ corresponds to the SM Higgs boson signal in addition to the background. Hypothesised values of $\mu$ are tested with a statistic $\lambda(\mu)$ based on the profile likelihood ratio [122]. This test statistic extracts the information on the signal strength from a full likelihood fit to the data. The likelihood function includes all the parameters that describe the systematic uncertainties and their correlations.

Exclusion limits are based on the $C L_{s}$ prescription [123]; a value of $\mu$ is regarded as excluded at $95 \% \mathrm{CL}$ when $C L_{s}$ is less than $5 \%$. A SM Higgs boson with mass $m_{H}$ is considered excluded at $95 \%$ confidence level (CL) when $\mu=1$ is excluded at that mass. The significance of an excess in the data is first quantified with the local $p_{0}$, the probability that the background can produce a fluctuation greater than or equal to the excess observed in data. The equivalent formulation in terms of number of standard deviations, $Z_{l}$, is referred to as the local significance. The global probability for the most significant excess to be observed anywhere in a given search region is estimated with the method described in Ref. [124]. The ratio of the global to the local probabilities, the trials factor used to correct for the "look elsewhere" effect, increases with the range of Higgs boson mass hypotheses considered, the mass resolutions of the channels involved in the combination, and the significance of the excess.

The statistical tests are performed in steps of values of the hypothesised Higgs boson mass $m_{H}$. The asymptotic approximation [122] upon which the results are based has been validated with the method described in Ref. [17].

The combination of individual search sub-channels for a specific Higgs boson decay, and the full combination of all search channels, are based on the global signal strength factor $\mu$ and on the identification of the nuisance parameters that correspond to the correlated sources of systematic uncertainty described in Section 8.

## 8. Correlated systematic uncertainties

The individual search channels that enter the combination are summarised in Table 6.

The main uncorrelated systematic uncertainties are described in Sections 4-6 for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow \gamma \gamma$ and $H \rightarrow$ $W W^{(*)} \rightarrow \ell \nu \ell \nu$ channels and in Ref. [17] for the other channels. They include the background normalisations or background model parameters from control regions or sidebands, the Monte Carlo simulation statistical uncertainties and the theoretical uncertainties affecting the background processes.

The main sources of correlated systematic uncertainties are the following.

1. Integrated luminosity: The uncertainty on the integrated luminosity is considered as fully correlated among channels and amounts to $\pm 3.9 \%$ for the 7 TeV data [132,133], except for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$ channels which were re-analysed; the uncertainty is $\pm 1.8 \%$ [92] for these channels. The uncertainty is $\pm 3.6 \%$ for the 8 TeV data.
2. Electron and photon trigger identification: The uncertainties in the trigger and identification efficiencies are treated as fully correlated for electrons and photons.
3. Electron and photon energy scales: The electron and photon energy scales in the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$ channels are described by five parameters, which provide a detailed account of the sources of systematic uncertainty. They are related to the calibration method, the presampler energy scale in the barrel and end-cap calorimeters, and the material description upstream of the calorimeters.
4. Muon reconstruction: The uncertainties affecting muons are separated into those related to the ID and MS, in order to obtain a better description of the correlated effects among channels using different muon identification criteria and different ranges of muon $p_{\mathrm{T}}$.
5. Jet energy scale and missing transverse energy: The jet energy scale and jet energy resolution are affected by uncertainties which depend on the $p_{\mathrm{T}}, \eta$, and flavour of the jet. A simplified scheme is used in which independent JES and JER nuisance parameters are associated with final states with significantly different kinematic selections and sensitivity to scattering processes with different kinematic distributions or flavour composition. This scheme includes a specific treatment for $b$-jets. The sensitivity of the results to various assumptions about the correlation between these sources of uncertainty has been found to be negligible. An uncorrelated component of the uncertainty on $E_{\mathrm{T}}^{\mathrm{miss}}$ is included, in
addition to the JES uncertainty, which is due to low energy jet activity not associated with reconstructed physics objects.
6. Theory uncertainties: Correlated theoretical uncertainties affect mostly the signal predictions. The QCD scale uncertainties for $m_{H}=125 \mathrm{GeV}$ amount to ${ }_{-8 \%}^{+7 \%}$ for the ggF process, $\pm 1 \%$ for the VBF and $W H / Z H$ processes, and ${ }_{-9 \%}^{+4 \%}$ for the $t \bar{t} H$ process [52,53]; the small dependence of these uncertainties on $m_{H}$ is taken into account. The uncertainties on the predicted branching ratios amount to $\pm 5 \%$. The uncertainties related to the parton distribution functions amount to $\pm 8 \%$ for the predominantly gluon-initiated ggF and $t \bar{t} H$ processes, and $\pm 4 \%$ for the predominantly quark-initiated VBF and $W H / Z H$ processes [78,134-136]. The theoretical uncertainty associated with the exclusive Higgs boson production process with additional jets in the $H \rightarrow \gamma \gamma, H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ and $H \rightarrow \tau^{+} \tau^{-}$channels is estimated using the prescription of Refs. [53,117,118], with the noticeable difference that an explicit calculation of the gluon-fusion process at NLO using MCFM [137] in the 2-jet category reduces the uncertainty on this non-negligible contribution to $25 \%$. An additional theoretical uncertainty on the signal normalisation of $\pm 150 \% \times\left(m_{H} / \mathrm{TeV}\right)^{3}$ (e.g. $\pm 4 \%$ for $m_{H}=$ 300 GeV ) accounts for effects related to off-shell Higgs boson production and interference with other SM processes [53].

Sources of systematic uncertainty that affect both the 7 TeV and the 8 TeV data are taken as fully correlated. The uncertainties on background estimates based on control samples in the data are considered uncorrelated between the 7 TeV and 8 TeV data.

## 9. Results

The addition of the 8 TeV data for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow$ $\gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow e \nu \mu \nu$ channels, as well as the improvements to the analyses of the 7 TeV data in the first two of these channels, bring a significant gain in sensitivity in the low-mass region with respect to the previous combined search [17].

### 9.1. Excluded mass regions

The combined 95\% CL exclusion limits on the production of the SM Higgs boson, expressed in terms of the signal strength parameter $\mu$, are shown in Fig. $7(\mathrm{a})$ as a function of $m_{H}$. The expected $95 \% \mathrm{CL}$ exclusion region covers the $m_{H}$ range from 110 GeV to

Fig. 7. Combined search results: (a) The observed (solid) $95 \%$ CL limits on the signal strength as a function of $m_{H}$ and the expectation (dashed) under the backgroundonly hypothesis. The dark and light shaded bands show the $\pm 1 \sigma$ and $\pm 2 \sigma$ uncertainties on the background-only expectation. (b) The observed (solid) local $p_{0}$ as a function of $m_{H}$ and the expectation (dashed) for a SM Higgs boson signal hypothesis $(\mu=1)$ at the given mass. (c) The best-fit signal strength $\hat{\mu}$ as a function of $m_{H}$. The band indicates the approximate $68 \%$ CL interval around the fitted value.

582 GeV . The observed $95 \%$ CL exclusion regions are $111-122 \mathrm{GeV}$ and $131-559 \mathrm{GeV}$. Three mass regions are excluded at $99 \% \mathrm{CL}$, $113-114,117-121$ and $132-527 \mathrm{GeV}$, while the expected exclusion range at $99 \% \mathrm{CL}$ is $113-532 \mathrm{GeV}$.

### 9.2. Observation of an excess of events

An excess of events is observed near $m_{H}=126 \mathrm{GeV}$ in the $H \rightarrow$ $Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$ channels, both of which provide fully reconstructed candidates with high resolution in invariant mass, as shown in Figs. 8(a) and 8(b). These excesses are confirmed by the highly sensitive but low-resolution $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channel, as shown in Fig. 8(c).

The observed local $p_{0}$ values from the combination of channels, using the asymptotic approximation, are shown as a function of $m_{H}$ in Fig. 7(b) for the full mass range and in Fig. 9 for the low mass range.

The largest local significance for the combination of the 7 and 8 TeV data is found for a SM Higgs boson mass hypothesis of $m_{H}=126.5 \mathrm{GeV}$, where it reaches $6.0 \sigma$, with an expected value in the presence of a SM Higgs boson signal at that mass of $4.9 \sigma$ (see also Table 7). For the 2012 data alone, the maximum local significance for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow \gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow$

Fig. 8. The observed local $p_{0}$ as a function of the hypothesised Higgs boson mass for the (a) $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$, (b) $H \rightarrow \gamma \gamma$ and (c) $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channels. The dashed curves show the expected local $p_{0}$ under the hypothesis of a SM Higgs boson signal at that mass. Results are shown separately for the $\sqrt{s}=7 \mathrm{TeV}$ data (dark, blue in the web version), the $\sqrt{s}=8 \mathrm{TeV}$ data (light, red in the web version), and their combination (black).

Fig. 9. The observed (solid) local $p_{0}$ as a function of $m_{H}$ in the low mass range. The dashed curve shows the expected local $p_{0}$ under the hypothesis of a SM Higgs boson signal at that mass with its $\pm 1 \sigma$ band. The horizontal dashed lines indicate the $p$-values corresponding to significances of 1 to $6 \sigma$.
$e \nu \mu \nu$ channels combined is $4.9 \sigma$, and occurs at $m_{H}=126.5 \mathrm{GeV}$ (3.8 $\sigma$ expected).

The significance of the excess is mildly sensitive to uncertainties in the energy resolutions and energy scale systematic uncertainties for photons and electrons; the effect of the muon energy scale systematic uncertainties is negligible. The presence of these

Table 7
Characterisation of the excess in the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow \gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channels and the combination of all channels listed in Table 6 . The mass value $m_{\max }$ for which the local significance is maximum, the maximum observed local significance $Z_{l}$ and the expected local significance $E\left(Z_{l}\right)$ in the presence of a SM Higgs boson signal at $m_{\max }$ are given. The best fit value of the signal strength parameter $\hat{\mu}$ at $m_{H}=126 \mathrm{GeV}$ is shown with the total uncertainty. The expected and observed mass ranges excluded at $95 \% \mathrm{CL}\left(99 \% \mathrm{CL}\right.$, indicated by a ${ }^{*}$ ) are also given, for the combined $\sqrt{s}=7 \mathrm{TeV}$ and $\sqrt{s}=8 \mathrm{TeV}$ data.

| Search channel | Dataset | $m_{\text {max }}[\mathrm{GeV}]$ | $Z_{l}[\sigma]$ | $E\left(Z_{l}\right)[\sigma]$ | $\hat{\mu}\left(m_{H}=126 \mathrm{GeV}\right)$ | Expected exclusion [GeV] | Observed exclusion [GeV] |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ | 7 TeV | 125.0 | 2.5 | 1.6 | $1.4 \pm 1.1$ |  |  |
|  | 8 TeV | 125.5 | 2.6 | 2.1 | $1.1 \pm 0.8$ |  |  |
|  | $7 \& 8 \mathrm{TeV}$ | 125.0 | 3.6 | 2.7 | $1.2 \pm 0.6$ | 124-164, 176-500 | 131-162, 170-460 |
| $H \rightarrow \gamma \gamma$ | 7 TeV | 126.0 | 3.4 | 1.6 | $2.2 \pm 0.7$ |  |  |
|  | 8 TeV | 127.0 | 3.2 | 1.9 | $1.5 \pm 0.6$ |  |  |
|  | 7 \& 8 TeV | 126.5 | 4.5 | 2.5 | $1.8 \pm 0.5$ | 110-140 | 112-123, 132-143 |
| $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ | 7 TeV | 135.0 | 1.1 | 3.4 | $0.5 \pm 0.6$ |  |  |
|  | 8 TeV | 120.0 | 3.3 | 1.0 | $1.9 \pm 0.7$ |  |  |
|  | 7 \& 8 TeV | 125.0 | 2.8 | 2.3 | $1.3 \pm 0.5$ | 124-233 | 137-261 |
| Combined | 7 TeV | 126.5 | 3.6 | 3.2 | $1.2 \pm 0.4$ |  |  |
|  | 8 TeV | 126.5 | 4.9 | 3.8 | $1.5 \pm 0.4$ |  |  |
|  | $7 \& 8 \mathrm{TeV}$ | 126.5 | 6.0 | 4.9 | $1.4 \pm 0.3$ | $\begin{aligned} & 110-582 \\ & 113-532 \text { (*) }^{*} \end{aligned}$ | $\begin{aligned} & 111-122,131-559 \\ & 113-114,117-121,132-527 \text { (*) }^{*} \end{aligned}$ |

uncertainties, evaluated as described in Ref. [138], reduces the local significance to $5.9 \sigma$.

The global significance of a local $5.9 \sigma$ excess anywhere in the mass range $110-600 \mathrm{GeV}$ is estimated to be approximately $5.1 \sigma$, increasing to $5.3 \sigma$ in the range $110-150 \mathrm{GeV}$, which is approximately the mass range not excluded at the $99 \%$ CL by the LHC combined SM Higgs boson search [139] and the indirect constraints from the global fit to precision electroweak measurements [12].

### 9.3. Characterising the excess

The mass of the observed new particle is estimated using the profile likelihood ratio $\lambda\left(m_{H}\right)$ for $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$, the two channels with the highest mass resolution. The signal strength is allowed to vary independently in the two channels, although the result is essentially unchanged when restricted to the SM hypothesis $\mu=1$. The leading sources of systematic uncertainty come from the electron and photon energy scales and resolutions. The resulting estimate for the mass of the observed particle is $126.0 \pm 0.4$ (stat) $\pm 0.4$ (sys) GeV .

The best-fit signal strength $\hat{\mu}$ is shown in Fig. 7(c) as a function of $m_{H}$. The observed excess corresponds to $\hat{\mu}=1.4 \pm 0.3$ for $m_{H}=$ 126 GeV , which is consistent with the SM Higgs boson hypothesis $\mu=1$. A summary of the individual and combined best-fit values of the strength parameter for a SM Higgs boson mass hypothesis of 126 GeV is shown in Fig. 10, while more information about the three main channels is provided in Table 7.

In order to test which values of the strength and mass of a signal hypothesis are simultaneously consistent with the data, the profile likelihood ratio $\lambda\left(\mu, m_{H}\right)$ is used. In the presence of a strong signal, it will produce closed contours around the best-fit point $\left(\hat{\mu}, \hat{m}_{H}\right)$, while in the absence of a signal the contours will be upper limits on $\mu$ for all values of $m_{H}$.

Asymptotically, the test statistic $-2 \ln \lambda\left(\mu, m_{H}\right)$ is distributed as a $\chi^{2}$ distribution with two degrees of freedom. The resulting $68 \%$ and $95 \% \mathrm{CL}$ contours for the $H \rightarrow \gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channels are shown in Fig. 11, where the asymptotic approximations have been validated with ensembles of pseudo-experiments. Similar contours for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ channel are also shown in Fig. 11, although they are only approximate confidence intervals due to the smaller number of candidates in this channel. These contours in the $\left(\mu, m_{H}\right)$ plane take into account uncertainties in the energy scale and resolution.

The probability for a single Higgs boson-like particle to produce resonant mass peaks in the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$

Fig. 10. Measurements of the signal strength parameter $\mu$ for $m_{H}=126 \mathrm{GeV}$ for the individual channels and their combination.

Fig. 11. Confidence intervals in the $\left(\mu, m_{H}\right)$ plane for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow$ $\gamma \gamma$, and $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channels, including all systematic uncertainties. The markers indicate the maximum likelihood estimates $\left(\hat{\mu}, \hat{m}_{H}\right)$ in the corresponding channels (the maximum likelihood estimates for $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ coincide).
channels separated by more than the observed mass difference, allowing the signal strengths to vary independently, is about $8 \%$.

The contributions from the different production modes in the $H \rightarrow \gamma \gamma$ channel have been studied in order to assess any tension between the data and the ratios of the production cross

Fig. 12. Likelihood contours for the $H \rightarrow \gamma \gamma$ channel in the $\left(\mu_{\mathrm{ggF}+t \bar{t} H}, \mu_{\mathrm{VBF}+V H}\right)$ plane including the branching ratio factor $B / B_{S M}$. The quantity $\mu_{\mathrm{ggF}+t \bar{t} H}^{\mathrm{g}}\left(\mu_{\mathrm{VBF}+V H}\right)$ is a common scale factor for the ggF and $t \bar{t} H$ (VBF and $V H$ ) production cross sections. The best fit to the data ( + ) and $68 \%$ (full) and $95 \%$ (dashed) CL contours are also indicated, as well as the SM expectation ( $\times$ ).
sections predicted in the Standard Model. A new signal strength parameter $\mu_{i}$ is introduced for each production mode, defined by $\mu_{i}=\sigma_{i} / \sigma_{i, \mathrm{SM}}$. In order to determine the values of ( $\mu_{i}, \mu_{j}$ ) that are simultaneously consistent with the data, the profile likelihood ratio $\lambda\left(\mu_{i}, \mu_{j}\right)$ is used with the measured mass treated as a nuisance parameter.

Since there are four Higgs boson production modes at the LHC, two-dimensional contours require either some $\mu_{i}$ to be fixed, or multiple $\mu_{i}$ to be related in some way. Here, $\mu_{\text {ggF }}$ and $\mu_{t \bar{t} H}$ have been grouped together as they scale with the $t \bar{t} H$ coupling in the SM, and are denoted by the common parameter $\mu_{\text {ggF }+t \bar{t} H}$. Similarly, $\mu_{\mathrm{VBF}}$ and $\mu_{V H}$ have been grouped together as they scale with the $W W H / Z Z H$ coupling in the SM, and are denoted by the common parameter $\mu_{\mathrm{VBF}+V H}$. Since the distribution of signal events among the 10 categories of the $H \rightarrow \gamma \gamma$ search is sensitive to these factors, constraints in the plane of $\mu_{\mathrm{ggF}+\mathrm{t} \overline{\mathrm{H}} \mathrm{H}} \times B / B_{\mathrm{SM}}$ and $\mu_{\mathrm{VBF}+V H} \times B / B_{\mathrm{SM}}$, where $B$ is the branching ratio for $H \rightarrow \gamma \gamma$, can be obtained (Fig. 12). Theoretical uncertainties are included so that the consistency with the SM expectation can be quantified. The data are compatible with the SM expectation at the $1.5 \sigma$ level.

## 10. Conclusion

Searches for the Standard Model Higgs boson have been performed in the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell, H \rightarrow \gamma \gamma$ and $H \rightarrow W W^{(*)} \rightarrow$ $e \nu \mu \nu$ channels with the ATLAS experiment at the LHC using 5.8$5.9 \mathrm{fb}^{-1}$ of $p p$ collision data recorded during April to June 2012 at a centre-of-mass energy of 8 TeV . These results are combined with earlier results [17], which are based on an integrated luminosity of $4.6-4.8 \mathrm{fb}^{-1}$ recorded in 2011 at a centre-of-mass energy of 7 TeV , except for the $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$ channels, which have been updated with the improved analyses presented here.

The Standard Model Higgs boson is excluded at 95\% CL in the mass range $111-559 \mathrm{GeV}$, except for the narrow region 122131 GeV . In this region, an excess of events with significance $5.9 \sigma$, corresponding to $p_{0}=1.7 \times 10^{-9}$, is observed. The excess is driven by the two channels with the highest mass resolution, $H \rightarrow Z Z^{(*)} \rightarrow 4 \ell$ and $H \rightarrow \gamma \gamma$, and the equally sensitive but lowresolution $H \rightarrow W W^{(*)} \rightarrow \ell \nu \ell \nu$ channel. Taking into account the entire mass range of the search, $110-600 \mathrm{GeV}$, the global significance of the excess is $5.1 \sigma$, which corresponds to $p_{0}=1.7 \times 10^{-7}$.

These results provide conclusive evidence for the discovery of a new particle with mass $126.0 \pm 0.4$ (stat) $\pm 0.4$ (sys) GeV . The signal strength parameter $\mu$ has the value $1.4 \pm 0.3$ at the fitted mass,
which is consistent with the SM Higgs boson hypothesis $\mu=1$. The decays to pairs of vector bosons whose net electric charge is zero identify the new particle as a neutral boson. The observation in the diphoton channel disfavours the spin- 1 hypothesis [140, 141]. Although these results are compatible with the hypothesis that the new particle is the Standard Model Higgs boson, more data are needed to assess its nature in detail.

## Acknowledgements

The results reported in this Letter would not have been possible without the outstanding performance of the LHC. We warmly thank CERN and the entire LHC exploitation team, including the operation, technical and infrastructure groups, and all the people who have contributed to the conception, design and construction of this superb accelerator. We thank also the support staff at our institutions without whose excellent contributions ATLAS could not have been successfully constructed or operated so efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

# Measurement of the inclusive isolated prompt photon cross section in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

G. Aad et al.*<br>(ATLAS Collaboration)

(Received 20 December 2010; published 18 March 2011)

#### Abstract

A measurement of the cross section for the inclusive production of isolated prompt photons in $p p$ collisions at a center-of-mass energy $\sqrt{s}=7 \mathrm{TeV}$ is presented. The measurement covers the pseudorapidity ranges $\left|\eta^{\gamma}\right|<1.37$ and $1.52 \leq\left|\eta^{\gamma}\right|<1.81$ in the transverse energy range $15 \leq E_{\mathrm{T}}^{\gamma}<100 \mathrm{GeV}$. The results are based on an integrated luminosity of $880 \mathrm{nb}^{-1}$, collected with the ATLAS detector at the Large Hadron Collider. Photon candidates are identified by combining information from the calorimeters and from the inner tracker. Residual background in the selected sample is estimated from data based on the observed distribution of the transverse isolation energy in a narrow cone around the photon candidate. The results are compared to predictions from next-to-leading-order perturbative QCD calculations.

## I. INTRODUCTION

Prompt photon production at hadron colliders provides a handle for testing perturbative QCD (pQCD) predictions [1,2]. Photons provide a colorless probe of quarks in the hard partonic interaction and the subsequent partonshower. Their production is directly sensitive to the gluon content of the proton through the $q g \rightarrow q \gamma$ process, which dominates at leading-order (LO). The measurement of the prompt photon production cross section can thus be exploited to constrain the gluon density function [3,4]. Furthermore, photon identification is important for many physics signatures, including searches for Higgs boson [5] and graviton decays [6] to photon pairs, decays of excited fermions [7], and decays of pairs of supersymmetric particles characterized by the production of two energetic photons and large missing transverse energy [8-10].

Prompt photons include both "direct" photons, which take part in the hard scattering subprocess (mostly quarkgluon Compton scattering, $q g \rightarrow q \gamma$, or quark-antiquark annihilation, $q \bar{q} \rightarrow g \gamma$ ), and "fragmentation" photons, which are the result of the fragmentation of a high- $p_{T}$ parton [11,12]. In this analysis, an isolation criterion is applied based on the amount of transverse energy inside a cone of radius $R=\sqrt{\left(\eta-\eta^{\gamma}\right)^{2}+\left(\phi-\phi^{\gamma}\right)^{2}}=0.4$ centered around the photon direction in the pseudorapidity $(\eta)$ and azimuthal angle ( $\phi$ ) plane [13]. After the isolation requirement is applied the relative contribution to the total cross section from fragmentation photons decreases, though it remains non-negligible especially at low

transverse energies [12]. The isolation requirement also significantly reduces the main background of nonprompt photon candidates from decays of energetic $\pi^{0}$ and $\eta$ mesons inside jets.

Early studies of prompt photon production were carried out at the ISR collider [14,15]. Subsequent studies, for example [16-18], further established prompt photons as a useful probe of parton interactions. More recent measurements at hadron colliders were performed at the Tevatron, in $p \bar{p}$ collisions at a center-of-mass energy $\sqrt{s}=1.96 \mathrm{TeV}$. The measurement by the D 0 Collaboration [19] is based on $326 \mathrm{pb}^{-1}$ and covers a pseudorapidity range $\left|\eta^{\gamma}\right|<0.9$ and a transverse energy range $23<E_{\mathrm{T}}^{\gamma}<300 \mathrm{GeV}$, while the measurement by the CDF Collaboration [20] is based on $2.5 \mathrm{fb}^{-1}$ and covers a pseudorapidity range $\left|\eta^{\gamma}\right|<1.0$ and a transverse energy range $30<E_{\mathrm{T}}^{\gamma}<400 \mathrm{GeV}$. Both D0 and CDF measure an isolated prompt photon cross section in agreement with next-to-leading-order (NLO) pQCD calculations, with a slight excess seen in the CDF data between 30 and 50 GeV . Measurements of the inclusive prompt photon production cross section have also been performed in ep collisions, both in photoproduction and deep inelastic scattering, by the H1 [21,22] and ZEUS [23,24] Collaborations. The most recent measurement of the inclusive isolated prompt photon production was done with $2.9 \mathrm{pb}^{-1}$ at $\sqrt{s}=7 \mathrm{TeV}$ by the CMS Collaboration [25]. That measurement, which covers $21<E_{\mathrm{T}}^{\gamma}<$ 300 GeV and $\left|\eta^{\gamma}\right|<1.45$, is in good agreement with NLO predictions for the full $E_{\mathrm{T}}^{\gamma}$ range.

This paper describes the extraction of a signal of isolated prompt photons using $880 \mathrm{nb}^{-1}$ of data collected with the ATLAS detector at the Large Hadron Collider (LHC). A measurement of the production cross section in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ is presented, in the pseudorapidity ranges $\left|\eta^{\gamma}\right|<0.6,0.6 \leq\left|\eta^{\gamma}\right|<1.37$ and $1.52 \leq\left|\eta^{\gamma}\right|<$ 1.81, for photons with transverse energies between 15 GeV and 100 GeV .

The paper is organized as follows. The detector is described in Sec. II, followed by a summary of the data and the simulated samples used in the measurement in Sec. III. Section IV introduces the theoretical predictions to which the measurement is compared. Section V describes the photon reconstruction and identification algorithms; their performance is given in Sec. VI. Section VII describes the methods used to estimate the residual background in the data and to extract the prompt photon signal, followed by a discussion of the data corrections for the cross section measurement in Sec. VIII. The sources of systematic uncertainties on the cross section measurement are discussed in Sec. IX. Section X contains the main experimental results and the comparison of the observed cross sections with the theoretical predictions, followed by the conclusions in Sec. XI.

## II. THE ATLAS DETECTOR

The ATLAS detector is described in detail in Refs. [26,27]. For the measurement presented in this paper, the calorimeter, with mainly its electromagnetic section, and the inner detector are of particular relevance.

The inner detector consists of three subsystems: at small radial distance $r$ from the beam axis ( $50.5<r<150 \mathrm{~mm}$ ), pixel silicon detectors are arranged in three cylindrical layers in the barrel and in three disks in each end-cap; at intermediate radii ( $299<r<560 \mathrm{~mm}$ ), double layers of single-sided silicon microstrip detectors are used, organized in four cylindrical layers in the barrel and nine disks in each end-cap; at larger radii $(563<r<1066 \mathrm{~mm})$, a straw tracker with transition-radiation detection capabilities divided into one barrel section (with 73 layers of straws parallel to the beam line) and two end-caps (with 160 layers each of straws radial to the beam line) is used. These three systems are immersed in a 2 T axial magnetic field provided by a superconducting solenoid. The inner detector has full coverage in $\phi$. The silicon pixel and microstrip subsystems cover the pseudorapidity range $|\eta|<2.5$, while the transition-radiation tracker acceptance is limited to the range $|\eta|<2.0$. The inner detector allows an accurate reconstruction of tracks from the primary proton-proton collision region, and also identifies tracks from secondary vertices, permitting the efficient reconstruction of photon conversions in the inner detector up to a radius of $\approx 80 \mathrm{~cm}$.

The electromagnetic calorimeter is a lead-liquid argon ( $\mathrm{Pb}-\mathrm{LAr}$ ) sampling calorimeter with an accordion geometry. It is divided into a barrel section, covering the pseudorapidity region $|\eta|<1.475$, and two end-cap sections, covering the pseudorapidity regions $1.375<|\eta|<3$.2. It consists of three longitudinal layers. The first one, with a thickness between 3 and 5 radiation lengths, is segmented into high granularity strips in the $\eta$ direction (width between 0.003 and 0.006 depending on $\eta$, with the exception of the regions $1.4<|\eta|<1.5$ and $|\eta|>2.4$ ), sufficient to
provide an event-by-event discrimination between singlephoton showers and two overlapping showers coming from a $\pi^{0}$ decay. The second layer of the electromagnetic calorimeter, which collects most of the energy deposited in the calorimeter by the photon shower, has a thickness around 17 radiation lengths and a granularity of $0.025 \times 0.025$ in $\eta \times \phi$ (corresponding to one cell). A third layer, with thickness varying between 4 and 15 radiation lengths, is used to correct leakage beyond the calorimeter for highenergy showers. In front of the accordion calorimeter a thin presampler layer, covering the pseudorapidity interval $|\eta|<1.8$, is used to correct for energy loss before the calorimeter. The sampling term $a$ of the energy resolution $(\sigma(E) / E \approx a / \sqrt{E[\mathrm{GeV}]})$ varies between $10 \%$ and $17 \%$ as a function of $|\eta|$ and is the largest contribution to the resolution up to about 200 GeV , where the global constant term, estimated to be $0.7 \%$ [28], starts to dominate.

The total amount of material before the first active layer of the electromagnetic calorimeter (including the presampler) varies between 2.5 and 6 radiation lengths as a function of pseudorapidity, excluding the transition region ( $1.37 \leq|\eta|<1.52$ ) between the barrel and the end-caps, where the material thickness increases to 11.5 radiation lengths. The central region $(|\eta|<0.6)$ has significantly less material than the outer barrel $(0.6 \leq|\eta|<1.37)$, which motivates the division of the barrel into two separate regions in pseudorapidity.

A hadronic sampling calorimeter is located beyond the electromagnetic calorimeter. It is made of steel and scintillating tiles in the barrel section $(|\eta|<1.7)$, with depth around 7.4 interaction lengths, and of two end-caps of copper and liquid argon, with depth around 9 interaction lengths.

A three-level trigger system is used to select events containing photon candidates during data-taking [29]. The first level trigger (level-1) is hardware based: using a coarser cell granularity ( $0.1 \times 0.1$ in $\eta \times \phi$ ) than that of the electromagnetic calorimeter, it searches for electromagnetic clusters within a fixed window of size $0.2 \times 0.2$ and retains only those whose total transverse energy in two adjacent cells is above a programmable threshold. The second and third level triggers (collectively referred to as the "high-level" trigger) are implemented in software. The high-level trigger exploits the full granularity and precision of the calorimeter to refine the level-1 trigger selection, based on improved energy resolution and detailed information on energy deposition in the calorimeter cells.

## III. COLLISION DATA AND SIMULATED SAMPLES

## A. Collision data

The measurement presented here is based on protonproton collision data collected at a center-of-mass energy $\sqrt{s}=7 \mathrm{TeV}$ between April and August 2010. Events in
which the calorimeters or the inner detector are not fully operational, or show data quality problems, are excluded. Events are triggered using a single-photon high-level trigger with a nominal transverse energy threshold of 10 GeV , seeded by a level-1 trigger with nominal threshold equal to 5 GeV . The selection criteria applied by the trigger on shower-shape variables computed from the energy profiles of the showers in the calorimeters are looser than the photon identification criteria applied in the offline analysis, and allow ATLAS to reach a plateau of constant efficiency close to $100 \%$ for true prompt photons with $E_{\mathrm{T}}^{\gamma}>15 \mathrm{GeV}$ and pseudorapidity $\left|\eta^{\gamma}\right|<1.81$. In addition, samples of minimum-bias events, triggered by using two sets of scintillator counters located at $z= \pm 3.5 \mathrm{~m}$ from the collision center, are used to estimate the single-photon trigger efficiency. The total integrated luminosity of the sample passing data quality and trigger requirements amounts to $(880 \pm 100) \mathrm{nb}^{-1}$.

In order to reduce noncollision backgrounds, events are required to have at least one reconstructed primary vertex consistent with the average beam spot position and with at least three associated tracks. The efficiency of this requirement is expected to be greater than $99.9 \%$ in events containing a prompt photon with $E_{\mathrm{T}}^{\gamma}>15 \mathrm{GeV}$ and lying within the calorimeter acceptance. The total number of selected events in data after this requirement is $9.6 \times$ $10^{6}$. The remaining amount of noncollision background is estimated using control samples collectedduring normal data-taking conditions-with dedicated, low threshold triggers that are activated in events where either no proton bunch or only one of the two beams crosses the interaction region. The estimated contribution to the final photon sample is less than $0.1 \%$ and is therefore neglected.

## B. Simulated events

To study the characteristics of signal and background events, Monte Carlo (MC) samples are generated using PYTHIA 6.4.21 [30], a leading-order parton-shower MC generator, with the modified leading-order MRST2007 [31] parton distribution functions (PDFs). It accounts for QED radiation emitted off quarks in the initial state (ISR) and in the final state (FSR). PYTHIA simulates the underlying event using the multiple-parton interaction model, and uses the Lund string model for hadronisation [32]. The event generator parameters are set according to the ATLAS MC09 tune [33], and the detector response is simulated using the GEANT4 program [34]. These samples are then reconstructed with the same algorithms used for data. More details on the event generation and simulation infrastructure are provided in Ref. [35]. For the study of systematic uncertainties related to the choice of the event generator and the parton-shower model, alternative samples are also generated with HERWIG 6.5 [36]. This generator also uses LO pQCD matrix elements, but has a different
parton-shower model (angle-ordered instead of $p_{\mathrm{T}}$-ordered), a different hadronisation model (the cluster model) and a different underlying event model, which is generated using the JIMMY package [37] with multipleparton interactions enabled. The HERWIG event generation parameters are also set according to the MC09 tune.

To study the main background processes, simulated samples of all relevant $2 \rightarrow 2 \mathrm{QCD}$ hard subprocesses involving only partons are used. The prompt photon contribution arising from initial and final state radiation emitted off quarks is removed from these samples in studies of the background.

Two different simulated samples are employed to study the properties of the prompt photon signal. The first sample consists of leading-order $\gamma$-jet events, and contains primarily direct photons produced in the hard subprocesses $q g \rightarrow q \gamma$ and $q \bar{q} \rightarrow g \gamma$. The second signal sample includes ISR and FSR photons emitted off quarks in all $2 \rightarrow 2$ QCD processes involving only quarks and gluons in the hard scatter. This sample is used to study the contribution to the prompt photon signal by photons from fragmentation, or from radiative corrections to the direct process, that are less isolated than those from the LO direct processes.

Finally, a sample of $W \rightarrow e \nu$ simulated events is used for the efficiency and purity studies involving electrons from $W$ decays.

## IV. THEORETICAL PREDICTIONS

The expected isolated prompt photon production cross section as a function of the photon transverse energy $E_{\mathrm{T}}^{\gamma}$ is calculated with the JETPHOX Monte Carlo program [11], which implements a full NLO QCD calculation of both the direct and the fragmentation contributions to the total cross section. In the calculation performed for this measurement, the total transverse energy carried by the partons inside a cone of radius $R=0.4$ in the $\eta-\phi$ space around the photon direction is required to be less than 4 GeV . The NLO photon fragmentation function [38] and the CTEQ 6.6 parton density functions [39] provided by the LHAPDF package [40] are used. The nominal renormalization $\left(\mu_{R}\right)$, factorization $\left(\mu_{F}\right)$ and fragmentation $\left(\mu_{f}\right)$ scales are set to the photon transverse energy $E_{\mathrm{T}}^{\gamma}$. Varying the CTEQ PDFs within the $68 \%$ C.L. intervals causes the cross section to vary between 5\% and $2 \%$ as $E_{\mathrm{T}}$ increases between 15 and 100 GeV . The variation of the three scales independently between 0.5 and 2.0 times the nominal scale changes the predicted cross section by $20 \%$ at low $E_{\mathrm{T}}$ and $10 \%$ at high $E_{\mathrm{T}}$, while the variation of the isolation requirement between 2 and 6 GeV changes the predicted cross section by no more than $2 \%$. The MSTW 2008 PDFs [41] are used as a cross-check of the choice of PDF. The central values obtained with the MSTW 2008 PDFs are between $3 \%$ and $5 \%$ higher than those predicted using the CTEQ 6.6 PDFs.

The NLO calculation provided by JETPHOX predicts a cross section at parton-level, which does not include effects of hadronisation nor the underlying event and pile-up (i.e. multiple proton-proton interactions in the same bunch crossing). The nonperturbative effects on the cross section due to hadronisation are evaluated using the simulated PYTHIA and HERWIG signal samples described in Sec. III B, by evaluating the ratio of the cross section before and after hadronisation and underlying event simulation. The ratios are estimated to be within $1 \%$ (2\%) of unity in PYTHIA (HERWIG) for all $E_{\mathrm{T}}$ and $\eta$ regions under study. To account for the effect of the underlying event and pile-up on the measured isolation energy, a correction to the photon transverse isolation energy measured in data is applied, using a procedure described in Sec. V C.

## V. PHOTON RECONSTRUCTION, IDENTIFICATION AND ISOLATION

## A. Photon reconstruction and preselection

Photon reconstruction is seeded by clusters in the electromagnetic calorimeter with transverse energies exceeding 2.5 GeV , measured in projective towers of $3 \times 5$ cells in $\eta \times \phi$ in the second layer of the calorimeter. An attempt is made to match these clusters with tracks that are reconstructed in the inner detector and extrapolated to the calorimeter. Clusters without matching tracks are directly classified as "unconverted" photon candidates. Clusters with matched tracks are considered as electron candidates. To recover photon conversions, clusters matched to pairs of tracks originating from reconstructed conversion vertices in the inner detector are considered as "converted" photon candidates. To increase the reconstruction efficiency of converted photons, conversion candidates where only one of the two tracks is reconstructed (and does not have any hit in the innermost layer of the pixel detector) are also retained $[27,28]$.

The final energy measurement, for both converted and unconverted photons, is made using only the calorimeter, with a cluster size that depends on the photon classification. In the barrel, a cluster corresponding to $3 \times 5(\eta \times \phi)$ cells in the second layer is used for unconverted photons, while a cluster of $3 \times 7(\eta \times \phi)$ cells is used for converted photon candidates (to compensate for the opening between the conversion products in the $\phi$ direction due to the magnetic field). In the end-cap, a cluster size of $5 \times 5$ is used for all candidates. A dedicated energy calibration [27] is then applied separately for converted and unconverted photon candidates to account for upstream energy loss and both lateral and longitudinal leakage.

Photon candidates with calibrated transverse energies $\left(E_{\mathrm{T}}^{\gamma}\right)$ above 15 GeV are retained for the successive analysis steps. To minimize the systematic uncertainties related to the efficiency measurement at this early stage of the experiment, the cluster barycenter in the second layer of the electromagnetic calorimeter is required to lie in
the pseudorapidity region $\left|\eta^{\gamma}\right|<1.37$, or $1.52 \leq\left|\eta^{\gamma}\right|<$ 1.81. Photon candidates with clusters containing cells overlapping with few problematic regions of the calorimeter readout are removed. After the above preselection, $1.3 \times 10^{6}$ photon candidates remain in the data sample.

## B. Photon identification

Shape variables computed from the lateral and longitudinal energy profiles of the shower in the calorimeters are used to discriminate signal from background $[27,42]$. The exact definitions of the discriminating variables are provided in Appendix A. Two sets of selection criteria (denoted "loose" and "tight") are defined, each based on independent requirements on several shape variables. The selection criteria do not depend on the photon candidate transverse energy, but vary as a function of the photon reconstructed pseudorapidity, to take into account variations in the total thickness of the upstream material and in the calorimeter geometry.

## 1. Loose identification criteria

A set of loose identification criteria for photons is defined based on independent requirements on three quantities:
(i) the leakage $R_{\text {had }}$ in the first layer of the hadronic compartment beyond the electromagnetic cluster, defined as the ratio between the transverse energy deposited in the first layer of the hadronic calorimeter and the transverse energy of the photon candidate;
(ii) the ratio $R_{\eta}$ between the energy deposits in $3 \times 7$ and $7 \times 7$ cells in the second layer of the electromagnetic calorimeter;
(iii) the root mean square (RMS) width $w_{2}$ of the energy distribution along $\eta$ in the second layer of the electromagnetic calorimeter.

True prompt photons are expected to have small hadronic leakage (typically below $1 \%-2 \%$ ) and a narrower energy profile in the electromagnetic calorimeter, more concentrated in the core of the cluster, with respect to background photon candidates from jets.

The loose identification criteria on $R_{\text {had }}, R_{\eta}$ and $w_{2}$ are identical for converted and unconverted candidates. They have been chosen, using simulated prompt photon events, in order to obtain a prompt photon efficiency, with respect to reconstruction, rising from $97 \%$ at $E_{\mathrm{T}}^{\gamma}=20 \mathrm{GeV}$ to above $99 \%$ for $E_{\mathrm{T}}^{\gamma}>40 \mathrm{GeV}$ for both converted and unconverted photons [28]. The number of photon candidates in data passing the preselection and loose photon identification criteria is $0.8 \times 10^{6}$.

## 2. Tight identification criteria

To further reject the background, the selection requirements on the quantities used in the loose identification are
tightened. In addition, the transverse shape along the $\phi$ direction in the second layer (the variable $R_{\phi}$, computed from the ratio between the energy deposits in $3 \times 3$ and $3 \times 7$ cells) and the shower shapes in the first layer of the calorimeter are examined. Several variables that discriminate single-photon showers from overlapping nearby showers (in particular those which originate from neutral meson decays to photon pairs) are computed from the energy deposited in the first layer:
(i) the total RMS width $w_{s, \text { tot }}$ of the energy distribution along $\eta$;
(ii) the asymmetry $E_{\text {ratio }}$ between the first and second maxima in the energy profile along $\eta$;
(iii) the energy difference $\Delta E$ between the second maximum and the minimum between the two maxima;
(iv) the fraction $F_{\text {side }}$ of the energy in seven strips centered (in $\eta$ ) around the first maximum that is not contained in the three core strips;
(v) the RMS width $w_{s, 3}$ of the energy distribution computed with the three core strips.
The first variable rejects candidates with wide showers consistent with jets. The second and third variables provide rejection against cases where two showers give separated energy maxima in the first layer. The last two variables provide rejection against cases where two showers are merged in a wider maximum.

The tight selection criteria are optimized independently for unconverted and converted photons to account for the quite different developments of the showers in each case. They have been determined using samples of simulated signal and background events prior to data-taking, aiming to obtain an average efficiency of $85 \%$ with respect to reconstruction for true prompt photons with transverse energies greater than 20 GeV [28]. About $0.2 \times 10^{6}$ photon candidates are retained in the data sample after applying the tight identification requirements.

## C. Photon transverse isolation energy

An experimental isolation requirement, based on the transverse energy deposited in the calorimeters in a cone around the photon candidate, is used in this measurement to identify isolated prompt photons and to further suppress the main background from $\pi^{0}$ (or other neutral hadrons decaying in two photons), where the $\pi^{0}$ is unlikely to carry the full original jet energy. The transverse isolation energy $\left(E_{\mathrm{T}}^{\mathrm{iso}}\right)$ is computed using calorimeter cells from both the electromagnetic and hadronic calorimeters, in a cone of radius 0.4 in the $\eta-\phi$ space around the photon candidate. The contributions from $5 \times 7$ electromagnetic calorimeter cells in the $\eta-\phi$ space around the photon barycenter are not included in the sum. The mean value of the small leakage of the photon energy outside this region, evaluated as a function of the photon transverse energy, is subtracted from the measured value of $E_{\mathrm{T}}^{\text {iso }}$. The typical size of this
correction is a few percent of the photon transverse energy. After this correction, $E_{\mathrm{T}}^{\text {iso }}$ for truly isolated photons is nominally independent of the photon transverse energy.

In order to make the measurement of $E_{\mathrm{T}}^{\text {iso }}$ directly comparable to parton-level theoretical predictions, such as those described in Sec. IV, $E_{\mathrm{T}}^{\text {iso }}$ is further corrected by subtracting the estimated contributions from the underlying event and from pile-up. This correction is computed on an event-by-event basis using a method suggested in Refs. [43,44]. Based on the standard seeds for jet reconstruction, which are noise-suppressed three-dimensional topological clusters [26], and for two different pseudorapidity regions ( $|\eta|<1.5$ and $1.5<|\eta|<3.0$ ), a $k_{\mathrm{T}}$ jetfinding algorithm [45,46], implemented in FASTJET [47], is used to reconstruct all jets without any explicit transverse momentum threshold. During reconstruction, each jet is assigned an area via a Voronoi tessellation [48] of the $\eta-\phi$ space. According to the algorithm, every point within a jet's assigned area is closer to the axis of that jet than of any other jet. The transverse energy density for each jet is then computed from the ratio between the jet transverse energy and its area. The ambient-transverseenergy density for the event, from pile-up and underlying event, is taken to be the median jet transverse energy density. Finally, this ambient-transverse-energy density is multiplied by the area of the isolation cone to compute the correction to $E_{\mathrm{T}}^{\text {iso }}$.

The estimated ambient-transverse-energy fluctuates significantly event-by-event, reflecting the fluctuations in the underlying event and pile-up activity in the data. The mean correction to the calorimeter transverse energy in a cone of radius $R=0.4$ for an event with one $p p$ interaction is around 440 MeV in events simulated with PYTHIA and 550 MeV in HERWIG. In the data, the mean correction is 540 MeV for events containing at least one photon candidate with $E_{\mathrm{T}}>15 \mathrm{GeV}$ and exactly one reconstructed primary vertex, and increases by an average of 170 MeV with each additional reconstructed primary vertex. The average number of reconstructed primary vertices for the sample under study is 1.56 . The distribution of measured ambient-transverse-energy densities for photons passing the tight selection criteria is shown in Fig. 1. The impact of this correction on the measured cross section is discussed in Sec. IX B. For a consistent comparison of this measurement to a theoretical prediction which incorporates an underlying event model, the method described above should be applied to the generated final state in order to evaluate and apply the appropriate event-by-event corrections.

After the leakage and ambient-transverse-energy corrections, the $E_{\mathrm{T}}^{\text {iso }}$ distribution for direct photons in simulated events is centered at zero, with an RMS width of around 1.5 GeV (which is dominated by electronic noise in the calorimeter). In the following, all photon candidates with $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$ are considered to be experimentally isolated.

FIG. 1. The measured ambient-transverse-energy densities, using the jet-area method, for events with at least one tight photon. The ambient-transverse-energy contains contributions from both the underlying event and pile-up. The broad distribution reflects the large event-to-event fluctuations.

This criterion can be related to a cut on the transverse isolation energy calculated at the parton-level in PYTHIA, in order to mimic the isolation criterion implemented in JETPHOX. This parton-level isolation is the total transverse energy of all partons that lie inside a cone of radius $R=0.4$ around the photon direction and originated from the same quark emitting the photon in either ISR or FSR. The efficiency of the experimental isolation cut at 3 GeV for photons radiated off partons in PYTHIA is close to the efficiency of a parton-level isolation cut at 4 GeV . This cut on the parton-level isolation is equivalent to the same cut on a particle-level isolation, which measures the transverse energy in a cone of radius $R=0.4$ around the photon after hadronisation (with the underlying event removed). The experimental isolation criterion is expected to reject roughly $50 \%$ of background candidates with transverse energy greater than 15 GeV .

FIG. 2. Transverse energy distribution of photon candidates selected in data, after reconstruction and preselection (open triangles) and after requiring tight identification criteria and transverse isolation energy lower than 3 GeV (full circles). The photon candidates have pseudorapidity $\left|\eta^{\gamma}\right|<1.37$ or $1.52 \leq\left|\eta^{\gamma}\right|<1.81$.

The number of photon candidates satisfying the tight identification criteria and having $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$ is 110442 : 73614 are reconstructed as unconverted photons and 36828 as converted photons. The transverse energy distribution of these candidates is shown in Fig. 2. For comparison, the initial distribution of all photon candidates after the reconstruction and preselection is also shown.

## VI. SIGNAL EFFICIENCY

## A. Reconstruction and preselection efficiency

The reconstruction and preselection efficiency, $\varepsilon_{\text {reco }}$, is computed from simulated events as a function of the true photon transverse energy for each pseudorapidity interval under study. It is defined as the ratio between the number of true prompt photons that are reconstructed-after prese-lection-in a certain pseudorapidity interval and have reconstructed $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$, and the number of true photons with true pseudorapidity in the same pseudorapidity interval and with particle-level transverse isolation energy lower than 4 GeV . The efficiency of the requirement $E_{\mathrm{T}}^{\gamma}>15 \mathrm{GeV}$ for prompt photons of true transverse energy greater than the same threshold is taken into account in Sec. VIII.

The reconstruction and preselection efficiencies are calculated using a cross-section-weighted mixture of direct photons produced in simulated $\gamma$-jet events and of fragmentation photons produced in simulated dijet events. The uncertainty on the reconstruction efficiency due to the difference between the efficiency for direct and fragmentation photons, and the unknown ratio of the two in the final sample of selected signal photons, are taken into account as sources of systematic uncertainty in Sec. IX A.

The average reconstruction and preselection efficiency for isolated prompt photons with $\left|\eta_{\text {true }}^{\gamma}\right|<1.37$ or $1.52 \leq$ $\left|\eta_{\text {true }}^{\gamma}\right|<1.81$ is around $82 \%$; the $18 \%$ inefficiency is due to the inefficiency of the reconstruction algorithms at low photon transverse energy (a few \%), to the inefficiency of the isolation requirement ( $5 \%$ ) and to the acceptance loss from a few inoperative optical links of the calorimeter readout [49].

## B. Identification efficiency

The photon identification efficiency, $\varepsilon_{\mathrm{ID}}$, is similarly computed as a function of transverse energy in each pseudorapidity region. It is defined as the efficiency for reconstructed (true) prompt photons, with measured $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$, to pass the tight photon identification criteria described in Sec. VB. The identification efficiency is determined from simulation after shifting the photon shower shapes by "shower-shape correction factors" that account for the observed average differences between the discriminating variables' distributions in data and MC. The simulated sample used contains all the main QCD signal and background processes. The average differences

FIG. 3 (color online). Efficiency of the tight identification criteria as a function of the reconstructed photon transverse energy for prompt isolated photons. Systematic uncertainties are included.
between data and simulation are computed after applying the tight identification criteria. The typical size of the correction factors is $10 \%$ of the RMS of the distribution of the corresponding variable in data, with a maximum of $50 \%$ of the RMS for the variable $\left(R_{\eta}\right)$ where the simulation is in worse agreement with the data. The corresponding correction to the MC efficiency is typically around $-3 \%$ and is always between $-5 \%$ and zero. The photon identification efficiency after all selection criteria (including isolation) are applied is shown in Fig. 3 and in Table I, including the systematic uncertainties that are discussed in more detail in Sec. IX A. The efficiencies for converted photons are, on average, $3 \%-4 \%$ lower than for unconverted photons with the same pseudorapidity and transverse energy.

As a cross-check, photon identification efficiencies are also inferred from the efficiencies of the same identification criteria applied to electrons selected in data from $W$
decays. Events containing $W \rightarrow e \nu$ candidates are selected by requiring: a missing transverse energy greater than 25 GeV (corresponding to the undetected neutrino); an opening azimuthal angle larger than 2.5 radians between the missing transverse energy vector and any energetic jets ( $E_{\mathrm{T}}>15 \mathrm{GeV}$ ) in the event; an electron transverse isolation energy in a cone of radius 0.4 in the $\eta-\phi$ space smaller than 0.3 times the electron transverse momentum; and a track, associated to the electron, that passes trackquality cuts, such as the minimum requirement on the measured transition-radiation in the transition-radiation tracker and the requirement of the presence of hits in the silicon trackers. These selection criteria, which do not rely on the shape of the electron shower in the calorimeter, are sufficient to select a $W \rightarrow e \nu$ sample with a purity (measured using a calorimeter isolation technique similar to that described in Sec. 6.1 of Ref. [50]) greater than $95 \%$. The identification efficiency of converted photons is taken from the efficiency for selected electrons to pass the tight photon selection criteria. This approximation is expected to hold to within $3 \%$ from studies of simulated samples of converted isolated prompt photons and of isolated electrons from $W$ decays. For unconverted photons, the electrons in data are used to infer shower-shape corrections. These corrections are then applied to unconverted photons in simulation, in order to calculate the unconverted photon efficiency from Monte Carlo. The results from the electron extrapolation method are consistent with those from the simulation, with worse precision due to the limited statistics of the selected electron sample.

## C. Trigger efficiency

The efficiency of the calorimeter trigger, relative to the photon reconstruction and identification selection, is defined as the probability for a true prompt photon, passing the tight photon identification criteria and with $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$, to pass the trigger selection. It is estimated in two steps. First, using a prescaled sample of minimum-bias triggers, the efficiency of a lower threshold ( $\approx 3.5 \mathrm{GeV}$ ) level-1 calorimeter trigger is determined. The measured efficiency of this trigger is $100 \%$ for all photon

TABLE I. Isolated prompt photon identification efficiency in the intervals of the photon pseudorapidity and transverse energy under study.

| $E_{\mathrm{T}}^{\gamma}[\mathrm{GeV}]$ | $0.00 \leq\left\|\eta^{\gamma}\right\|<0.60$ | Identification Efficiency $[\%]$ <br> $0.60 \leq\left\|\eta^{\gamma}\right\|<1.37$ | $1.52 \leq\left\|\eta^{\gamma}\right\|<1.81$ |
| :--- | :---: | :---: | :---: |
| $[15,20)$ | $63.3 \pm 6.6$ | $63.5 \pm 6.9$ | $72.2 \pm 8.4$ |
| $[20,25)$ | $73.5 \pm 6.1$ | $73.5 \pm 6.8$ | $81.6 \pm 8.3$ |
| $[25,30)$ | $80.2 \pm 5.4$ | $80.8 \pm 5.7$ | $86.7 \pm 6.6$ |
| $[30,35)$ | $85.5 \pm 4.5$ | $85.3 \pm 4.8$ | $90.4 \pm 5.9$ |

| $[60,100)$ | $92.2 \pm 2.6$ | $94.8 \pm 2.6$ | $94.2 \pm 2.9$ |

FIG. 4. Photon trigger efficiency, with respect to reconstructed isolated photon passing the tight identification criteria, as measured in data (circles) and simulated background events (triangles).
candidates with reconstructed $E_{\mathrm{T}}^{\gamma}>15 \mathrm{GeV}$ passing tight identification criteria. Then, the efficiency of the high-level trigger is measured using the sample of events that pass the level-1 calorimeter trigger with the 3.5 GeV threshold.

The trigger efficiency for reconstructed photon candidates passing tight selection criteria, isolated and with $E_{\mathrm{T}}^{\gamma}>15 \mathrm{GeV}$ is found to be $\varepsilon^{\text {trig }}=(99.5 \pm 0.5) \%$, constant within uncertainties over the full $E_{\mathrm{T}}$ and $\eta$ ranges under study. The quoted uncertainty is obtained from the estimation of the possible bias introduced by using photon candidates from data, which are a mixture of signal and background photon candidates. Using Monte Carlo samples the absolute difference of the trigger efficiency for a pure signal sample and for a pure background sample is found to be smaller than $0.5 \%$ for isolated tight photon candidates with $E_{\mathrm{T}}^{\gamma}>15 \mathrm{GeV}$.

A comparison between the high-level trigger efficiency in data and in the background predicted by the simulation is shown in Fig. 4.

## VII. BACKGROUND SUBTRACTION AND SIGNAL YIELD DETERMINATION

A non-negligible residual contribution of background candidates is expected in the selected photon sample, even after the application of the tight identification and isolation requirements. Two methods are used to estimate the background contribution from data and to measure the prompt photon signal yield. The first one is used for the final cross section measurement, while the second one is used as a cross-check of the former. All estimates are made separately for each region of pseudorapidity and transverse energy.

## A. Isolation vs identification sideband counting method

The first technique for measuring the prompt photon yield uses the number of photon candidates observed in the sidebands of a two-dimensional distribution to estimate
the amount of background in the signal region. The two dimensions are defined by the transverse isolation energy $E_{\mathrm{T}}^{\text {iso }}$ on one axis, and the photon identification $\left(\gamma_{\mathrm{ID}}\right)$ of the photon candidate on the other axis. On the isolation axis, the signal region contains photon candidates with $E_{\mathrm{T}}^{\mathrm{iso}}<3 \mathrm{GeV}$, while the sideband contains photon candidates with $E_{\mathrm{T}}^{\mathrm{iso}}>5 \mathrm{GeV}$. On the other axis, photon candidates passing the tight identification criteria (tight candidates) belong to the $\gamma_{\mathrm{ID}}$ signal region, while those that fail the tight identification criteria but pass a background-enriching selection ("nontight" candidates) belong to the $\gamma_{\mathrm{ID}}$ sideband. The nontight selection requires photon candidates to fail at least one of a subset of the photon tight identification criteria, but to pass all criteria not in that subset. All the shower-shape variables based on the energy measurement in the first layer of the electromagnetic calorimeter are used to define the backgroundenriching selection, with the exception of $w_{s, \text { tot }}$, since it is found to be significantly correlated with the $E_{\mathrm{T}}^{\text {iso }}$ of background photon candidates, while the photon yield measurement relies on the assumption of negligible (or small) correlations between the transverse isolation energy and the shower-shape quantities used to define the backgroundenriching selection.

The signal region (region " $A$ ") is therefore defined by photon candidates passing the tight photon identification criteria and having experimental $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$. The three background control regions consist of photon candidates either:
(i) passing the tight photon identification criteria but having experimental $E_{\mathrm{T}}^{\text {iso }}>5 \mathrm{GeV}$ (region " B ")
(ii) having $E_{\mathrm{T}}^{\mathrm{iso}}<3 \mathrm{GeV}$ and passing the backgroundenriching identification criteria (region "C")
(iii) having $E_{\mathrm{T}}^{\text {iso }}>5 \mathrm{GeV}$ and passing the backgroundenriching identification criteria (region " $D$ ").

A sketch of the two-dimensional plane and of the signal and background control region definitions is shown in Fig. 5.

The method assumes that the signal contamination in the three background control regions is small, and that the isolation profile in the nontight regions is the same as that of the background in the tight regions. If these assumptions hold, then the number of background candidates in the signal region can be calculated by taking the ratio of candidates in the two nontight regions $\left(N_{C} / N_{D}\right)$, and multiplying it by the number of candidates in the tight, nonisolated region $\left(N_{B}\right)$. The number of isolated prompt photons passing the tight identification criteria is therefore:

$$
\begin{equation*}
N_{A}^{\text {sig }}=N_{A}-N_{B} \frac{N_{C}}{N_{D}}, \tag{1}
\end{equation*}
$$

where $N_{A}$ is the observed number of photon candidates in the signal region.

FIG. 5 (color online). Illustration of the two-dimensional plane, defined by means of the transverse isolation energy and a subset of the photon identification (ID) variables, used for estimating, from the observed yields in the three control regions $(B, C, D)$, the background yield in the signal region $(A)$.

The assumption that the signal contamination in the background control regions is small is checked using prompt photon MC samples. As the number of signal events in the background control regions is always positive and nonzero, corrections are applied to limit the effects on the final result. For this purpose, Eq. (1) is modified in the following way:

$$
\begin{equation*}
N_{A}^{\mathrm{sig}}=N_{A}-\left(N_{B}-c_{B} N_{A}^{\mathrm{sig}}\right) \frac{\left(N_{C}-c_{C} N_{A}^{\mathrm{sig}}\right)}{\left(N_{D}-c_{D} N_{A}^{\mathrm{sig}}\right)}, \tag{2}
\end{equation*}
$$

where $c_{K} \equiv \frac{N_{K}^{\text {it }}}{N_{A}^{\mathrm{E}_{8}}}($ for $K \in\{B, C, D\})$ are the signal leakage fractions extracted from simulation. Typical values for $c_{B}$ are between $3 \%$ and $17 \%$, increasing with the photon candidate transverse energy; for $c_{C}$, between $2 \%$ and $14 \%$, decreasing with $E_{\mathrm{T}}^{\gamma}$. $c_{D}$ is always less than $2 \%$. The total effect of these corrections on the measured signal photon purities is typically less than $5 \%$.

The isolated prompt photon fraction measured with this method, as a function of the photon reconstructed

FIG. 6 (color online). Fraction of isolated prompt photons as a function of the photon transverse energy, as obtained with the two-dimensional sideband method.
transverse energy, is shown in Fig. 6. The numbers of isolated prompt photon candidates measured in each pseudorapidity and transverse energy interval are also reported in Table II. The systematic uncertainties on the measured prompt photon yield and fraction in the selected sample are described in Sec. IX B.

## B. Isolation template fit method

The second method relies on a binned maximum likelihood fit to the $E_{\mathrm{T}}^{\mathrm{iso}}$ distribution of photon candidates selected in data which pass the tight identification criteria. The distribution is fit to the sum of a signal template and a background template, determined from control samples extracted from data. This is similar to the technique employed in [20], but relies less on simulation for signal and background templates. The signal template is determined from the $E_{\mathrm{T}}^{\text {iso }}$ distribution of electrons from $W$ and $Z$

TABLE II. Observed number of isolated prompt photons in the photon transverse energy and pseudorapidity intervals under study. The first uncertainty is statistical, the second is the systematic uncertainty, evaluated as described in Sec. IX B.

|  | Isolated prompt photon yield |  |  |
| :--- | :---: | :---: | :---: |
| $E_{\mathrm{T}}^{\gamma}[\mathrm{GeV}]$ | $0.00 \leq\left\|\eta^{\gamma}\right\|<0.60$ | $0.60 \leq\left\|\eta^{\gamma}\right\|<1.37$ | $1.52 \leq\left\|\eta^{\gamma}\right\|<1.81$ |
| $[15,20)$ | $\left(119 \pm 3_{-20}^{+12}\right) \times 10^{2}$ | $\left(130 \pm 4_{-11}^{+40}\right) \times 10^{2}$ | $\left(72 \pm 2_{-7}^{+20}\right) \times 10^{2}$ |

| $[25,30)$ | $\left(260 \pm 7_{-21}^{+20}\right) \times 10^{1}$ | $\left(306 \pm 10_{-18}^{+46}\right) \times 10^{1}$ | $\left(135 \pm 6_{-10}^{+16}\right) \times 10^{1}$ |
| $[30,35)$ | $\left(146 \pm 5_{-6}^{+9}\right) \times 10^{1}$ | $\left(160 \pm 6_{-9}^{+19}\right) \times 10^{1}$ | $\left(73 \pm 4_{-5}^{+8}\right) \times 10^{1}$ |
| $[35,40)$ | $\left(82 \pm 4_{-4}^{+5}\right) \times 10^{1}$ | $\left(102 \pm 4_{-6}^{+9}\right) \times 10^{1}$ | $\left(44 \pm 3_{-3}^{+5}\right) \times 10^{1}$ |
| $[40,50)$ | $\left(77 \pm 3_{-4}^{+5}\right) \times 10^{1}$ | $\left(98 \pm 4_{-7}^{+9}\right) \times 10^{1}$ | $\left(38 \pm 2_{-2}^{+3}\right) \times 10^{1}$ |
| $[50,60)$ | $\left(329 \pm 20_{-14}^{+17}\right) \times 10^{0}$ | $(420 \pm 20 \pm 30) \times 10^{0}$ | $\left(147 \pm 16_{-17}^{+16}\right) \times 10^{0}$ |
| $[60,100)$ | $\left(329 \pm 20_{-15}^{+19}\right) \times 10^{0}$ | $\left(370 \pm 20_{-20}^{+30}\right) \times 10^{0}$ | $\left(154 \pm 12_{-8}^{+12}\right) \times 10^{0}$ |

decays, selected using the criteria described in [50]. Electrons from $W$ decays are required to fulfill tight selection criteria on the shapes of their showers in the electromagnetic calorimeter and to pass track-quality requirements, including the presence of transition-radiation hits. They must also be accompanied by $E_{\mathrm{T}}^{\text {miss }}>25 \mathrm{GeV}$, and the electron- $E_{\mathrm{T}}^{\text {miss }}$ system must have a transverse mass larger than 40 GeV . Electrons from $Z$ decays are selected with looser criteria, but the pair must have an invariant mass close to the $Z$ mass. A single signal template is constructed for each region in $|\eta|$, exploiting the independence of $E_{\mathrm{T}}^{\text {iso }}$ from the transverse energy of the object (after applying the corrections described in Sec. V C) to maximize the available statistics. A small bias is expected due to differences between the electron and photon $E_{\mathrm{T}}^{\text {iso }}$ distributions, especially in regions where there is significant material upstream of the calorimeter. A shift of the signal template is applied to the electron distributions extracted from data to compensate for the differences between electrons and photons seen in simulation. This shift, computed using simulated photon and electron samples, increases from 100 MeV to 600 MeV with increasing $\left|\eta^{\gamma}\right|$. The background template is extracted from data for each $\left(E_{\mathrm{T}},|\eta|\right)$ bin, using the same reverse-cuts procedure as in the two-dimensional sideband technique. A simulationbased correction, typically of the order of $3 \%-4 \%$, is applied to the final photon fraction to account for a signal which leaks into the background template. The fit is performed in each region of $\left|\eta^{\gamma}\right|$ for the individual bins in transverse energy, and the signal yield and fraction are extracted. An example of such a fit is shown in Fig. 7. The results from this alternative technique are in good agreement with those from the simpler counting method described in the previous subsection, with differences

FIG. 7 (color online). Example of a fit to extract the fraction of prompt photons using the isolation template technique in the region $0 \leq|\eta|<0.6$ and $35 \leq E_{\mathrm{T}}^{\gamma}<40 \mathrm{GeV}$. The signal template is derived from electrons selected from $W$ or $Z$ decays, and is shown with a dashed line. The background template is derived from a background-enriched sample, and is represented by a dotted line. The estimated photon fraction is 0.85 and its statistical uncertainty is 0.01 .
typically smaller than $2 \%$ and within the systematic uncertainties that are uncorrelated between the two methods.

## C. Electron background subtraction

The background of prompt electrons misidentified as photons needs also to be considered. The dominant electron production mechanisms are semileptonic hadron decays (mostly from hadrons containing heavy flavor quarks) and decays of electroweak bosons (the largest contribution being from $W$ decays). Electrons from the former are often produced in association with jets, and have $E_{\mathrm{T}}^{\text {iso }}$ profiles similar to the dominant backgrounds from light mesons. They are therefore taken into account and subtracted using the two-dimensional sideband technique described in Sec. VII A. Conversely, electrons from $W$ and $Z$ decays have $E_{\mathrm{T}}^{\mathrm{iso}}$ profiles that are similar to those of signal photons. The contribution of this background to the signal yield computed in Sec. VII A needs therefore to be removed before the final measurement of the cross section.

The fraction of electrons reconstructed as photon candidates is estimated from the data, as a function of the electron transverse energy and pseudorapidity, using a control sample of $Z \rightarrow e^{+} e^{-}$decays. The average electron misidentification probability is around $8 \%$. Using the $W \rightarrow e \nu$ and $Z \rightarrow e e$ cross section times branching ratio measured by ATLAS in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ [50], the estimated fraction of photon candidates due to isolated electrons is found to be on average $\sim 0.5 \%$, varying significantly with transverse energy. A maximum contamination of $(2.5 \% \pm 0.8 \%)$ is estimated for transverse energies between 40 and 50 GeV , due to the kinematic distribution of electrons from $W$ and $Z$ decays. The uncertainties on these estimates are less than $1 \%$ of the photon yield.

## VIII. CROSS SECTION MEASUREMENT

The differential cross section is measured by computing:

$$
\begin{equation*}
\frac{d \sigma}{d E_{\mathrm{T}}^{\gamma}}=\frac{N_{\text {yield }} U}{\left(\int \mathcal{L} d t\right) \Delta E_{\mathrm{T}}^{\gamma} \varepsilon_{\text {trigger }} \varepsilon_{\mathrm{reco}} \varepsilon_{\mathrm{ID}}} \tag{3}
\end{equation*}
$$

The observed signal yield ( $N_{\text {yield }}$ ) is divided by the widths of the $E_{\mathrm{T}}$-intervals $\left(\Delta E_{\mathrm{T}}^{\gamma}\right)$ and by the product of the photon identification efficiency ( $\varepsilon_{\mathrm{ID}}$, determined in Sec. VIB) and of the trigger efficiency relative to photon candidates passing the identification criteria ( $\varepsilon_{\text {trigger }}$, determined in Sec. VIC). The spectrum obtained this way, which depends on the reconstructed transverse energy of the photon candidates, is then corrected for detector energy resolution and energy scale effects using bin-by-bin correction factors (the "unfolding coefficients" $U$ ) evaluated using simulated samples. The corrected spectrum, which is then a function of the true photon energy, is divided by the photon reconstruction efficiency $\varepsilon_{\text {reco }}$ (Sec. VI A) and by the integrated luminosity of the data sample, $\int \mathcal{L} d t$.

The unfolding coefficients are evaluated from the ratio of the true to reconstructed $E_{\mathrm{T}}$ distributions of photon candidates, using PYTHIA isolated prompt photon simulated samples. This procedure is justified by the small bin-to-bin migrations (typically of the order of a few \%) that are expected, given the good electromagnetic calorimeter energy resolution compared to the width of the transverse energy intervals used in this analysis (between 5 and 40 GeV ). The values of the unfolding coefficients are slightly higher than 1 and decrease as a function of $E_{\mathrm{T}}$, approaching 1 . They differ from 1 by less then $2 \%$ in the $\left|\eta^{\gamma}\right|$ region between 0.0 and 0.6 , and by less than $5 \%-7 \%$ in the other two $\left|\eta^{\gamma}\right|$ regions, where more material upstream of the electromagnetic calorimeter is present.

## IX. SYSTEMATIC UNCERTAINTIES

Several sources of systematic uncertainties on the cross section are identified and evaluated as described in the following sections. The total systematic uncertainty is obtained by combining the various contributions, taking into account their correlations: uncorrelated uncertainties are summed in quadrature while a linear sum of correlated uncertainties is performed.

## A. Reconstruction, identification, trigger efficiencies

The systematic uncertainty on the reconstruction efficiency from the experimental isolation requirement is evaluated from the prompt photon simulation varying the value of the isolation criterion by the average difference (of the order of 500 MeV ) observed for electrons from $W$ and $Z$ decays in simulation and data. It is $2.5 \%$ in the pseudorapidity regions covered by the barrel calorimeter and $4.5 \%$ in the end-caps.

The systematic uncertainty on the identification efficiency due to the photon shower-shape corrections is divided into two parts. The first term evaluates the impact of treating the differences between the distributions of the shower-shape variables in data and simulation as an average shift. This uncertainty is evaluated in the following way:
(i) A modified description of the detector material is used to produce a second sample of simulated photon candidates. These candidates have different showershape distributions, due to the different amount of material upstream of and within the calorimeter. This alternative model contains an additional $10 \%$ of material in the inactive volumes of the inner detector and $10 \%$ of a radiation length in front of the electromagnetic calorimeter. This model is estimated to represent a conservative upper limit of the additional detector material that is not accounted for by the nominal simulation.
(ii) The correction procedure is applied to the nominal simulation to estimate the differences between the nominal and the alternative simulation. The shifts between the discriminating variable distributions in the nominal and the alternative simulation are eval-
uated, and are used to correct the shower-shape variable distributions of the nominal simulation.
(iii) The photon efficiency from the nominal simulation is recomputed after applying these corrections, and compared with the efficiency obtained from the alternative simulation.

The difference between the efficiency estimated from the nominal simulation (after applying the corrections) and the efficiency measured directly in the alternative sample (with no corrections) ranges from $3 \%$ at $E_{\mathrm{T}}^{\gamma} \sim 20 \mathrm{GeV}$ to less than $1 \%$ at $E_{\mathrm{T}}^{\gamma} \sim 80 \mathrm{GeV}$.

The second part of the systematic uncertainty on the identification efficiency accounts for the uncertainty on the extracted shower-shape correction factors. The correction factors were extracted by comparing tight photons in data and simulation; to evaluate the uncertainty associated with this choice, the same correction factors are extracted using loose photons. The difference in the final efficiency when applying the tight corrections and the loose corrections is then taken as the uncertainty. This uncertainty drops from $4 \%$ to $1 \%$ with increasing $E_{\mathrm{T}}^{\gamma}$.

Additional systematic uncertainties that may affect both the reconstruction and the identification efficiencies are evaluated simultaneously for the product of the two, to take into account possible correlations. These sources of uncertainty include the amount of material upstream of the calorimeter; the impact of pile-up; the relative fraction of direct and fragmentation photons in data with respect to simulation; the misidentification of a converted photon as unconverted; the difference between the PYTHIA and HERWIG simulation models; the impact of a sporadic faulty calibration of the cell energies in the electromagnetic calorimeter; and the imperfect simulation of acceptance losses due to inoperative readout links in the calorimeter.

Of all the uncertainties which contribute to this measurement, the largest ones come from the uncertainty on the amount of material upstream of the calorimeter (absolute uncertainties ranging between $1 \%$ and $8 \%$ and are larger at low $E_{\mathrm{T}}^{\gamma}$ ), and from the uncertainty on the identification efficiency due to the photon shower-shape corrections (the absolute uncertainties are in the range $1 \%-5 \%$, and are larger at low $E_{\mathrm{T}}^{\gamma}$ ).

The uncertainty on the trigger efficiency, evaluated as described in Sec. VIC, is $0.5 \%$ and is nearly negligible compared to all other sources.

## B. Signal yield estimates

The following sources of systematic uncertainties affecting the accuracy of the signal yield measurement using the two-dimensional sideband technique are considered.

## 1. Background isolation control region definition

The signal yield is evaluated after changing the isolation control region definition. The minimum value of $E_{\mathrm{T}}^{\text {iso }}$ re-
quired for candidates in the nonisolated control regions, which is set to 5 GeV in the nominal measurement, is changed to 4 and 6 GeV . This check is sensitive to uncertainties in the contribution of prompt photons from QED radiation from quarks: these photons are less isolated than those originating from the hard process. Alternative measurements are also performed where a maximum value of $E_{\mathrm{T}}^{\text {iso }}$ is set to 10 or 15 GeV for candidates in the nonisolated control regions, in order to reduce the correlation between the isolation variable and the shower-shape distributions seen in simulated events for candidates belonging to the upper tail of the isolation distribution. The largest positive and negative variations of the signal yield with respect to the nominal result are taken as systematic uncertainties. The signal photon fraction changes by at most $\pm 2 \%$ in all the transverse energy and pseudorapidity intervals.

## 2. Background photon identification control region definition

The measurement is repeated reversing the tight identification criteria on a number of strip variables ranging between two (only $F_{\text {side }}$ and $w_{s 3}$ ) and five (all the variables based on the first layer of the electromagnetic calorimeter). The largest positive and negative variations of the signal yield (with respect to the nominal result) from these three alternative measurements are taken as systematic uncertainties. The effect on the signal photon fraction decreases with increasing photon transverse energy, and is around $10 \%$ for $E_{\mathrm{T}}^{\gamma}$ between 15 and 20 GeV .

## 3. Signal leakage into the photon identification background control region

From the photon identification efficiency studies, an upper limit of $5 \%$ is set on the uncertainty on the fraction $c_{C}$ of signal photons passing all the tight photon identification criteria except those used to define the photon identification control region. The signal yields in each $E_{\mathrm{T}}^{\gamma},\left|\eta^{\gamma}\right|$ interval are thus measured again after varying the estimated signal contamination in the photon identification control regions ( $c_{C}$ and $c_{D} / c_{B}$ ) by this uncertainty, and the difference with the nominal result is taken as a systematic uncertainty. The signal fraction variations are always below $6 \%$.

## 4. Signal leakage into the isolation background control region

The fractions $c_{B}$ and $c_{D}$ of signal photons contaminating the isolation control regions depend on the relative amount of direct and fragmentation photons in the signal selected in a certain $E_{\mathrm{T}}^{\gamma},\left|\eta^{\gamma}\right|$ interval, since the latter are characterized by larger nearby activity, and therefore usually have slightly larger transverse isolation energies. In the nominal measurement, the values of $c_{B}$ and $c_{D}$ are computed with
the relative fractions of direct and fragmentation photons predicted by PYTHIA. A systematic uncertainty is assigned by repeating the measurement after varying these fractions between $0 \%$ and $100 \%$. The measured signal photon fraction varies by less than $5 \%$.

## 5. Signal photon simulation

The signal yield is estimated using samples of prompt photons simulated with HERWIG instead of PYTHIA to determine the fraction of signal leaking into the three background control regions. The variations of the signal photon fractions in each $E_{\mathrm{T}}^{\gamma},\left|\eta^{\gamma}\right|$ interval are below $2 \%$.

## 6. Correlations between the isolation and the photon identification variables for background candidates

Non-negligible correlations between the isolation variable and the photon identification quantities would affect Eq. (2): the true number of isolated tight prompt photon candidates would be

$$
\begin{equation*}
N_{A}^{\mathrm{sig}}=N_{A}-R^{\mathrm{bkg}}\left(N_{B}-c_{B} N_{A}^{\mathrm{sig}}\right) \frac{\left(N_{C}-c_{C} N_{A}^{\mathrm{sig}}\right)}{\left(N_{D}-c_{D} N_{A}^{\mathrm{sig}}\right)} \tag{4}
\end{equation*}
$$

where $R^{\mathrm{bkg}} \equiv \frac{N_{A}^{\mathrm{bkg}} N_{D}^{\mathrm{bkg}}}{N_{B}^{\mathrm{bg} \mathrm{g}} N_{C}^{\mathrm{bg}}}$ would then be different from unity. The simulation of background events shows a small but non-negligible correlation between the isolation and the discriminating shower-shape variables used to define the photon identification signal and background control regions. The signal yields are therefore recomputed with the formula in Eq. (4), using for $R^{\text {bkg }}$ the value predicted by the PYTHIA background simulation, and compared with the nominal results. The effect is smaller than $0.6 \%$ in the $\left|\eta^{\gamma}\right|<1.37$ intervals and around $3.6 \%$ for $1.52 \leq$ $\left|\eta^{\gamma}\right|<1.81$.

## 7. Transverse isolation energy corrections

The effects of the $E_{\mathrm{T}}^{\text {iso }}$ correction for the underlying event on the estimated signal yield are also investigated. The impact of this correction is evaluated by estimating the signal yield, with and without the correction applied, for events with only one reconstructed primary vertex (to eliminate any effects of pile-up). The estimated signal yields using the uncorrected values of $E_{\mathrm{T}}^{\text {iso }}$, normalized to the yields derived using the corrected values, show no trend in $E_{\mathrm{T}}^{\gamma}$ or $\eta$. Furthermore, the impact on the cross section of the event-by-event corrections is equivalent to that of an average correction of 540 MeV applied to the transverse isolation energies of all photon candidates. Similar studies in PYTHIA and HERWIG MC yield identical results.

## C. Unfolding coefficients

The unfolding coefficients used to correct the measured cross section for $E_{\mathrm{T}}$ bin-by-bin migrations are computed
using simulated samples. There are three sources of uncertainties on these coefficients.

## 1. Energy scale uncertainty

The uncertainty on the energy scale was estimated to be $\pm 3 \%$ in test beam studies [51], and is confirmed to be below this value from the comparison of the $Z \rightarrow e^{+} e^{-}$ invariant mass peak in data and Monte Carlo. The unfolding coefficients are thus recomputed using simulated signal events where the true photon energy is shifted by $\pm 3 \%$. The coefficients change by $\pm 10 \%$. This uncertainty introduces a relative uncertainty of about $10 \%$ on the measured cross section which is fully correlated between the different $E_{\mathrm{T}}^{\gamma}$ intervals within each pseudorapidity range.

## 2. Energy resolution uncertainty

The uncertainty on the energy resolution may affect bin-by-bin migrations between adjacent $E_{\mathrm{T}}$ bins. Test beam studies indicate that the sampling terms of the resolution in data and simulation have a relative difference within $20 \%$. Furthermore, studies of the $Z \rightarrow e^{+} e^{-}$invariant mass distribution in data indicate that the constant term of the calorimeter energy resolution is below $1.5 \%$ in the barrel and $3.0 \%$ in the end-cap (it is $0.7 \%$ in the simulation). The unfolding coefficients are thus recomputed after smearing the reconstructed energy of simulated photons to take into account a $20 \%$ relative increase of the sampling term and a constant term of $1.5 \%$ in the barrel and $3.0 \%$ in the endcap. The resulting variation of the unfolding coefficients is always less than $1 \%$. The uncertainty arising from nongaussian tails of the energy resolution function is estimated by recomputing the coefficients using a prompt photon simulation where a significant amount of material is added to the detector model. The variations of the unfolding coefficients are smaller than $1 \%$ in all the pseudorapidity and transverse energy intervals under study.

## 3. Simulated photon transverse energy distribution

The unfolding coefficients, computed in $E_{\mathrm{T}}^{\gamma}$ intervals of non-negligible size, depend on the initial $E_{\mathrm{T}}^{\gamma}$ distribution predicted by PYTHIA. An alternative unfolding technique [52] is therefore used, which relies on the repeated application of Bayes' theorem to iteratively obtain an improved estimate of the unfolded spectrum. This technique relies less on the simulated original $E_{\mathrm{T}}$ distribution of the prompt photons. The differences between the cross-sections estimated using the bin-by-bin unfolding and the iterative Bayesian unfolding are within $2 \%$, and are taken into account as an additional systematic uncertainty.

## D. Luminosity

The integrated luminosity is determined for each run by measuring interaction rates using several ATLAS subdetectors at small angles to the beam line, with the absolute
calibration obtained from beam position scans [53]. The relative systematic uncertainty on the luminosity measurement is estimated to be $11 \%$ and translates directly into an $11 \%$ relative uncertainty on the cross section.

## X. RESULTS AND DISCUSSION

The measured inclusive isolated prompt photon production cross sections $d \sigma / d E_{\mathrm{T}}^{\gamma}$ are shown in Fig. 8-10. They are presented as a function of the photon transverse energy, for each of the three considered pseudorapidity intervals. They are also presented in tabular form in Appendix B. The measurements extend from $E_{\mathrm{T}}^{\gamma}=15 \mathrm{GeV}$ to $E_{\mathrm{T}}^{\gamma}=$ 100 GeV spanning almost 3 orders of magnitude. The data are compared to NLO pQCD calculations, obtained with the JETPHOX program as described in Sec. IV. The error bars on the data points represent the combination of the statistical and systematic uncertainties (summed in quadrature): systematic uncertainties dominate over the whole considered kinematic range. The contribution from the luminosity uncertainty ( $11 \%$ ) is shown separately (dotted bands) as it represents a possible global offset of all the measurements. The total systematic uncertainties on the theoretical predictions are represented with a solid band. They are obtained by summing in quadrature the contributions from the scale uncertainty, the PDF uncertainty (at $68 \%$ C.L.) and the uncertainty associated with the choice of the parton-level isolation criterion. The same quantities are also shown, in the bottom panels of Fig. 8-10, after having been normalized to the expected NLO pQCD cross sections.

In general, the theoretical predictions agree with the measured cross sections for $E_{\mathrm{T}}^{\gamma}>25 \mathrm{GeV}$. For lower $E_{\mathrm{T}}$

FIG. 8 (color online). Measured (dots) and expected (full line) inclusive prompt photon production cross sections, as a function of the photon transverse energies above 15 GeV and in the pseudorapidity range $\left|\eta^{\gamma}\right|<0.6$. The bottom panel shows the ratio between the measurement and the theoretical prediction.

FIG. 9 (color online). Measured (dots) and expected (full line) inclusive prompt photon production cross sections, as a function of the photon transverse energies above 15 GeV and in the pseudorapidity range $0.6 \leq\left|\eta^{\gamma}\right|<1.37$. and in the two pseudorapidity regions $\left|\eta^{\gamma}\right|<0.6$ and $0.6 \leq\left|\eta^{\gamma}\right|<1.37$, the cross section predicted by JETPHOX is larger than that measured in data. Such low transverse energies at the LHC correspond to extremely small values of $x_{\mathrm{T}}=2 E_{\mathrm{T}}^{\gamma} / \sqrt{s}$, where NLO theoretical predictions are less accurate. In such a regime the appropriate values of the different scales are not clearly defined, and the uncertainties associated with these scales in the theoretical predictions may not be well modeled by simple

FIG. 10 (color online). Measured (dots) and expected (full line) inclusive prompt photon production cross sections, as a function of the photon transverse energies above 15 GeV and in the pseudorapidity range $1.52 \leq\left|\eta^{\gamma}\right|<1.81$. The bottom panel shows the ratio between the measurement and the theoretical prediction.
variations of any one scale about the default value of $E_{\mathrm{T}}^{\gamma}$ [54]. As the low- $E_{\mathrm{T}}^{\gamma}$ region is where the fragmentation component has the most significant contribution to the total cross section, the total uncertainty associated with the NLO predictions at low $E_{\mathrm{T}}^{\gamma}$ may be underestimated.

## XI. CONCLUSION

The inclusive isolated prompt photon production cross section in $p p$ collisions at a center-of-mass energy $\sqrt{s}=7 \mathrm{TeV}$ has been measured using $880 \mathrm{nb}^{-1}$ of $p p$ collision data collected by the ATLAS detector at the Large Hadron Collider.

The differential cross section has been measured as a function of the prompt photon transverse energy between 15 and 100 GeV , in the three pseudorapidity intervals $\left|\eta^{\gamma}\right|<0.6, \quad 0.6 \leq\left|\eta^{\gamma}\right|<1.37$ and $1.52 \leq\left|\eta^{\gamma}\right|<1.81$, estimating the background from the selected photon sample and using the photon identification efficiency measurement described in this paper. The photon identification using the fine granularity of the calorimeters. A photon isolation criterion is used, after an in situ subtraction of the effects of the underlying event that may also be applied to theoretical predictions.

The observed cross sections rapidly decrease as a function of the increasing photon transverse energy, spanning almost 3 orders of magnitude. The precision of the measurement is limited by its systematic uncertainty, which receives important contributions from the energy scale uncertainty, the luminosity, the photon identification efficiency, and the uncertainty on the residual background contamination in the selected photon sample.

The NLO pQCD predictions agree with the observed cross sections for transverse energies greater than 25 GeV , while for transverse energies below 25 GeV the cross sections predicted by JETPHOX are higher than measured. However, the precision of this comparison below 25 GeV is limited by large systematic uncertainties on the measurement and on the theoretical predictions at such low values of $x_{\mathrm{T}}=2 E_{\mathrm{T}}^{\gamma} / \sqrt{s}$.

The measured prompt photon production cross section is more than a factor of 30 larger than that measured at the Tevatron, and a factor of $10^{4}$ larger than for photoproduction at HERA, assuming a similar kinematic range in transverse energy and pseudorapidity. This will allow the extension of the measurement up to energies in the TeV range after only a few years of data-taking at the LHC.

## ACKNOWLEDGMENTS

We wish to thank CERN for the efficient commissioning and operation of the LHC during this initial high-energy data-taking period as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF,

Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular, from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CCIN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

## APPENDIX A: DEFINITION OF PHOTON IDENTIFICATION DISCRIMINATING VARIABLES

In this Appendix, the quantities used in the selection of photon candidates, based on the reconstructed energy deposits in the ATLAS calorimeters, are summarized.
(1) Leakage in the hadronic calorimeter

The following discriminating variable is defined, based on the energy deposited in the hadronic calorimeter:
(a) Normalized hadronic leakage

$$
\begin{equation*}
R_{\mathrm{had}}=\frac{E_{\mathrm{T}}^{\mathrm{had}}}{E_{\mathrm{T}}} \tag{A1}
\end{equation*}
$$

is the total transverse energy $E_{\mathrm{T}}^{\text {had }}$ deposited in the hadronic calorimeter, normalized to the total transverse energy $E_{\mathrm{T}}$ of the photon candidate.

In the $|\eta|$ interval between 0.8 and 1.37 the energy deposited in the whole hadronic calorimeter is used, while in the other pseudorapidity intervals only the leakage in the first layer of the hadronic calorimeter is used.
(2) Variables using the second ("middle") layer of the electromagnetic calorimeter
The discriminating variables based on the energy deposited in the second layer of the electromagnetic calorimeter are the following:
(a) Middle $\eta$ energy ratio

$$
\begin{equation*}
R_{\eta}=\frac{E_{3 \times 7}^{S 2}}{E_{7 \times 7}^{S 2}} \tag{A2}
\end{equation*}
$$

is the ratio between the sum $E_{3 \times 7}^{S 2}$ of the energies of the second layer cells of the electromagnetic calorimeter contained in a $3 \times 7$ rectangle in $\eta \times \phi$ (measured in cell units), and the sum $E_{7 \times 7}^{S 2}$ of the energies in a $7 \times 7$ rectangle, both centered around the cluster seed.
(b) Middle $\phi$ energy ratio

$$
\begin{equation*}
R_{\phi}=\frac{E_{3 \times 3}^{S 2}}{E_{3 \times 7}^{S 2}} \tag{A3}
\end{equation*}
$$

is defined similarly to $R_{\eta}$. $R_{\phi}$ behaves very differently for unconverted and converted photons, since the electrons and positrons generated by the latter bend in different directions in $\phi$ because of the solenoid magnetic field, producing larger showers in the $\phi$ direction than the unconverted photons.
(c) Middle lateral width

$$
\begin{equation*}
w_{2}=\sqrt{\frac{\sum E_{i} \eta_{i}^{2}}{\sum E_{i}}-\left(\frac{\sum E_{i} \eta_{i}}{\sum E_{i}}\right)^{2}} \tag{A4}
\end{equation*}
$$

measures the shower lateral width in the second layer of the electromagnetic calorimeter, using all cells in a window $\eta \times \phi=3 \times 5$ measured in cell units.
(3) Variables using the first ("front") layer of the electromagnetic calorimeter
The discriminating variables based on the energy deposited in the first layer of the electromagnetic calorimeter are the following:
(a) Front side energy ratio

$$
\begin{equation*}
F_{\text {side }}=\frac{E( \pm 3)-E( \pm 1)}{E( \pm 1)} \tag{A5}
\end{equation*}
$$

measures the lateral containment of the shower, along the $\eta$ direction. $E( \pm n)$ is the energy in the $\pm n$ strip cells around the one with the largest energy.
(b) Front lateral width (3 strips)

$$
\begin{equation*}
w_{s, 3}=\sqrt{\frac{\sum E_{i}\left(i-i_{\max }\right)^{2}}{\sum E_{i}}} \tag{A6}
\end{equation*}
$$

measures the shower width along $\eta$ in the first layer of the electromagnetic calorimeter, using two strip cells around the maximal energy deposit. The index $i$ is the strip identification number, $i_{\text {max }}$ identifies the strip cells with the greatest energy, $E_{i}$ is the energy deposit in each strip cell.
(c) Front lateral width (total)
$w_{s, \text { tot }}$ measures the shower width along $\eta$ in the first layer of the electromagnetic calorimeter using all

TABLE III. The measured isolated prompt photon production cross section, for $0.00 \leq\left|\eta^{\gamma}\right|<0.60$. cells in a window $\Delta \eta \times \Delta \phi=0.0625 \times 0.2$, corresponding approximately to $20 \times 2$ strip cells in $\eta \times \phi$, and is computed as $w_{s, 3}$.
(d) Front second maximum difference.

$$
\begin{equation*}
\Delta E=\left[E_{2^{\text {nd }} \max }^{S 1}-E_{\min }^{S 1}\right] \tag{A7}
\end{equation*}
$$

is the difference between the energy of the strip cell with the second greatest energy $E_{2^{\text {nd }} \text { max }}^{S 1}$, and the energy in the strip cell with the least energy found between the greatest and the second greatest energy $E_{\min }^{S 1}(\Delta E=0$ when there is no second maximum).
(e) Front maxima relative ratio
measures the relative difference between the energy of the strip cell with the greatest energy $E_{1^{\text {st }} \max }^{S 1}$ and the energy in the strip cell with second greatest energy $E_{2^{\text {nd }} \max }^{\text {n }^{1}}$ ( 1 when there is no second maximum).

## APPENDIX B: CROSS SECTION MEASUREMENTS

Table III, IV, and V list the values of the measured isolated prompt photon production cross sections, for the $0.00 \leq\left|\eta^{\gamma}\right|<0.60,0.60 \leq\left|\eta^{\gamma}\right|<1.37$ and $1.52 \leq$ $\left|\eta^{\gamma}\right|<1.81$ regions, respectively. The various systematic uncertainties originating from the purity measurement, the photon selection and identification efficiency, the photon energy scale and the luminosity are shown. The total uncertainty includes both the statistical and all systematic uncertainties, except for the uncertainty on the luminosity.

[13] The ATLAS reference system is a Cartesian right-handed coordinate system, with the nominal collision point at the origin. The anticlockwise beam direction defines the positive $z$-axis, while the positive $x$-axis is defined as pointing from the collision point to the center of the LHC ring and the positive $y$-axis points upwards. The azimuthal angle $\phi$ is measured around the beam axis, and the polar angle $\theta$ is measured with respect to the $z$-axis. Pseudorapidity is defined as $\eta=-\ln \tan (\theta / 2)$, and transverse energy is defined as $E_{\mathrm{T}}=E \sin \theta$.

# Measurement of the isolated diphoton cross section in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS detector 

G. Aad et al.*<br>(ATLAS Collaboration)

(Received 4 July 2011; published 11 January 2012)

#### Abstract

The ATLAS experiment has measured the production cross section of events with two isolated photons in the final state, in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$. The full data set acquired in 2010 is used, corresponding to an integrated luminosity of $37 \mathrm{pb}^{-1}$. The background, consisting of hadronic jets and isolated electrons, is estimated with fully data-driven techniques and subtracted. The differential cross sections, as functions of the di-photon mass ( $m_{\gamma \gamma}$ ), total transverse momentum ( $p_{\mathrm{T}, \gamma \gamma}$ ), and azimuthal separation $\left(\Delta \phi_{\gamma \gamma}\right)$, are presented and compared to the predictions of next-to-leading-order QCD.

## I. INTRODUCTION

The production of di-photon final states in protonproton collisions may occur through quark-antiquark $t$-channel annihilation, $q \bar{q} \rightarrow \gamma \gamma$, or via gluon-gluon interactions, $g g \rightarrow \gamma \gamma$, mediated by a quark box diagram. Despite the higher order of the latter, the two contributions are comparable, due to the large gluon flux at the LHC. Photon-parton production with photon radiation also contributes in processes such as $q \bar{q}, g g \rightarrow g \gamma \gamma$, and $q g \rightarrow q \gamma \gamma$. During the parton fragmentation process, more photons may also be produced. In this analysis, all such photons are considered as signal if they are isolated from other activity in the event. Photons produced after the hadronization by neutral hadron decays, or coming from radiative decays of other particles, are considered as part of the background.

The measurement of the di-photon production crosssection at the LHC is of great interest as a probe of QCD, especially in some particular kinematic regions. For instance, the distribution of the azimuthal separation, $\Delta \phi_{\gamma \gamma}$, is sensitive to the fragmentation model, especially when both photons originate from fragmentation. On the other hand, for balanced back-to-back di-photons ( $\Delta \phi_{\gamma \gamma} \simeq$ $\pi$ and small total transverse momentum, $p_{\mathrm{T}, \gamma \gamma}$ ) the production is sensitive to soft gluon emission, which is not accurately described by fixed-order perturbation theory.

Di-photon production is also an irreducible background for some new physics processes, such as the Higgs decay into photon pairs [1]: in this case, the spectrum of the invariant mass, $m_{\gamma \gamma}$, of the pair is analyzed, searching for a resonance. Moreover, di-photon production is a

characteristic signature of some exotic models beyond the standard model. For instance, universal extra dimensions predict nonresonant di-photon production associated with significant missing transverse energy [2,3]. Other extra-dimension models, such as Randall-Sundrum [4], predict the production of gravitons, which would decay into photon pairs with a narrow width.

Recent cross-section measurements of di-photon production at hadron colliders have been performed by the D0 [5] and CDF [6] collaborations, at the Tevatron protonantiproton collider with a center-of-mass energy $\sqrt{s}=$ 1.96 TeV .

In this document, di-photon production is studied in proton-proton collisions at the LHC, with a center-ofmass energy $\sqrt{s}=7 \mathrm{TeV}$. After a short description of the ATLAS detector (Sec. II), the analyzed collision data and the event selection are detailed in Sec. III, while the supporting simulation samples are listed in Sec. IV. The isolation properties of the signal and of the hadronic background are studied in Sec. V. The evaluation of the di-photon signal yield is obtained by subtracting the backgrounds from hadronic jets and from isolated electrons, estimated with data-driven methods as explained in Sec. VI. Section VII describes how the event selection efficiency is evaluated and how the final yield is obtained. Finally, in Sec. VIII, the differential cross-section of diphoton production is presented as a function of $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}$, and $\Delta \phi_{\gamma \gamma}$.

## II. THE ATLAS DETECTOR

The ATLAS detector [7] is a multipurpose particle physics apparatus with a forward-backward symmetric cylindrical geometry and near $4 \pi$ coverage in solid angle. ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the $z$ axis along the beam pipe. The $x$ axis points from the IP to the center of the LHC ring, and the $y$ axis points upward. Cylindrical coordinates $(r, \phi)$ are
used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln [\tan (\theta / 2)]$. The transverse momentum is defined as $p_{T}=p \sin \theta=$ $p / \cosh \eta$, and a similar definition holds for the transverse energy $E_{\mathrm{T}}$.

The inner tracking detector (ID) covers the pseudorapidity range $|\eta|<2.5$ and consists of a silicon pixel detector, a silicon microstrip detector, and a transition radiation tracker in the range $|\eta|<2.0$. The ID is surrounded by a superconducting solenoid providing a 2 T magnetic field. The inner detector allows an accurate reconstruction of tracks from the primary proton-proton collision region and also identifies tracks from secondary vertices, permitting the efficient reconstruction of photon conversions in the inner detector up to a radius of $\approx 80 \mathrm{~cm}$.

The electromagnetic calorimeter (ECAL) is a leadliquid argon (LAr) sampling calorimeter with an accordion geometry. It is divided into a barrel section, covering the pseudorapidity region $|\eta|<1.475$, and two endcap sections, covering the pseudorapidity regions $1.375<|\eta|<$ 3.2. It consists of three longitudinal layers. The first one, in the ranges $|\eta|<1.4$ and $1.5<|\eta|<2.4$, is segmented into high granularity "strips" in the $\eta$ direction, sufficient to provide an event-by-event discrimination between single photon showers and two overlapping showers coming from a $\pi^{0}$ decay. The second layer of the electromagnetic calorimeter, which collects most of the energy deposited in the calorimeter by the photon shower, has a thickness of about 17 radiation lengths and a granularity of $0.025 \times 0.025$ in $\eta \times \phi$ (corresponding to one cell). A third layer is used to correct leakage beyond the ECAL for high-energy showers. In front of the accordion calorimeter a thin presampler layer, covering the pseudorapidity interval $|\eta|<1.8$, is used to correct for energy loss before the calorimeter.

The hadronic calorimeter (HCAL), surrounding the ECAL, consists of an iron-scintillator tile calorimeter in the range $|\eta|<1.7$ and two copper-LAr calorimeters spanning $1.5<|\eta|<3.2$. The acceptance is extended by two tungsten-LAr forward calorimeters up to $|\eta|<4.9$. The muon spectrometer, located beyond the calorimeters, consists of three large air-core superconducting toroid systems, precision tracking chambers providing accurate muon tracking over $|\eta|<2.7$, and fast detectors for triggering over $|\eta|<2.4$.

A three-level trigger system is used to select events containing two photon candidates. The first level trigger (level-1) is hardware based: using a coarser cell granularity ( $0.1 \times 0.1$ in $\eta \times \phi$ ), it searches for electromagnetic deposits with a transverse energy above a programmable threshold. The second and third level triggers (collectively referred to as the "high-level" trigger) are implemented in software and exploit the full granularity and energy calibration of the calorimeter.

## III. COLLISION DATA AND SELECTIONS

The analyzed data set consists of proton-proton collision data at $\sqrt{s}=7 \mathrm{TeV}$ collected in 2010, corresponding to an integrated luminosity of $37.2 \pm 1.3 \mathrm{pb}^{-1}$ [8]. The events are considered only when the beam condition is stable and the trigger system, the tracking devices, and the calorimeters are operational.

## A. Photon reconstruction

A photon is defined starting from a cluster in the ECAL. If there are no tracks pointing to the cluster, the object is classified as an unconverted photon. In case of converted photons, one or two tracks may be associated to the cluster, thereby creating an ambiguity in the classification with respect to electrons. This is addressed as described in Ref [9].

A fiducial acceptance is required in pseudorapidity, $\left|\eta^{\gamma}\right|<2.37$, with the exclusion of the barrel/endcap transition $1.37<\left|\eta^{\gamma}\right|<1.52$. This corresponds to the regions where the ECAL strips granularity is more effective for photon identification and jet background rejection [9]. Moreover, photons reconstructed near to regions affected by readout or high-voltage failures are not considered.

In the considered acceptance range, the uncertainty on the photon energy scale is estimated to be $\sim \pm 1 \%$. The energy resolution is parametrized as $\sigma_{E} / E \simeq a / \sqrt{E[\mathrm{GeV}]}$ $\oplus c$, where the sampling term $a$ varies between $10 \%$ and $20 \%$ depending on $\eta^{\gamma}$, and the constant term $c$ is estimated to be $1.1 \%$ in the barrel and $1.8 \%$ in the endcap. Such a performance has been measured in $Z \rightarrow e^{+} e^{-}$events observed in proton-proton collision data in 2010.

## B. Photon selection

The photon sample suffers from a major background due to hadronic jets, which generally produce calorimetric deposits broader and less isolated than electromagnetic showers, with sizable energy leaking to the HCAL. Most of the background is reduced by applying requirements (referred to as the LOOSE selection, $\mathbf{L}$ ) on the energy fraction measured in the HCAL, and on the shower width measured by the second layer of the ECAL. The remaining background is mostly due to photon pairs from neutral hadron decays (mainly $\pi^{0}$ ) with a small opening angle and reconstructed as single photons. This background is further reduced by applying a more stringent selection on the shower width in the second ECAL layer, together with additional requirements on the shower shape measured by the first ECAL layer: a narrow shower width and the absence of a second significant maximum in the energy deposited in contiguous strips. The combination of all these requirements is referred to as the TIGHT selection (T). Since converted photons tend to have broader shower shapes than unconverted ones, the cuts of the TIGHT selection are tuned differently for the two photon categories.

More details on these selection criteria are given in Ref. [10].

To reduce the jet background further, an isolation requirement is applied: the isolation transverse energy $E_{\mathrm{T}}^{\text {iso }}$, measured by the calorimeters in a cone of angular radius $R=\sqrt{\left(\eta-\eta^{\gamma}\right)^{2}+\left(\phi-\phi^{\gamma}\right)^{2}}<0.4$, is required to satisfy $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$ (isolated photon, $\mathbf{I}$ ). The calculation of $E_{\mathrm{T}}^{\text {iso }}$ is performed summing over ECAL and HCAL cells surrounding the photon candidate, after removing a central core that contains most of the photon energy. An out-ofcore energy correction [10] is applied, to make $E_{\mathrm{T}}^{\text {iso }}$ essentially independent of $E_{\mathrm{T}}^{\gamma}$, and an ambient energy correction, based on the measurement of soft jets [11,12] is applied on an event-by-event basis, to remove the contribution from the underlying event and from additional proton-proton interactions ("in-time pile-up").

## C. Event selection

The di-photon candidate events are selected according to the following steps:
(i) The events are selected by a di-photon trigger, in which both photon candidates must satisfy the trigger selection and have a transverse energy $E_{\mathrm{T}}^{\gamma}>$ 15 GeV . To select genuine collisions, at least one primary vertex with three or more tracks must be reconstructed.
(ii) The event must contain at least two photon candidates, with $E_{\mathrm{T}}^{\gamma}>16 \mathrm{GeV}$, in the acceptance defined in Sec. III A and passing the LOOSE selection. If more than two such photons exist, the two with highest $E_{\mathrm{T}}^{\gamma}$ are chosen.
(iii) To avoid a too large overlap between the two isolation cones, an angular separation $\Delta R_{\gamma \gamma}=$ $\sqrt{\left(\eta_{1}^{\gamma}-\eta_{2}^{\gamma}\right)^{2}+\left(\phi_{1}^{\gamma}-\phi_{2}^{\gamma}\right)^{2}}>0.4$ is required.
(iv) Both photons must satisfy the TIGHT selection (TT sample).
(v) Both photons must satisfy the isolation requirement $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$ (TITI sample).

In the analyzed data set, there are 63673 events where both photons satisfy the LOOSE selection and the $\Delta R_{\gamma \gamma}$ separation requirement. Among these, 5365 events belong to the TT sample, and 2022 to the TITI sample.

## IV. SIMULATED EVENTS

The characteristics of the signal and background events are investigated with Monte Carlo samples, generated using PYTHIA 6.4.21 [13]. The simulated samples are generated with pile-up conditions similar to those under which most of the data were taken. Particle interactions with the detector materials are modeled with GEANT4 [14] and the detector response is simulated. The events are reconstructed with the same algorithms used for collision data.

More details on the event generation and simulation infrastructure are provided in Ref [15].

The di-photon signal is generated with PYTHIA, where photons from both hard scattering and quark bremsstrahlung are modeled. To study systematic effects due to the generator model, an alternative di-photon sample has been produced with SHERPA [16].

The background processes are generated with the main physical processes that produce (at least) two sizable calorimetric deposits: these include di-jet and photon-jet final states, but minor contributions, e.g. from $W, Z$ bosons, are also present. Such a Monte Carlo sample, referred to as "di-jet-like," provides a realistic mixture of the main final states expected to contribute to the selected data sample. Moreover, dedicated samples of $W \rightarrow e \nu$ and $Z \rightarrow e^{+} e^{-}$ simulated events are used for the electron/photon comparison in isolation and background studies.

## V. PROPERTIES OF THE ISOLATION TRANSVERSE ENERGY

The isolation transverse energy, $E_{\mathrm{T}}^{\text {iso }}$, is a powerful discriminating variable to estimate the jet background contamination in the sample of photon candidates. The advantage of using this quantity is that its distribution can be extracted directly from the observed collision data, both for the signal and the background, without relying on simulations.

Section VA describes a method to extract the distribution of $E_{\mathrm{T}}^{\text {iso }}$ for background and signal, from observed photon candidates. An independent method to extract the signal $E_{\mathrm{T}}^{\text {iso }}$ distribution, based on observed electrons, is described in Sec. V B. Finally, the correlation between isolation energies in events with two photon candidates is discussed in Sec. V C.

## A. Background and signal isolation from photon candidates

For the background study, a control sample is defined by reconstructed photons that fail the TIGHT selection but pass a looser one, where some cuts are released on the shower shapes measured by the ECAL strips. Such photons are referred to as NONTIGHT. A study carried out on the "di-jet-like" Monte Carlo sample shows that the $E_{\mathrm{T}}^{\text {iso }}$ distribution in the NONTIGHT sample reproduces that of the background, as shown in Fig. 1(a).

The TIGHT photon sample contains a mixture of signal and background. However, a comparison between the shapes of the $E_{\mathrm{T}}^{\text {iso }}$ distributions from TIGHT and NONTIGHT samples [Fig. 1(b)] shows that for $E_{\mathrm{T}}^{\text {iso }}>7 \mathrm{GeV}$ there is essentially no signal in the TIGHT sample. Therefore, the background contamination in the TIGHT sample can be subtracted by using the NONTIGHT sample, normalized such that the integrals of the two distributions are equal for $E_{\mathrm{T}}^{\text {iso }}>7 \mathrm{GeV}$. The $E_{\mathrm{T}}^{\text {iso }}$ distribution of the signal alone

FIG. 1 (color online). Extraction of the isolation energy ( $E_{\mathrm{T}}^{\text {iso }}$ ) distributions for signal and background. The plots are made with a "di-jet-like" Monte Carlo sample: the "signal" and "background" classifications are based on the Monte Carlo information. (a) Normalized $E_{\mathrm{T}}^{\text {iso }}$ distribution for the background and for the NONTIGHT sample. (b) $E_{\mathrm{T}}^{\text {iso }}$ distribution, for the TIGHT and the nontight samples: the latter is scaled as explained in the text. (c) Normalized $E_{\mathrm{T}}^{\text {iso }}$ distribution for the signal and for the TIGHT sample, after subtracting the scaled NONTIGHT sample. In ( $\mathrm{a}, \mathrm{c}$ ) the vertical line shows the isolation cut $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$.
is thus extracted. Figure 1(c) shows the result, for photons in the "di-jet-like" Monte Carlo sample.

In collision data, events with two photon candidates are used to build the TIGHT and NONTIGHT samples, for the leading and subleading candidate separately. The points in Fig. 2 display the distribution of $E_{\mathrm{T}}^{\text {iso }}$ for the leading and subleading photons. In each of the two distributions, one bin has higher content, reflecting opposing fluctuations in the subtracted input distributions in those bins. The effect on the di-photon cross-section measurement is negligible.

The main source of systematic error comes from the definition of the NONTIGHT control sample. There are three sets of strips cuts that could be released: the first set concerns the shower width in the core, the second tests for the presence of two maxima in the cluster, and the third is a cut on the full shower width in the strips. The choice adopted is to release only the first two sets of cuts, as the best compromise between maximizing the statistics in the control sample, while keeping the background $E_{\mathrm{T}}^{\text {iso }}$ distribution fairly unbiased. To test the effect of this choice, the sets of released cuts have been changed, either by releasing only the cuts on the shower core width in the strips, or by releasing all the strips cuts. A minor effect is also due to the choice of the region $E_{\mathrm{T}}^{\text {iso }}>7 \mathrm{GeV}$, to normalize the

FIG. 2 (color online). Data-driven signal isolation distributions for the leading (top) and subleading (bottom) photons obtained using the photon candidates (solid circles) or extrapolated from electrons (continuous lines).

NONTIGHT control sample: the cut has therefore been moved to 6 and 8 GeV .

More studies with the "di-jet-like" Monte Carlo sample have been performed, to test the robustness of the $E_{\mathrm{T}}^{\text {iso }}$ extraction against model-dependent effects such as (i) signal leakage into the NONTIGHT sample; (ii) correlations between $E_{\mathrm{T}}^{\text {iso }}$ and strips cuts; (iii) different signal composition, i.e. fraction of photons produced by the hard scattering or by the fragmentation process; (iv) different background composition, i.e. fraction of photon pairs from $\pi^{0}$ decays. In all cases, the overall systematic error, computed as described above, covers the differences between the true and data-driven results as evaluated from these Monte Carlo tests.

## B. Signal isolation from electron extrapolation

An independent method of extracting the $E_{\mathrm{T}}^{\text {iso }}$ distribution for the signal photons is provided by the "electron extrapolation." In contrast to photons, it is easy to select a pure electron sample from data, from $W^{ \pm} \rightarrow e^{ \pm} \nu$ and $Z \rightarrow$ $e^{+} e^{-}$events [17]. The main differences between the
electron and photon $E_{\mathrm{T}}^{\text {iso }}$ distributions are (i) the electron $E_{\mathrm{T}}^{\mathrm{iso}}$ in the bulk of the distribution is slightly larger, because of bremsstrahlung in the material upstream of the calorimeter; (ii) the photon $E_{\mathrm{T}}^{\text {iso }}$ distribution exhibits a larger tail because of the contribution of the photons from fragmentation, especially for the subleading photon. Such differences are quantified with $W^{ \pm} \rightarrow e^{ \pm} \nu, Z \rightarrow e^{+} e^{-}$, and $\gamma \gamma$ Monte Carlo samples by fitting the $E_{\mathrm{T}}^{\text {iso }}$ distributions with crystal ball functions [18] and comparing the parameters. Then, the electron/photon differences are propagated to the selected electrons from collision data. The result is shown by the continuous lines in Fig. 2, agreeing well with the $E_{\mathrm{T}}^{\text {iso }}$ distributions obtained from the NONTIGHT sample subtraction (circles).

## C. Signal and background isolation in events with two photon candidates

In events with two photon candidates, possible correlations between the two isolation energies have been investigated by studying the signal and background $E_{\mathrm{T}}^{\text {iso }}$ distributions of a candidate ("probe") under different isolation conditions of the other candidate ("tag"). The signal $E_{\mathrm{T}}^{\text {iso }}$ shows negligible dependence on the tag conditions. In contrast, the background $E_{\mathrm{T}}^{\mathrm{iso}}$ exhibits a clear positive correlation with the isolation transverse energy of the tag: if the tag passes (or fails) the isolation requirement, the probe background candidate is more (or less) isolated. This effect is visible especially in di-jet final states, which can be directly studied in collision data by requiring both photon candidates to be NONTIGHT, and is taken into account in the jet background estimation (Sec. VI A).

This correlation is also visible in the "di-jet-like" Monte Carlo sample.

## VI. BACKGROUND SUBTRACTION AND SIGNAL YIELD DETERMINATION

The main background to selected photon candidates consists of hadronic jets. This is reduced by the photon TIGHT selection described in Sec. III B. However a significant component is still present and must be subtracted. The techniques to achieve this are described in Sec. VI A.

Another sizable background component comes from isolated electrons, mainly originating from $W$ and $Z$ decays, which look similar to photons from the calorimetric point of view. The subtraction of such a contamination is addressed in Sec. VIB.

The background due to cosmic rays and to beam-gas collisions has been studied on dedicated data sets, selected by special triggers. Its impact is found to be negligible.

## A. Jet background

The jet background is due to photon-jet and di-jet final states. This section describes three methods, all based on
the isolation transverse energy, $E_{\mathrm{T}}^{\text {iso }}$, aiming to separate the TITI sample into four categories:

FIG. 3 (color online). Differential $\gamma \gamma$ yields in the TITI sample ( $N_{\gamma \gamma}^{\text {TITI }}$ ), as a function of the three observables $m_{\gamma \gamma}$, $p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$, obtained with the three methods. In each bin, the yield is divided by the bin width. The vertical error bars display the total errors, accounting for both the statistical uncertainties and the systematic effects. The points are artificially shifted horizontally, to better display the three results.
according to their physical final states- $\gamma \mathrm{j}$ and $\mathrm{j} \gamma$ differ by the jet faking, respectively, the subleading or the leading photon candidate. The signal yield $N_{\gamma \gamma}^{\text {TITI }}$ is evaluated in bins of the three observables $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$, as in Fig. 3. Because of the dominant back-to-back topology of di-photon events, the kinematic selection produces a turnon in the distribution of the di-photon invariant mass, at $m_{\gamma \gamma} \gtrsim 2 E_{\mathrm{T}}^{\text {cut }}$ ( $E_{\mathrm{T}}^{\text {cut }}=16 \mathrm{GeV}$ being the applied cut on the photon transverse energy), followed by the usual decrease typical of the continuum processes. The region at lower $m_{\gamma \gamma}$ is populated by di-photon events with low $\Delta \phi$.

The excess in the mass bin $80<m_{\gamma \gamma}<100 \mathrm{GeV}$, due to a contamination of electrons from Z-decays, is addressed in Sec. VI B.

From the evaluation of the background yields $\left(N_{\gamma \mathrm{j}}^{\text {TITI }}+\right.$ $N_{\mathrm{j} \gamma}^{\mathrm{TITI}}$ and $\left.N_{\mathrm{jj}}^{\mathrm{TITI}}\right)$, the average fractions of photon-jet and di-jet events in the TITI sample are $\sim 26 \%$ and $\sim 9 \%$, respectively.

The three results shown in Fig. 3 are compatible. This suggests that there are no hidden biases induced by the analyses. However, the three measures cannot be combined, as all make use of the same quantities- $E_{\mathrm{T}}^{\text {iso }}$ and shower shapes-and use the NONTIGHT background control region, so they may have correlations. None of the methods has striking advantages with respect to the others, and the systematic uncertainties are comparable. The "event weighting" method (Sec. VI A 1) is used for the crosssection evaluation, since it provides event weights that are also useful in the event efficiency evaluation, and its sources of systematic uncertainties are independent of those related to the signal modelling and reconstruction.

$$
\left(\begin{array}{cc}
\epsilon_{1} \epsilon_{2} & \epsilon_{1} f_{2} \\
\epsilon_{1}\left(1-\epsilon_{2}\right) & \epsilon_{1}\left(1-f_{2}\right) \\
\left(1-\epsilon_{1}\right) \epsilon_{2} & \left(1-\epsilon_{1}\right) f_{2} \\
\left(1-\epsilon_{1}\right)\left(1-\epsilon_{2}\right) & \left(1-\epsilon_{1}\right)\left(1-f_{2}\right)
\end{array}\right.
$$

where $\epsilon_{i}$ and $f_{i}(i=1,2$ for the leading/subleading candidate) are the probabilities that a signal or a fake photon, respectively, pass the isolation cut. These are obtained from the $E_{\mathrm{T}}^{\text {iso }}$ distributions extracted from collision data, as described in Sec. VA. The value of $\epsilon$ is essentially independent of $E_{\gamma}$ and changes with $\eta^{\gamma}$, ranging between $80 \%$ and $95 \%$. The value of $f$ depends on both $E_{\mathrm{T}}$ and $\eta$ and takes values between $20 \%$ and $40 \%$. Given such dependence on the kinematics, the matrix $\mathbf{E}^{(k)}$ is also evaluated for each event.

Because of the presence of correlation, the matrix coefficients in Eq. (2) actually involve conditional probabilities, depending on the pass/fail status of the other candidate (tag) of the pair. For instance, the first two coefficients in the last column become

## 1. Event weighting

Each event satisfying the TIGHT selection on both photons (sample TT) is classified according to whether the photons pass or fail the isolation requirement, resulting in a PP, PF, FP, or FF classification. These are translated into four event weights $W_{\gamma \gamma}, W_{\gamma \mathrm{j}}, W_{\mathrm{j} \gamma}, W_{\mathrm{jj}}$, which describe how likely the event is to belong to each of the four final states. A similar approach has already been used by the D0 [5] and CDF [6] collaborations.

The connection between the pass/fail outcome and the weights, for the $k$-th event, is:

$$
\left(\begin{array}{c}
S_{\mathrm{PP}}^{(k)}  \tag{1}\\
S_{\mathrm{PF}}^{(k)} \\
S_{\mathrm{FP}}^{(k)} \\
S_{\mathrm{FF}}^{(k)}
\end{array}\right)=\mathbf{E}^{(k)}\left(\begin{array}{c}
W_{\gamma \gamma}^{(k)} \\
W_{\gamma j}^{(k)} \\
W_{\mathrm{j} \gamma}^{(k)} \\
W_{\mathrm{jj}}^{(k)}
\end{array}\right) .
$$

If applied to a large number of events, the quantities $S_{X Y}$ would be the fractions of events satisfying each pass/fail classification, and the weights would be the fractions of events belonging to the four different final states. On an event-by-event approach, $S_{X Y}^{(k)}$ are boolean status variables (e.g. for an event where both candidates are isolated, $S_{\mathrm{PP}}^{(k)}=$ 1 and $S_{\mathrm{PF}}^{(k)}=S_{\mathrm{FP}}^{(k)}=S_{\mathrm{FF}}^{(k)}=0$ ). The quantity $\mathbf{E}^{(k)}$ is a $4 \times 4$ matrix, whose coefficients give the probability that a given final state produces a certain pass/fail status. If there were no correlation between the isolation transverse energies of the two candidates, it would have the form
$\left.\begin{array}{cc}f_{1} \epsilon_{2} & f_{1} f_{2} \\ f_{1}\left(1-\epsilon_{2}\right) & f_{1}\left(1-f_{2}\right) \\ \left(1-f_{1}\right) \epsilon_{2} & \left(1-f_{1}\right) f_{2} \\ \left(1-f_{1}\right)\left(1-\epsilon_{2}\right) & \left(1-f_{1}\right)\left(1-f_{2}\right)\end{array}\right)$,

$$
\begin{aligned}
f_{1} f_{2} & \rightarrow \frac{1}{2}\left[f_{1}^{\hat{\mathrm{P}}} f_{2}+f_{1} f_{2}^{\hat{\mathrm{P}}}\right] \\
f_{1}\left(1-f_{2}\right) & \rightarrow \frac{1}{2}\left[f_{1}^{\hat{\mathrm{P}}}\left(1-f_{2}\right)+f_{1}\left(1-f_{2}^{\hat{\mathrm{P}}}\right)\right]
\end{aligned}
$$

where the superscripts $\hat{P}$ and $\hat{F}$ denote the pass/fail status of the tag. The ambiguity in the choice of the tag is solved by taking both choices and averaging them. All the conditional $\left(\epsilon_{i}^{\hat{P}, \hat{F}}, f_{i}^{\hat{\mathrm{P}}, \hat{\mathrm{F}}}\right)$ probabilities are derived from collision data, as discussed in Sec. V C.

The signal yield in the TITI sample can be computed as a sum of weights running over all events in the TT sample:

$$
\begin{equation*}
N_{\gamma \gamma}^{\mathbf{T I T I}}=\sum_{k \in \mathbf{T} \mathbf{T}} w^{(k)} \pm \sqrt{\sum_{k \in \mathbf{T} \mathbf{T}}\left[w^{(k)}\right]^{2}} \tag{3}
\end{equation*}
$$

where the weight $w^{(k)}$ for the $k$ th event is

$$
\begin{equation*}
w^{(k)}=W_{\gamma \gamma}^{(k)} \epsilon_{1}^{(k)} \epsilon_{2}^{(k)} \tag{4}
\end{equation*}
$$

and the sum over $k$ is carried out on the events in a given bin of the variable of interest ( $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$ ). The result is shown in Fig. 3, by the solid circles.

The main sources of systematic errors are (i) the definition of the NONTIGHT control sample: ${ }_{-9 \%}^{+12 \%}$; (ii) the normalization of the NONTIGHT sample: ${ }_{-2 \%}^{+0}$; (iii) the statistics used to compute the $E_{\mathrm{T}}^{\text {iso }}$ distributions, and hence the precision of the matrix coefficients: $\pm 9 \%$. Effects (i) and (ii) are estimated as explained in Sec. VA. Effect (iii) is quantified by increasing and decreasing the $\epsilon, f$ parameters by their statistical errors and recomputing the signal yield: the variations are then added in quadrature.

## 2. Two-dimensional fit

From all the di-photon events satisfying the TIGHT selection (sample TT), the observed 2-dimensional distribution $F^{\mathrm{obs}}\left(E_{\mathrm{T}, 1}^{\text {iso }}, E_{\mathrm{T}, 2}^{\text {iso }}\right)$ of the isolation energies of the leading and subleading photons is built. Then, a linear combination of four unbinned probability density functions (PDFs), $F_{\gamma \gamma}, F_{\gamma \mathrm{j}}, F_{\mathrm{j} \gamma}, F_{\mathrm{jj}}$, describing the 2-dimensional distributions of the four final states, is fit to the observed distribution. For the $\gamma \gamma, \gamma \mathrm{j}, \mathrm{j} \gamma$ final states, the correlation between $E_{\mathrm{T}, 1}^{\mathrm{iso}}$ and $E_{\mathrm{T}, 2}^{\mathrm{iso}}$ is assumed to be negligible; therefore, the 2-dimensional PDFs are factorized into the leading and subleading PDFs. The leading and subleading photon PDFs $F_{\gamma_{1}}, F_{\gamma_{2}}$ are obtained from the electron extrapolation, as described in Sec. V B. The background PDF $F_{\mathrm{j}_{2}}$ for $\gamma \mathrm{j}$ events is obtained from the NONTIGHT sample on the subleading candidate, for events where the leading candidate satisfies the TIGHT selection. The background PDF $F_{\mathrm{j}_{1}}$ for $\mathrm{j} \gamma$ events is obtained in a similar way. Both background PDFs are then smoothed with empirical parametric functions. The PDF for jj events cannot be factorized, due to the sizable correlation between the two candidates. Therefore, a 2-dimensional PDF is directly extracted from events where both candidates belong to the NONTIGHT sample, then smoothed.

The four yields in the TT sample come from an extended maximum likelihood fit of

$$
\begin{aligned}
& N^{\mathbf{T T}} F^{\mathrm{obs}}\left(E_{\mathrm{T}, 1}^{\mathrm{iso}}, E_{\mathrm{T}, 2}^{\mathrm{iso}}\right) \\
& =N_{\gamma \gamma}^{\mathrm{TT}} F_{\gamma_{1}}\left(E_{\mathrm{T}, 1}^{\mathrm{iso}}\right) F_{\gamma_{2}}\left(E_{\mathrm{T}, 2}^{\mathrm{iso}}\right)+N_{\gamma \mathrm{j}}^{\mathrm{TT}} F_{\gamma_{1}}\left(E_{\mathrm{T}, 1}^{\mathrm{iso}}\right) F_{\mathrm{j}_{2}}\left(E_{\mathrm{T}, 2}^{\mathrm{iso}}\right) \\
& \quad+N_{\mathrm{j} \gamma}^{\mathrm{TT}} F_{\mathrm{j}_{1}}\left(E_{\mathrm{T}, 1}^{\mathrm{iso}}\right) F_{\gamma_{2}}\left(E_{\mathrm{T}, 2}^{\mathrm{iso}}\right)+N_{\mathrm{jj}}^{\mathrm{TT}} F_{\mathrm{jj}}\left(E_{\mathrm{T}, 1}^{\mathrm{iso}}, E_{\mathrm{T}, 2}^{\mathrm{iso}}\right) .
\end{aligned}
$$

Figure 4 shows the fit result for the full TT data set.
The yields in the TITI sample are evaluated by multiplying $N_{\gamma \gamma}^{\mathrm{TT}}$ by the integral of the 2-dimensional signal PDF in the region defined by $E_{\mathrm{T}, 1}^{\mathrm{iso}}<3 \mathrm{GeV}$ and $E_{\mathrm{T}, 2}^{\mathrm{iso}}<3 \mathrm{GeV}$. The procedure is applied to the events belonging to each

FIG. 4 (color online). Projections of the 2-dimensional PDF fit on transverse isolation energies of the two photon candidates: leading photon (top) and subleading photon (bottom). Solid circles represent the observed data. The continuous curve is the fit result, while the dashed-dotted curve shows the $\gamma \gamma$ component. The dashed line represents the background component of the leading and subleading photon sample, respectively.
bin of the observables $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$. The result is displayed in Fig. 3, by the open triangles.

The main sources of systematic uncertainties are (i) definition of the NONTIGHT control sample: ${ }_{-0 \%}^{+13 \%}$;
(ii) signal composition: $\pm 8 \%$; (iii) effect of material knowledge on signal: ${ }_{0 \%}^{+1.6 \%}$; (iv) signal PDF parameters: $\pm 0.7 \%$; (v) jet PDF parameters: $\pm 1.2 \%$; (vi) di-jet PDF parameters: $\pm 1 \%$; (vii) signal contamination in the NONTIGHT sample: ${ }_{0 \%}^{+1.2 \%}$. Effect (i) is estimated by changing the number of released strips cuts, as explained in Sec. VA. Effect (ii) has been estimated by artificially setting the fraction of fragmentation photons to $0 \%$ or to $100 \%$. Effect (iii) has been quantified by repeating the $e \rightarrow$ $\gamma$ extrapolation based on Monte Carlo samples with a distorted geometry. Effects (iv, v) have been estimated by randomly varying the parameters of the smoothing functions, within their covariance ellipsoid, and repeating the

2-dimensional fit. Effect (vi) has been estimated by randomly extracting a set of ( $\left.E_{\mathrm{T}, 1}^{\mathrm{iso}}, E_{\mathrm{T}, 2}^{\mathrm{iso}}\right)$ pairs, comparable to the experimental statistics, from the smoothed $F_{\mathrm{jj}} \mathrm{PDF}$, then resmoothing the obtained distribution and repeating the 2-dimensional fit. Effect (vii) has been estimated by taking the signal contamination from simulationneglected when computing the central value.

## 3. Isolation vs identification sideband counting (2D sidebands)

This method has been used in ATLAS in the inclusive photon cross-section measurement [10] and in the background decomposition in the search for the Higgs boson decaying into two photons [19].

The base di-photon sample must fulfil the selection with the strips cuts released, defined by the union of TIGHT and NONTIGHT samples and here referred to as LOOSE' $\left(\mathbf{L}^{\prime}\right)$. The leading photons in the $\mathbf{L}^{\prime} \mathbf{L}^{\prime}$ sample are divided into four categories $A, B, C, D$, depending on whether they satisfy the TIGHT selection and/or the isolation require-ment-see Fig. 5 (top). The signal region, defined by TIGHT and isolated photons (TI), contains $N_{A}$ candidates, whereas the three control regions contain $N_{B}, N_{C}, N_{D}$ candidates. Under the hypothesis that regions $B, C, D$ are largely dominated by background, and that the isolation energy of the background has little dependence on the TIGHT selection (as discussed in Sec. VA), the number of genuine leading photons $N_{A}^{\text {sig }}$ in region $A$, coming from $\gamma \gamma$ and $\gamma \mathrm{j}$ final states, can be computed [10] by solving the equation
$N_{A}^{\mathrm{sig}}=N_{A}-\left[\left(N_{B}-c_{1} N_{A}^{\mathrm{sig}}\right) \frac{N_{C}-c_{2} N_{A}^{\mathrm{sig}}}{N_{D}-c_{1} c_{2} N_{A}^{\mathrm{sig}}}\right] R^{\mathrm{bkg}}$.

Here, $c_{1}$ and $c_{2}$ are the signal fractions failing, respectively, the isolation requirement and the TIGHT selection. The former is computed from the isolation distributions, as extracted in Sec. VA; the latter is evaluated from Monte Carlo simulation, after applying the corrections to adapt it to the experimental shower shapes distributions [10]. The parameter $R^{\mathrm{bkg}}=\frac{N_{A}^{\mathrm{bkg}} N_{D}^{\mathrm{bkg}}}{N_{C}^{\mathrm{bg}} N_{B}^{\mathrm{kg}}}$ measures the degree of correlation between the isolation energy and the photon selection in the background: it is set to 1 to compute the central values, then varied according to the "di-jet-like" Monte Carlo prediction for systematic studies.

When the leading candidate is in the TI region, the subleading one is tested, and four categories $A^{\prime}, B^{\prime}, C^{\prime}$, $D^{\prime}$ are defined, as in the case of the leading candidate-see Fig. 5 (bottom). The number of genuine subleading photons $N_{A}^{\text {sig }}$, due to $\gamma \gamma$ and $\mathrm{j} \gamma$ final states, is computed by solving an equation analogous to (5).

PHYSICAL REVIEW D 85, 012003 (2012)

FIG. 5 (color online). Schematic representation of the twodimensional sideband method. The top plane displays the isolation ( x axis) and TIGHT identification (y axis) criteria for the classification of the leading photon candidate. When the leading photon belongs to region $A$, the same classification is applied to the subleading photon, as described by the bottom plane.
$N_{A}^{\text {sig }}$ and $N_{A}^{\prime}$ sig are related to the yields by

$$
N_{A}^{\mathrm{sig}}=\frac{N_{\gamma \gamma}^{\mathrm{TITI}}}{\epsilon^{\prime}}+\frac{N_{\gamma \mathrm{j}}^{\mathrm{TITI}}}{f^{\prime}}, \quad N_{A}^{\prime} \text { sig }=N_{\gamma \gamma}^{\mathrm{TITI}}+N_{\mathrm{j} \gamma}^{\mathrm{TITI}},
$$

where $\epsilon^{\prime}=\frac{1}{\left(1+c_{1}^{\prime}\right)\left(1+c_{2}^{\prime}\right)}$ is the probability that a subleading photon satisfies the TIGHT selection and isolation requirement, while $f^{\prime}$ is the analogous probability for a jet faking a subleading photon. The di-photon yield is therefore computed as

$$
\begin{equation*}
N_{\gamma \gamma}^{\mathrm{TITI}}=\frac{\epsilon^{\prime}\left(\alpha f^{\prime} N_{A}^{\mathrm{sig}}+(\alpha-1) N_{A}^{\prime \text { sig }}\right)}{(\alpha-1) \epsilon^{\prime}+\alpha f^{\prime}}, \tag{6}
\end{equation*}
$$

and $f^{\prime}$ can be computed from the observed quantities to be $f^{\prime}=\frac{N_{A}^{\prime}-N_{A}^{\text {Sisg }}}{N_{A}-N_{A}^{\text {sig }} / \epsilon^{\prime}}$. The parameter $\alpha$ is defined as the fraction of photon-jet events in which the jet fakes the leading photon, $\alpha=\frac{N_{i \gamma}^{\text {TITI }}}{N_{\gamma j}^{\text {TTI }}+N_{\text {ivT }}^{\text {TIT }}}$, whose value is taken from the PYTHIA photon-jet simulation.

The counts $N_{A}, N_{B}, N_{C}, N_{D}, N_{A}^{\prime}, N_{B}^{\prime}, N_{C}^{\prime}, N_{D}^{\prime}$, and hence the yield, can be computed for all events entering a given bin of $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$. The result is displayed in Fig. 3, by the open squares.

The main source of systematic error is the definition of the NONTIGHT sample: it induces an error of ${ }_{-10 \%}^{+7 \%}$. The other effects come from the uncertainties of the parameters entering Eq. (6). The main effects come from: (i) variation of $c_{1}^{\prime}: \pm 4 \%$; (ii) variation of $\alpha: \pm 3 \%$; (iii) variations of $R^{\mathrm{bkg}}, R^{\mathrm{bkg}}{ }_{-1.5 \%}^{+0 \%}$. The variations of $c_{1}, c_{2}, c_{2}^{\prime}$ have negligible impact.

## B. Electron background

Background from isolated electrons contaminates mostly the selected converted photon sample. The contamination in the di-photon analysis comes from several physical channels: (i) $e^{+} e^{-}$final states from Drell-Yan processes, $Z \rightarrow$ $e^{+} e^{-}$decay, $W^{+} W^{-} \rightarrow e^{+} e^{-} \nu \bar{\nu}$; (ii) $\gamma e^{ \pm}$final states from di-boson production, e.g. $\gamma W^{ \pm} \rightarrow \gamma e^{ \pm} \nu, \gamma Z \rightarrow \gamma e^{+} e^{-}$. The effect of the $Z \rightarrow e^{+} e^{-}$contamination is visible in Fig. 3 in the mass bin $80<m_{\gamma \gamma}<100 \mathrm{GeV}$.

Rather than quantifying each physical process separately, a global approach is chosen. The events reconstructed with $\gamma \gamma, \gamma e$, and $e e$ final states are counted, thus obtaining counts $N_{\gamma \gamma}, N_{\gamma e}$, and $N_{e e}$. Only photons and electrons satisfying a TIGHT selection and the calorimetric isolation $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$ are considered, and electrons are counted only if they are not reconstructed at the same time as photons. Such counts are related to the actual underlying yields $N_{\gamma \gamma}^{\text {true }}, N_{\gamma e}^{\text {tue }}, N_{e e}^{\text {tue }}$, defined as the number of reconstructed final states where both particles are correctly classified. Introducing the ratio $f_{e \rightarrow \gamma}=\frac{N_{e \rightarrow \gamma}}{N_{e \rightarrow e}}$ between genuine electrons that are wrongly and correctly classified, and likewise $f_{\gamma \rightarrow e}=\frac{N_{\gamma-e}}{N_{\gamma \gamma \gamma}}$ for genuine photons, the relationship between the $N$ and $N^{\text {true }}$ quantities is described by the following linear system:

$$
\left.\begin{array}{rl}
\left(\begin{array}{c}
N_{\gamma \gamma} \\
N_{\gamma e} \\
N_{e e}
\end{array}\right)= & \left(\begin{array}{ccc}
1 & f_{e \rightarrow \gamma} & \left(f_{e \rightarrow \gamma}\right)^{2} \\
2 f_{\gamma \rightarrow e} & \left(1+f_{e \rightarrow \gamma} f_{\gamma \rightarrow e}\right) & 2 f_{e \rightarrow \gamma} \\
\left(f_{\gamma \rightarrow e}\right)^{2} & f_{\gamma \rightarrow e} & 1
\end{array}\right) \\
& \times\left(\begin{array}{l}
N_{\gamma \gamma}^{\text {true }} \\
N_{\gamma e}^{\text {true }} \\
N_{e e}^{\text {true }}
\end{array}\right.
\end{array}\right)
$$

which can be solved for the unknown $N_{\gamma \gamma}^{\text {true }}$.

The value of $f_{e \rightarrow \gamma}$ is extracted from collision data, as $f_{e \rightarrow \gamma}=\frac{N_{\gamma e}}{2 N_{e e}}$, from events with an invariant mass within $\pm 5 \mathrm{GeV}$ of the $Z$ mass. The continuum background is removed using symmetric sidebands. The result is $f_{e \rightarrow \gamma}=$ $0.112 \pm 0.005$ (stat) $\pm 0.003$ (syst), where the systematic error comes from variations of the mass window and of the sidebands. This method has been tested on "di-jetlike" and $Z \rightarrow e^{+} e^{-}$Monte Carlo samples and shown to be unbiased. The value of $f_{\gamma \rightarrow e}$ is taken from the "di-jetlike" Monte Carlo: $f_{\gamma \rightarrow e}=0.0077$. To account for imperfect modelling, this value has also been set to 0 , or to 3 times the nominal value, and the resulting variations are considered as a source of systematic error.

The electron contamination is estimated for each bin of $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}$. and $\Delta \phi_{\gamma \gamma}$, and subtracted from the di-photon yield. The result, as a function of $m_{\gamma \gamma}$, is shown in Fig. 6. The fractional contamination as a function of $p_{\mathrm{T}, \gamma \gamma}$ and $\Delta \phi_{\gamma \gamma}$ is rather flat, amounting to $\sim 5 \%$.

FIG. 6 (color online). Electron background subtraction as a function of $m_{\gamma \gamma}$. The top plot displays the impurity, overall and for the $\gamma e$ and ee separately. The bottom plot shows the diphoton yield before (open squares) and after (solid circles) the electron background subtraction. The points are artificially shifted horizontally, to better display the different values.

## VII. EFFICIENCIES AND UNFOLDING

The signal is defined as a di-photon final state, which must satisfy precise kinematic cuts (referred to as "fiducial acceptance"'):
(i) both photons must have a transverse momentum $p_{\mathrm{T}}^{\gamma}>16 \mathrm{GeV}$ and must be in the pseudorapidity acceptance $\left|\eta^{\gamma}\right|<2.37$, with the exclusion of the region $1.37<\left|\eta^{\gamma}\right|<1.52$;
(ii) the separation between the two photons must be

$$
\Delta R_{\gamma \gamma}=\sqrt{\left(\eta_{1}^{\gamma}-\eta_{2}^{\gamma}\right)^{2}+\left(\phi_{1}^{\gamma}-\phi_{2}^{\gamma}\right)^{2}}>0.4
$$

(iii) both photons must be isolated, i.e. the transverse energy flow $E_{\mathrm{T}}^{\text {iso(part) }}$ due to interacting particles in a cone of angular radius $R<0.4$ must be $E_{\mathrm{T}}^{\text {iso(part) }}<$ 4 GeV .

These kinematic cuts define a phase space similar to the experimental selection described in Sec. III. In particular, the requirement on $E_{\mathrm{T}}^{\text {iso(part) }}$ has been introduced to match approximately the experimental cut on $E_{\mathrm{T}}^{\text {iso }}$. The value of $E_{\mathrm{T}}^{\text {iso(part) }}$ is corrected for the ambient energy, similarly to what is done for $E_{\mathrm{T}}^{\mathrm{iso}}$. From studies on a PYTHIA di-photon Monte Carlo sample, there is a high correlation between the two variables, and $E_{\mathrm{T}}^{\text {iso }}=3 \mathrm{GeV}$ corresponds to $E_{\mathrm{T}}^{\text {iso(part) }} \simeq 4 \mathrm{GeV}$.

A significant number of di-photon events lying outside the fiducial acceptance pass the experimental selection because of resolution effects: these are referred to as "below threshold" (BT) events.

The background subtraction provides the di-photon signal yields for events passing all selections (TITI). Such yields are called $N_{i}^{\text {TITI }}$, where the index $i$ flags the bins of the reconstructed observable $X^{\text {rec }}$ under consideration ( $X$ being $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$ ). The relationship between $N_{i}^{\text {TITI }}$ and the true yields $n_{\alpha}$ ( $\alpha$ being the bin index of the true value $X^{\text {true }}$ ) is:

$$
\begin{gather*}
N_{i}^{\mathrm{TITI}}=\epsilon^{\mathrm{trigger}} \epsilon_{i}^{\mathrm{TT}} N_{i}^{\mathrm{II}},  \tag{8}\\
N_{i}^{\mathrm{II}}\left(1-f_{i}^{B T}\right)=\sum_{\alpha} M_{i \alpha} \epsilon_{\alpha}^{R A} n_{\alpha}, \tag{9}
\end{gather*}
$$

where $N_{i}^{\mathrm{II}}$ is the number of reconstructed isolated diphoton events in the $i$ th bin, and
(i) $\epsilon^{\text {trigger }}$ is the trigger efficiency, computed for events where both photons satisfy the TIGHT identification and the calorimetric isolation;
(ii) $\epsilon_{i}^{\mathrm{TT}}$ is the efficiency of the TIGHT identification, for events where both photons satisfy the calorimetric isolation;
(iii) $f_{i}^{B T}$ is the fraction of "below-threshold" events;
(iv) $M_{i \alpha}$ is a "migration probability", i.e. the probability that an event with $X^{\text {true }}$ in bin- $\alpha$ is reconstructed with $X^{\text {rec }}$ in bin- $i$;
(v) $\epsilon_{\alpha}^{R A}$ accounts for both the reconstruction efficiency and the acceptance of the experimental cuts (kinematics and calorimetric isolation).

## A. Trigger efficiency

The trigger efficiency is computed from collision data, for events containing two reconstructed photons with transverse energy $E_{\mathrm{T}}^{\gamma}>16 \mathrm{GeV}$, both satisfying the TIGHT identification and the calorimetric isolation requirement (TITI). The computation is done in three steps.

First, a level-1 $e / \gamma$ trigger with an energy threshold of 5 GeV is studied: its efficiency, for reconstructed TI photons, is measured on an inclusive set of minimumbias events: for $E_{\mathrm{T}}^{\gamma}>16 \mathrm{GeV}$ it is $\epsilon_{0}=100.0_{-0.1}^{+0.0} \%-$ therefore such a trigger does not bias the sample. Next, a high-level photon trigger with a 15 GeV threshold is studied, for reconstructed TI photons selected by the level-1 trigger: its efficiency is $\epsilon_{1}=99.1_{-0.4}^{+0.3} \%$ for $E_{\mathrm{T}}^{\gamma}>$ 16 GeV . Finally, di-photon TITI events with the subleading photon selected by a high-level photon trigger are used to compute the efficiency of the di-photon 15 GeV threshold high-level trigger, obtaining $\epsilon_{2}=99.4_{-1.0}^{+0.5} \%$. The overall efficiency of the trigger is therefore $\epsilon^{\text {trigger }}=$ $\epsilon_{0} \epsilon_{1} \epsilon_{2}=\left(98.5_{-1.0}^{+0.6} \pm 1.0\right) \%$. The first uncertainty is statistical, the second is systematic and accounts for the contamination of photon-jet and di-jet events in the selected sample.

## B. Identification efficiency

The photon TIGHT identification efficiency $\epsilon^{\mathbf{T} \mid \mathbf{I}}$, for photon candidates satisfying the isolation cut $E_{\mathrm{T}}^{\text {iso }}<3 \mathrm{GeV}$, is computed as described in $\operatorname{Ref}$ [10], as a function of $\eta^{\gamma}$ and $E_{\mathrm{T}}^{\gamma}$. The efficiency is determined by applying the TIGHT selection to a Monte Carlo photon sample, where the shower shape variables have been shifted to better reproduce the observed distributions. The shift factors are obtained by comparing the shower shapes of photon candidates from a "di-jet-like" Monte Carlo sample to those observed in collision data. To enhance the photon component in the sample-otherwise overwhelmed by the jet background-only the photon candidates satisfying the TIGHT selection are considered. This procedure does not bias the bulk of the distribution under test appreciably, since the cuts have been tuned to reject only the tails of the photons' distributions. However, to check the systematic effect due to the selection, the shift factors are also recomputed applying the LOOSE selection.

Compared to Ref [10], the photon identification cuts have been reoptimized to reduce the systematic errors, and converted and unconverted photons treated separately. The photon identification efficiency is $\eta^{\gamma}$ dependent and increases with $E_{\mathrm{T}}^{\gamma}$, ranging from $\sim 60 \%$ for $16<E_{\mathrm{T}}^{\gamma}<$ 20 GeV to $\gtrsim 90 \%$ for $E_{\mathrm{T}}^{\gamma}>100 \mathrm{GeV}$. The overall systematic error is between $2 \%$ and $10 \%$, the higher values being
applicable at lower $E_{\mathrm{T}}^{\gamma}$ and for converted photons. The main sources of systematic uncertainty are (i) the systematic error on the shift factors; (ii) the knowledge of the detector material; (iii) the failure to detect a conversion, therefore applying the wrong TIGHT identification.

Rather than computing an event-level identification efficiency for each bin of each observable, the photon efficiency can be naturally accommodated into the event weights described in Sec. VI A 1, by dividing the weight $w^{(k)}$ of Eq. (4) by the product of the two photon efficiencies:

$$
\begin{equation*}
N_{i}^{\mathbf{I I}}=\sum_{k \in \operatorname{bin}-\mathrm{i}} \frac{w^{(k)}}{\left[\epsilon^{\mathbf{T} \mid \mathbf{I}}\left(\eta_{1}^{\gamma}, E_{\mathrm{T}}^{\gamma}\right) \epsilon^{\mathbf{T} \mid \mathbf{I}}\left(\eta_{2}^{\gamma}, E_{\mathrm{T}}^{2}{ }_{2}^{\gamma}\right)\right]^{(k)}}, \tag{10}
\end{equation*}
$$

where the sum is extended over all events in the TT sample and in the $i$ th bin. Here the identification efficiencies of the two photons are assumed to be uncorrelated-which is ensured by the separation cut $\Delta R>0.4$, and by the binning in $\eta^{\gamma}$ and $E_{\mathrm{T}}^{T}$.

The event efficiency, $\epsilon_{i}^{\mathrm{TT}}=\frac{N_{i}^{\text {TITI }}}{N_{i}^{\text {II }}}$, is essentially flat at $\sim 60 \%$ in $\Delta \phi_{\gamma \gamma}$, and increases with $m_{\gamma \gamma}$ and $p_{\mathrm{T}, \gamma \gamma}$, ranging from $\sim 55 \%$ to $\sim 80 \%$. Its total systematic error is $\sim 10 \%$, rather uniform over the $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$ ranges.

## C. Reconstruction, acceptance, isolation, and unfolding

The efficiency $\epsilon_{\alpha}^{R A}$ accounts for both the reconstruction efficiency and the acceptance of the experimental selection. It is computed for each bin of $X^{\text {true }}$, with Monte Carlo di-photon events generated with PYTHIA in the fiducial acceptance, as the fraction of events where both photons are reconstructed, pass the acceptance cuts and the calorimetric isolation. The value of $\epsilon_{\alpha}^{R A}$ ranges between $50 \%$ and $60 \%$. The two main sources of inefficiency are the local ECAL readout failures $(\sim-18 \%)$ and the calorimetric isolation ( $\sim-20 \%$ ).

The energy scale differences between Monte Carlo and collision data-calibrated on $Z \rightarrow e^{+} e^{-}$events-are taken into account. The uncertainties on the energy scale and resolution are propagated as systematic errors through the evaluation: the former gives an effect between $+3 \%$ and $-1 \%$ on the signal rate, while the latter has negligible impact.

In Monte Carlo, the calorimetric isolation energy, $E_{T}^{\text {iso }}$, needs to be corrected to match that observed in collision data. The correction is optimized on TIGHT photons, for which the background contamination can be removed (see Sec. VA), then it is applied to all photons in the Monte Carlo sample. The $E_{\mathrm{T}}^{\text {iso }}$ difference observed between Monte Carlo simulation and collision data may be entirely due to inaccurate GEANT4/detector modeling, or it can also be a consequence of the physical model in the generator (e.g. kinematics, fragmentation, hadronization). From the comparison between collision data and simulation, the two effects cannot be disentangled. To compute the central values of the results, the difference between simulation
and collision data is assumed to be entirely due to the detector simulation. As a cross-check, the opposite case is assumed: that the difference is entirely due to the generator model. In this case, the particle-level isolation $E_{\mathrm{T}}^{\text {iso(part) }}$ should also be corrected, using the $E_{\mathrm{T}}^{\text {iso(part) }} \rightarrow$ $E_{\mathrm{T}}^{\text {iso }}$ relationship described by the detector simulation. This modifies the definition of fiducial acceptance, and hence the values of $\epsilon_{\alpha}^{R A}$, resulting in a cross-section variation of $\sim-7 \%$, which is handled as an asymmetric systematic uncertainty.

The fraction of events "below threshold," $f_{i}^{B T}$, is computed from the same PYTHIA signal Monte Carlo sample,

TABLE I. Binned differential cross sections $d \sigma / d m_{\gamma \gamma}$, $d \sigma / d p_{\mathrm{T}, \gamma \gamma}, d \sigma / d \Delta \phi_{\gamma \gamma}$ for di-photon production. For each bin, the differential cross ection is quoted with its statistical and systematic uncertainties (symmetric and asymmetric, respectively). Values quoted as 0.000 are actually less than 0.0005 in absolute value.

for each bin of $X^{\text {rec }}$. Its value is maximum ( $\sim 12 \%$ ) for $m_{\gamma \gamma}$ about twice the $E_{\mathrm{T}}$ cut, and decreases to values $<5 \%$ for $m_{\gamma \gamma}>50 \mathrm{GeV}$.

The "migration matrix," $M_{i \alpha}$, is filled with PYTHIA Monte Carlo di-photon events in the fiducial acceptance, that are reconstructed, pass the acceptance cuts and the calorimetric isolation. The inversion of this matrix is
performed with an unfolding technique, based on Bayesian iterations [20]. The systematic uncertainties of the procedure have been estimated with a large number of toy data sets and found to be negligible. The result has also been tested to be independent of the initial ("prior") distributions. Moreover, it has been checked that a simpler bin-by-bin unfolding yields compatible results.

TABLE II. Breakdown of the total cross-section systematic uncertainty, for each bin of $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}$, and $\Delta \phi_{\gamma \gamma}$. The meaning of each column is as follows: " $\tilde{\mathbf{T}}$ " is the definition of the NONTIGHT control sample; " $\tilde{\mathbf{I}}$ " is the choice of the $E_{\mathrm{T}}^{\text {iso }}$ region used to normalize the NONTIGHT sample; "Matrix" refers to the statistical uncertainty of the matrix coefficients used by the event weighting; " $e \rightarrow \gamma$ " is the total systematic coming from the electron fake rate; "ID" is the overall uncertainty coming from the method used to derive the identification efficiency; "Material" is the effect of introducing a detector description with distorted material distribution; "Generator" shows the variation due to the usage of a different generator (SHERPA instead of PYTHIA); " $\sigma_{E}$ " and " $E$-scale" are due to uncertainties on energy resolution and scale; " $E_{\mathrm{T}}^{\mathrm{iso}(\text { part })}$ " is the effect of smearing the particle-level isolation $E_{\mathrm{T}}^{\text {iso(part) }}$; " $\int L d t$ " is the effect due to the total luminosity uncertainty. Values quoted as 0.000 are actually less than 0.0005 in absolute value.

As the evaluation of $\epsilon_{\alpha}^{R A}, f_{i}^{B T}, M_{i \alpha}$ may strongly depend on the simulation modeling, two additional Monte Carlo samples have been used, the first with more material modeled in front of the calorimeter, and the second with a different generator (SHERPA): the differences on the computed signal rates are $\sim+10 \%$ and $\lesssim+5 \%$ respectively, and are treated as systematic errors.

## VIII. CROSS-SECTION MEASUREMENT

The di-photon production cross section is evaluated from the corrected binned yields $n_{\alpha}$, divided by the integrated luminosity $\int L d t=(37.2 \pm 1.3) \mathrm{pb}^{-1}$ [8]. The results are presented as differential cross sections, as functions of the three observables $m_{\gamma \gamma}, p_{\mathrm{T}, \gamma \gamma}, \Delta \phi_{\gamma \gamma}$, for a phase space defined by the fiducial acceptance cuts in Sec. VII. In Table I, the differential cross section is quoted for each bin, with its statistical and systematic uncertainty. In Table II, all the considered sources of systematic errors are listed separately.

The experimental measurement is compared with theoretical predictions from the DIPHOX [21] and ResBos [22] NLO generators in Figs. 7-9. The DIPHOX and ResBos evaluation has been carried out using the NLO fragmentation function [23] and the CTEQ6.6 parton density function

FIG. 7 (color online). Differential cross-section $d \sigma / d m_{\gamma \gamma}$ of diphoton production. The solid circles display the experimental values, the hatched bands display the NLO computations by DIPHOX and ResBos. The bottom panels show the relative difference between the measurements and the NLO predictions. The data/ theory point in the bin $0<m_{\gamma \gamma}<30 \mathrm{GeV}$ lies above the frames.

FIG. 8 (color online). Differential cross-section $d \sigma / d p_{\mathrm{T}, \gamma \gamma}$ of di-photon production. The solid circles display the experimental values, the hatched bands display the NLO computations by DIPHOX and ResBos. The bottom panels show the relative difference between the measurements and the NLO predictions. The data point in the bin $150<p_{\mathrm{T}, \gamma \gamma}<200 \mathrm{GeV}$ in the main panel lies below the frame.
(PDF) set [24]. The fragmentation, normalization and factorization scales are set equal to $m_{\gamma \gamma}$. The same fiducial acceptance cuts introduced in the signal definition (Sec. VII) are applied. Since neither generator models the hadronization, it is not possible to apply a requirement on $E_{\mathrm{T}}^{\text {iso(part) }}$ : the closest isolation variable available in such generators is the "partonic isolation," which is therefore required to be less then 4 GeV . The computed cross section shows a weak dependence on the partonic isolation cut: moving it to 2 or 6 GeV produces variations within $5 \%$, smaller than the theoretical systematic errors.

The theory uncertainty error bands come from scale and PDF uncertainties evaluated from DIPHOX: (i) variation of renormalization, fragmentation, and factorization scales: each is varied to $\frac{1}{2} m_{\gamma \gamma}$ and $2 m_{\gamma \gamma}$, and the envelope of all variations is assumed as a systematic error; (ii) variation of the eigenvalues of the PDFs: each is varied by $\pm 1 \sigma$, and positive/negative variations are summed in quadrature separately. As an alternative, the MSTW 2008 PDF set has been used: the difference with respect to CTEQ6.6 is an overall increase by $\sim 10 \%$, which is covered by the CTEQ6.6 total systematic error.

The measured distribution of $d \sigma / d \Delta \phi_{\gamma \gamma}$ (Fig. 9) is clearly broader than the DIPHOX and ResBos predictions:

FIG. 9 (color online). Differential cross-section $d \sigma / d \Delta \phi_{\gamma \gamma}$ of di-photon production. The solid circles display the experimental values, the hatched bands display the NLO computations by DIPHOX and ResBos. The bottom panels show the relative difference between the measurements and the NLO predictions.
more photon pairs are seen in data at low $\Delta \phi_{\gamma \gamma}$ values, while the theoretical predictions favor a larger back-toback production ( $\Delta \phi_{\gamma \gamma} \simeq \pi$ ). This result is qualitatively in agreement with previous measurements at the Tevatron [5,6]. The distribution of $d \sigma / d m_{\gamma \gamma}$ (Fig. 7) agrees within the assigned uncertainties with both the DIPHOX and ResBos predictions, apart from the region $m_{\gamma \gamma}<2 E_{\mathrm{T}}^{\text {cut }}$ ( $E_{\mathrm{T}}^{\mathrm{cut}}=16 \mathrm{GeV}$ being the applied cut on the photon transverse momenta): as this region is populated by events with small $\Delta \phi_{\gamma \gamma}$, the poor quality of the predictions can be related to the discrepancy observed in the $\Delta \phi_{\gamma \gamma}$ distribution. The result for $d \sigma / d p_{\mathrm{T}, \gamma \gamma}$ (Fig. 8) is in agreement with both DIPHOX and ResBos: the maximum deviation, about $2 \sigma$, is observed in the region $50<p_{\mathrm{T}, \gamma \gamma}<60 \mathrm{GeV}$.

## IX. CONCLUSIONS

This paper describes the measurement of the production cross section of isolated di-photon final states in protonproton collisions, at a center-of-mass energy $\sqrt{s}=7 \mathrm{TeV}$, with the ATLAS experiment. The full data sample collected in 2010, corresponding to an integrated luminosity of $37.2 \pm 1.3 \mathrm{pb}^{-1}$, has been analyzed.

The selected sample consists of 2022 candidate events containing two reconstructed photons, with transverse
momenta $p_{\mathrm{T}}>16 \mathrm{GeV}$ and satisfying tight identification and isolation requirements. All the background sources have been investigated with data-driven techniques and subtracted. The main background source, due to hadronic jets in photon-jet and di-jet events, has been estimated with three computationally independent analyses, all based on shower shape variables and isolation, which give compatible results. The background due to isolated electrons from $W$ and $Z$ decays is estimated with collision data, from the proportions of observed $e e, \gamma e$, and $\gamma \gamma$ final states, in the $Z$-mass region and elsewhere.
The result is presented in terms of differential cross sections as functions of three observables: the invariant mass $m_{\gamma \gamma}$, the total transverse momentum $p_{\mathrm{T}, \gamma \gamma}$, and the azimuthal separation $\Delta \phi_{\gamma \gamma}$ of the photon pair. The experimental results are compared with NLO predictions obtained with DIPHOX and ResBos generators. The observed spectrum of $d \sigma / d \Delta \phi_{\gamma \gamma}$ is broader than the NLO predictions. The distribution of $d \sigma / d m_{\gamma \gamma}$ is in good agreement with both the DIPHOX and ResBos predictions, apart from the low mass region. The result for $d \sigma / d p_{\mathrm{T}, \gamma \gamma}$ is generally well described by DIPHOX and ResBos.

## ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC, and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST, and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNRF, DNSRC, and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG, and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP, and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society, and Leverhulme Trust, United Kingdom; DOE and NSF, USA. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular, from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NLT1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (USA) and in the Tier-2 facilities worldwide.

# Search for Diphoton Events with Large Missing Transverse Energy in 7 TeV Proton-Proton Collisions with the ATLAS Detector 

G. Aad et al.*<br>(ATLAS Collaboration)

(Received 20 December 2010; published 23 March 2011)

#### Abstract

A search for diphoton events with large missing transverse energy is presented. The data were collected with the ATLAS detector in proton-proton collisions at $\sqrt{s}=7 \mathrm{TeV}$ at the CERN Large Hadron Collider and correspond to an integrated luminosity of $3.1 \mathrm{pb}^{-1}$. No excess of such events is observed above the standard model background prediction. In the context of a specific model with one universal extra dimension with compactification radius $R$ and gravity-induced decays, values of $1 / R<729 \mathrm{GeV}$ are excluded at $95 \%$ C. L., providing the most sensitive limit on this model to date.

In the standard model (SM), the production in protonproton $(p p)$ collisions of diphoton $(\gamma \gamma)$ events with large missing transverse energy $\left(E_{T}^{\text {miss }}\right)$ is mainly due to $W / Z+$ $\gamma \gamma$ processes. Taking into account the branching ratios of $W / Z$ decays including at least one neutrino, the cross sections are only a few femtobarns for $7 \mathrm{TeV} p p$ collisions. In contrast, some new physics models predict much larger $\gamma \gamma+E_{T}^{\text {miss }}$ rates. This Letter reports the first $\gamma \gamma+E_{T}^{\text {miss }}$ search with LHC data, using data recorded with the ATLAS detector. The results are interpreted in the context of a universal extra dimension (UED) model.

UED models [1] postulate the existence of additional spatial dimensions in which all SM particles can propagate, leading to the existence for each SM particle of a series of excitations, known as a Kaluza-Klein (KK) tower. This analysis considers the case of a single $\mathrm{TeV}^{-1}$-sized UED, with compactification radius $R$. The masses of the states of successive levels in the tower are separated by $\approx 1 / R$. For a given KK level, the approximate mass degeneracy of the KK excitations is broken by radiative corrections [2]. The lightest KK particle (LKP) is the KK photon of the first level, denoted $\gamma^{*}$. At the LHC, the main UED process would be production via the strong interaction of a pair of first-level KK quarks and/or gluons [3], which would decay via cascades involving other KK particles until reaching the LKP at the end of the decay chain. If the UED model is embedded in a larger space with $N$ additional $\mathrm{eV}^{-1}$-sized dimensions accessible only to gravity [4], the LKP could decay gravitationally via $\gamma^{*} \rightarrow \gamma+G$ [5], where $G$ represents one of a tower of eV-spaced graviton states. With two decay chains per event, the final state would be $\gamma \gamma+E_{T}^{\text {miss }}+X$, where $E_{T}^{\text {miss }}$ results from

the escaping gravitons and $X$ represents SM particles emitted in the cascade decays.

The UED model considered is defined by specifying $R$ and $\Lambda$, the ultraviolet cutoff used in the calculation of radiative corrections to the KK masses. This analysis treats $R$ as a free parameter and, following the theory calculations [2], sets $\Lambda$ such that $\Lambda R=20$. For $1 / R=700 \mathrm{GeV}$, the masses of the first-level KK photon, quark, and gluon are 700,815 , and 865 GeV , respectively [6]. The $\gamma^{*}$ mass is insensitive to $\Lambda$, while other KK masses change by typically a few percent when varying $\Lambda R$ in the range 10-30. The gravitational decay widths of the KK particles are set by $N$ and $M_{D}$, the Planck scale in the $(4+N)$-dimensional theory. For the chosen values of $N=6$ and $M_{D}=5 \mathrm{TeV}$, and provided $1 / R<1 \mathrm{TeV}$, the LKP is the only KK particle to have an appreciable rate of gravitational decay. The same parameter values were used in the only previous study of this model, in which the D0 experiment excluded at $95 \% \mathrm{C}$. L. values of $1 / R<477 \mathrm{GeV}$ [7].

Monte Carlo (MC) signal samples were produced for a range of $1 / R$ values using the implementation [6] of the UED model in PYTHIA [8] version 6.421, and using the MC09 parameter tune [9]. The MC samples were processed through the ATLAS detector simulation [10] based on GEANT4 [11]. In addition to the two high transverse energy $\left(E_{T}\right)$ photons and large $E_{T}^{\text {miss }}$, the signal events typically include several high- $E_{T}$ jets due to the cascade decays, with the $E_{T}$ spectrum of the leading jet peaking at $\approx 100 \mathrm{GeV}$ for $1 / R=700 \mathrm{GeV}$.

The ATLAS detector [12] is a multipurpose particle physics apparatus with a forward-backward symmetric cylindrical geometry and nearly $4 \pi$ solid angle coverage. ATLAS uses a Cartesian right-handed coordinate system, with the nominal collision point at the origin. The anticlockwise beam direction defines the positive $z$ axis, while the positive $x$ axis points from the collision point to the center of the LHC ring and the positive $y$ axis points upward. The angles $\phi$ and $\theta$ are the azimuthal and polar angles. The pseudorapidity is defined as
$\eta=-\ln [\tan (\theta / 2)]$. Closest to the beam line are tracking detectors which use layers of silicon-based and straw-tube detectors, located inside a thin superconducting solenoid that provides a 2 T magnetic field, to measure the trajectories of charged particles. The solenoid is surrounded by a hermetic calorimeter system. A liquid-argon (LAr) sampling calorimeter is divided into a central barrel calorimeter and two end-cap calorimeters, each housed in a separate cryostat. Fine-grained LAr electromagnetic (EM) calorimeters, with excellent energy resolution, provide coverage for $|\eta|<3.2$. In the region $|\eta|<2.5$, the EM calorimeters are segmented into three longitudinal layers and the second layer, in which most of the EM shower energy is deposited, is divided into cells of granularity of $\Delta \eta \times \Delta \phi=0.025 \times$ 0.025. A presampler, covering $|\eta|<1.8$, is used to correct for energy lost upstream of the calorimeter. An ironscintillator tile calorimeter provides hadronic coverage in the range $|\eta|<1.7$. In the end caps $(|\eta|>1.5)$, LAr hadronic calorimeters match the outer $|\eta|$ limits of the end-cap EM calorimeters. LAr forward calorimeters provide both EM and hadronic energy measurements, and extend the coverage to $|\eta|<4.9$. Outside the calorimeters is an extensive muon system including large superconducting toroidal magnets.

The reconstruction of photons is described in detail in Ref. [13]. To select photon candidates, EM calorimeter clusters were required to pass several quality criteria and to lie outside problematic calorimeter regions. Photon candidates were required to have $|\eta|<1.81$ and to be outside the transition region $1.37<|\eta|<1.52$ between the barrel and the end-cap calorimeters. The analysis uses a "loose" photon selection, which includes cuts on the energy in the hadronic calorimeter as well as on variables that require the transverse width of the shower, measured in the second EM calorimeter layer, be consistent with the narrow width expected for an EM shower. The loose selection provides a high photon efficiency with modest rejection against the background from jets.

The reconstruction of $E_{T}^{\text {miss }}$ is based on topological calorimeter clusters [14] with $|\eta|<4.5$ that are seeded by any cell with energy higher than 4 times its noise level. In an iterative procedure, the cluster grows by including all neighboring cells with energy higher than twice the noise, plus all cells neighboring the boundary of this three-dimensional collection. Each cluster is classified as EM or hadronic, depending on its topology, and the cluster energy is calibrated to correct for the noncompensating calorimeter response, energy losses in dead material, and out-of-cluster energies. Events reconstructed with large $E_{T}^{\text {miss }}$ were studied in detail with early data [15]. Rare background events with large transverse energies, unrelated to the collision and concentrated in a few cells, due mainly to discharges and noise, have been observed. Cuts were applied to eliminate such backgrounds, rejecting less than $0.05 \%$ of the selected events while having a negligible impact on the signal efficiency.

The data sample was collected during stable beam periods of $7 \mathrm{TeV} p p$ collisions at the LHC, and corresponds to an integrated luminosity of $3.1 \mathrm{pb}^{-1}$. The events selected had to satisfy a trigger requiring at least one loose photon candidate with $E_{T}>20 \mathrm{GeV}$, and had to contain at least one reconstructed primary vertex consistent with the average beam spot position and with at least three associated tracks. The trigger and vertex requirements are $\approx 99 \%$ efficient for signal MC events. The presence of multiple $p p$ collisions within the same bunch crossing, known as "pileup," can be analyzed by examining $N_{v t x}$, the number of reconstructed primary vertices in each event. In this data sample, the average value of $N_{v t x}$ was $\approx 2.1$. The MC signal samples included the simulation of pileup and were weighted to match the $N_{v t x}$ distribution observed in data.

Events were retained if they had at least two photon candidates, each with $E_{T}>25 \mathrm{GeV}$. In addition, a photon isolation cut was applied, wherein the $E_{T}$ in a radius of 0.2 in the $\eta-\phi$ space around the center of the cluster, excluding the cells belonging to the cluster in a region corresponding to $5 \times 7$ cells in $\eta \times \phi$ in the second layer of the EM calorimeter, had to be less than 35 GeV . This requirement had a signal efficiency greater than $95 \%$ but rejected some of the background from multijet events. An event in which each of the two photon candidates satisfied the loose photon cuts was considered a $\gamma \gamma$ candidate event. An independent "misidentified jet" control sample, enriched in events with jets misidentified as photons, was defined as those events where at least one of the photon candidates did not pass the loose photon identification. After all cuts, the $\gamma \gamma$ and misidentified jet samples totaled 520 and 7323 events, respectively. Figure 1 shows the $E_{T}$ spectrum of the leading photon for the $\gamma \gamma$ candidates and for UED $1 / R=700 \mathrm{GeV}$ MC events; the UED spectrum extends to much higher $E_{T}$ values.

The background was evaluated entirely using data. Noncollision backgrounds, such as cosmic rays and beam-halo events, are reduced to a negligible level by the

FIG. 1. $E_{T}$ spectrum of the leading photon for the $\gamma \gamma$ candidate sample and for UED $1 / R=700 \mathrm{GeV}$ MC events (normalized to 100 times the leading order (LO) cross section).
selection cuts. The main background source, referred to hereafter as QCD background, arises from a mixture of SM processes including $\gamma \gamma$ production, and $\gamma+$ jet and multijet events with at least one jet misidentified as a photon. With the loose photon identification, it is expected that $\gamma+$ jet and multijet events dominate, with only a small $\gamma \gamma$ contribution. The misidentified jet sample provided a model of the $E_{T}^{\text {miss }}$ response for events with jets faking photons. The response for $\gamma \gamma$ events was modeled using the $E_{T}^{\text {miss }}$ spectrum measured in a high purity sample of $Z \rightarrow e e$ events, selected by a combination of kinematic cuts and electron identification requirements [14]. The $E_{T}^{\text {miss }}$ spectrum for $Z \rightarrow e e$ events, which is dominated by the calorimeter response to two genuine EM objects, was verified in MC simulations to model the $E_{T}^{\text {miss }}$ response in SM $\gamma \gamma$ processes, despite their kinematic differences. As shown in Fig. 2, $Z \rightarrow e e$ events typically have somewhat lower $E_{T}^{\text {miss }}$ values than events of the misidentified jet sample, as expected since the presence of jets faking photons should result in a broader $E_{T}^{\text {miss }}$ distribution. The spectrum for the $\gamma \gamma$ candidates, which for low $E_{T}^{\text {miss }}$ is dominated by the QCD background with an unknown mixture of events with zero, one, and two fake photons, lies between these two samples. The $E_{T}^{\text {miss }}$ spectrum of the total QCD background was modeled by a weighted sum of the spectra of the $Z \rightarrow e e$ and misidentified jet samples. The QCD background was normalized to have the same number of events as the $\gamma \gamma$ candidate sample in the region $E_{T}^{\text {miss }}<20 \mathrm{GeV}$, where any UED signal contribution can

FIG. 2 (color online). $\quad E_{T}^{\text {miss }}$ spectra for the $\gamma \gamma$ candidates, for the $Z \rightarrow e e$ and misidentified jet samples used to model the QCD background (each normalized to the number of $\gamma \gamma$ candidates with $\left.E_{T}^{\text {miss }}<20 \mathrm{GeV}\right)$, and for the $W(\rightarrow e \nu)+$ jets $/ \gamma$ background (normalized to its expected total of $\approx 0.4$ events). Variable sized bins are used, and the vertical error bars and shaded bands show the statistical errors.
be neglected. The relative contributions of the $Z \rightarrow e e$ and misidentified jet samples were determined by fitting the QCD background shape to the $E_{T}^{\text {miss }}$ spectrum of the $\gamma \gamma$ candidates in this same low $E_{T}^{\text {miss }}$ region. The fraction attributed to $\gamma \gamma$ production, as modeled with the $Z \rightarrow e e$ distribution, was determined to be $(36 \pm 22) \%$. The search result is not very sensitive to the exact composition of the QCD background, and the fit error was used to determine systematic uncertainties on the background prediction.

A small additional background results from $W \rightarrow e v$ events, which have genuine $E_{T}^{\text {miss }}$ and which can pass the selection if the electron is misidentified as a photon and the second photon is either a real photon in $W \gamma$ events or a jet faking a photon in $W+$ jets events. A high purity sample of inclusive $W \rightarrow e v$ events was selected by a combination of kinematic and electron identification cuts [14]. Requiring in addition a loose photon with $E_{T}^{\gamma}>25 \mathrm{GeV}$, a " $W+\gamma$ " sample of only 5 events was selected. Accounting for the probability for an electron to be misidentified as a loose photon, as determined using the $Z \rightarrow e e$ sample, the total background contribution due to $W \rightarrow e v$ events was then estimated to be only $\approx 0.4$ events. Since the number of $W \gamma$ events was too small to measure their $E_{T}^{\text {miss }}$ spectrum, a sample of $W+$ jets events was used instead, requiring a jet reconstructed with an anti- $k_{T}$ clustering algorithm [16] with radius parameter 0.4 and $E_{T}^{j}>25 \mathrm{GeV}$. The $W(\rightarrow e \nu)+$ jets $/ \gamma$ background contribution was then estimated by normalizing the $W+$ jets $E_{T}^{\text {miss }}$ spectrum to the expected total of $\approx 0.4$ events, as shown on Fig. 2.

Figure 3 shows the $E_{T}^{\text {miss }}$ spectrum of the $\gamma \gamma$ candidates, superimposed on the total background prediction, as well

FIG. 3 (color online). $E_{T}^{\text {miss }}$ spectrum for the $\gamma \gamma$ candidates, compared to the total SM background as estimated from data. Also shown are the expected UED signals for $1 / R=500 \mathrm{GeV}$ and 700 GeV . Variable sized bins are used, and the vertical error bars and shaded bands show the statistical errors.

TABLE I. The number of observed $\gamma \gamma$ candidates, as well as the SM backgrounds estimated from data and expected UED signal for $1 / R$ values of 500 and 700 GeV , given in various $E_{T}^{\text {miss }}$ ranges. The uncertainties are statistical only. The first row, for $E_{T}^{\text {miss }}<20 \mathrm{GeV}$, is the control region used to normalize the QCD background to the number of observed $\gamma \gamma$ candidates.

| $E_{T}^{\text {miss }}$ range | Data |  | Predicted background events |  | Expected UED signal events |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| $(\mathrm{GeV})$ | events | Total | QCD | $W(\rightarrow e \nu)+$ jets $/ \gamma$ | $1 / R=500 \mathrm{GeV}$ | $1 / R=700 \mathrm{GeV}$ |
| $0-20$ | 465 | $465.0 \pm 9.1$ | $465.0 \pm 9.1$ | - | $0.28 \pm 0.06$ | $0.02 \pm 0.01$ |

| $>75$ | 0 | $0.32 \pm 0.16$ | $0.28 \pm 0.15$ | $0.04 \pm 0.03$ | $40.45 \pm 0.62$ | $4.21 \pm 0.06$ |

as example UED signals. Table I summarizes the number of observed $\gamma \gamma$ candidates, as well as the expected backgrounds and example UED signal contributions, in several $E_{T}^{\text {miss }}$ ranges. The QCD background dominates, and falls steeply with rising $E_{T}^{\text {miss }}$, while the $W \rightarrow e v$ background is very small, and flatter as a function of $E_{T}^{\text {miss }}$. The UED signals would peak at large values of $E_{T}^{\text {miss }}$. There is good agreement between the data and predicted background over the entire $E_{T}^{\text {miss }}$ range, with no indication of an excess at high $E_{T}^{\mathrm{miss}}$ values.

The signal search region was chosen to be $E_{T}^{\text {miss }}>$ 75 GeV , before looking at the data, to obtain the best sensitivity to the UED signal. In the signal region, there are zero observed events, compared to an expectation of $0.32 \pm 0.16(\text { stat })_{-0.10}^{+0.37}($ syst $)$ background events. The systematic uncertainty was derived by studying variations of the background determination, including varying within its error the $\gamma \gamma$ fraction determined in the fit of the QCD background, varying the definition of the misidentified jet sample, and eliminating the photon isolation cut.

The UED signal efficiency, determined from MC simulations, increases smoothly from $\approx 43 \%$ for $1 / R=500 \mathrm{GeV}$ to $\approx 48 \%$ for $1 / R=700 \mathrm{GeV}$, with the lower efficiencies for smaller $1 / R$ due mostly to the $E_{T}^{\text {miss }}>75 \mathrm{GeV}$ definition of the signal region. The various relative systematic uncertainties on the extraction of the UED signal cross section are summarized in Table II, including the dominant $11 \%$ uncertainty on the integrated luminosity [17]. Uncertainties on the efficiency for reconstructing and identifying the $\gamma \gamma$ pair arise mainly due to

TABLE II. Relative systematic uncertainties on the expected UED signal yield. For more details, see the text.

| Source of uncertainty | Uncertainty |
| :--- | :---: |
| Integrated luminosity | $11 \%$ |
| Photon reconstruction and identification | $4 \%$ |
| Effect of pileup | $2 \%$ |
| $E_{T}^{\text {miss }}$ reconstruction and scale | $1 \%$ |
| Signal MC statistics | $1 \%$ |
| Total | $12 \%$ |

differences between MC simulations and data in the distributions of the photon identification variables, the need to extrapolate to the higher $E_{T}$ values (see Fig. 1) typical of the UED photons, the impact of the photon quality cuts, varying the scale of the photon $E_{T}$ cut, and uncertainties in the detailed material composition of the detector. Together these provide a systematic uncertainty of $4 \%$. The influence of pileup, evaluated by comparing MC samples with and without pileup, gives a systematic uncertainty of $2 \%$. Systematic effects on the $E_{T}^{\text {miss }}$ reconstruction [14], including pileup, varying the cluster energies within the current uncertainties, and varying the expected $E_{T}^{\text {miss }}$ resolution between the measured performance and MC expectations, combine to give a $1 \%$ uncertainty on the signal efficiency. Finally, the $1 \%$ statistical error on the signal efficiency as determined by MC simulations is treated as a systematic uncertainty on the result. Adding in quadrature, the total systematic uncertainty on the signal yield is $12 \%$.

Given the good agreement between the measured $E_{T}^{\text {miss }}$ spectrum and the expected background, a limit was set on $1 / R$ in the specific UED model considered here. A Bayesian approach was used to calculate a limit based on the number of observed and expected events with $E_{T}^{\mathrm{miss}}>$ 75 GeV . A Poisson distribution was used as the likelihood function for the expected number of signal events, and a flat prior was used for the signal cross section. Log-normal priors were used for the various sources of uncertainty, which were treated as nuisance parameters. It was verified that the result is not very sensitive to the detailed form of the assumed priors. Figure 4 depicts the resulting 95\%C.L. upper limit within the context of the UED model considered, together with the LO UED cross section as a function of $1 / R$. The LO cross section was used since higher order corrections have not been calculated for the UED model. An uncertainty on the signal cross section due to parton distribution functions (PDF's) was determined by comparing the predictions using MRST2007 [18] PDF's with those from the full set of error PDF's of CTEQ6.6 [19]. The resultant uncertainty, namely $\pm 8 \%$ essentially independent of $1 / R$, is shown by the width of the theory curve band. The observed $95 \%$ C.L. exclusion region is $1 / R<$ 729 GeV . The result depends weakly on the systematic

FIG. 4 (color online). 95\%C.L. upper limits on the UED production cross section, and the LO theory cross section prediction, as a function of $1 / R$. The shaded band shows the PDF uncertainty.
uncertainties, and would only increase to 732 GeV if they were neglected. Changing the $E_{T}^{\text {miss }}$ cut to 60 or 90 GeV would change the limit by only a few GeV . A cross-check using a higher purity $\gamma \gamma$ sample, achieved by requiring that both photons pass tighter identification cuts that reject more of the background from jets, produced a consistent result.

In conclusion, a search for $\gamma \gamma$ events with large $E_{T}^{\text {miss }}$, conducted using a $3.1 \mathrm{pb}^{-1}$ sample of $7 \mathrm{TeV} p p$ collisions recorded with the ATLAS detector at the LHC, found no evidence of an excess above the SM prediction. The results were used to set limits on a specific model with one UED and gravity-induced LKP decays, excluding at the $95 \% \mathrm{C}$.L. values of $1 / R<729 \mathrm{GeV}$, and significantly surpassing the only existing experimental limit [7] on this model.

We wish to thank CERN for the efficient commissioning and operation of the LHC during this initial high-energy data-taking period as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS,

# Measurement of Dijet Azimuthal Decorrelations in $p p$ Collisions at $\sqrt{s}=7 \mathrm{TeV}$ 

G. Aad et al.*<br>(ATLAS Collaboration)

(Received 14 February 2011; published 29 April 2011)

#### Abstract

Azimuthal decorrelations between the two central jets with the largest transverse momenta are sensitive to the dynamics of events with multiple jets. We present a measurement of the normalized differential cross section based on the full data set ( $\int \mathcal{L} d t=36 \mathrm{pb}^{-1}$ ) acquired by the ATLAS detector during the $2010 \sqrt{s}=7 \mathrm{TeV}$ proton-proton run of the LHC. The measured distributions include jets with transverse momenta up to 1.3 TeV , probing perturbative QCD in a high-energy regime.

## DOI: 10.1103/PhysRevLett.106.172002

The production of events containing high transversemomentum $\left(p_{T}\right)$ jets is a key signature of quantum chromodynamic ( QCD ) interactions between partons in $p p$ collisions at large center-of-mass energies $(\sqrt{s})$. The Large Hadron Collider (LHC) opens a window into the dynamics of interactions with high- $p_{T}$ jets in a new energy regime of $\sqrt{s}=7 \mathrm{TeV}$. QCD predicts the decorrelation in the azimuthal angle between the two most energetic jets, $\Delta \phi$, as a function of the number of partons produced. Events with only two high $-p_{T}$ jets have small azimuthal decorrelations, $\Delta \phi \sim \pi$, while $\Delta \phi \ll \pi$ is evidence of events with several high- $p_{T}$ jets. QCD also describes the evolution of the shape of the $\Delta \phi$ distribution, which narrows with increasing leading jet $p_{T}$. Distributions in $\Delta \phi$ therefore test perturbative QCD (pQCD) calculations for multiple jet production without requiring the measurement of additional jets. Furthermore, a detailed understanding of events with large azimuthal decorrelations is important to searches for new physical phenomena with dijet signatures, such as supersymmetric extensions to the standard model [1].

In this Letter, we present a measurement of dijet azimuthal decorrelations with jet $p_{T}$ up to 1.3 TeV as measured by the ATLAS detector, beyond the reach of previous colliders. The differential cross section $(1 / \sigma)(d \sigma / d \Delta \phi)$ is based upon an integrated luminosity $\int \mathcal{L} d t=$ ( $36 \pm 4$ ) $\mathrm{pb}^{-1}$ [2]. The $\Delta \phi$ distribution is normalized by the inclusive dijet cross section $\sigma$, integrated over the same phase space. This construction minimizes experimental and theoretical uncertainties. Previous measurements of $\Delta \phi$ from the D0 [3] and CMS [4] Collaborations are extended here to higher jet $p_{T}$ values.
Jets are reconstructed using the anti- $k_{t}$ algorithm [5] (implemented with FASTJET [6]) with radius $R=0.6$, and the jet four-momenta are constructed from a sum over its constituents, treating each as an $(E, \vec{p})$ four-vector with

zero mass. The anti- $k_{t}$ algorithm is well motivated since it is infrared safe to all orders, produces geometrically welldefined conelike jets, and is used for PQCD calculations (from partons), event generators (from stable particles), and the detector (from energy clusters [7]). The azimuthal decorrelation $\Delta \phi$ is defined as the absolute value of the difference in azimuthal angle between the jet with the highest $p_{T}$ in each event, $p_{T}^{\max }$, and the jet with the second-highest $p_{T}$ in the event. There are nine analysis regions in $p_{T}^{\text {max }}$, where the lowest region is bounded by $p_{T}^{\max }>110 \mathrm{GeV}$ and the highest region requires $p_{T}^{\max }>$ 800 GeV [7]. Only jets with $p_{T}>100 \mathrm{GeV}$ and $|y|<2.8$, where $y$ is the jet rapidity [8], are considered. The two leading jets that define $\Delta \phi$ are required to satisfy $|y|<0.8$, restricting the measurement to a central $y$ region where the momentum fractions ( $x$ ) of the interacting partons are roughly equal and the experimental acceptance for multijet production is increased. In this region where $0.02 \leqslant x \lesssim$ 0.14 , the parton distribution function (PDF) uncertainties are typically $\pm 3 \%$ (at fixed factorization scale) [9]. The cross sections, measured over the range $\pi / 2 \leq \Delta \phi \leq \pi$ and normalized independently for each analysis region, are compared with expectations from a pQCD calculation [10] that is next-to-leading order (NLO) in three-parton production. The perturbative prediction for the cross section is $\mathcal{O}\left(\alpha_{s}^{4}\right)$, where $\alpha_{s}$ is the strong coupling constant.

The angular decorrelation is sensitive to multijet configurations such as those produced by event generators like SHERPA [11], which matches higher-order tree-level pQCD diagrams with a dipole parton-shower model [12]. Samples for $2 \rightarrow 2-6$ jet production are combined using an improved parton matching scheme [13]. Event generators such as PYTHIA [14] and HERWIG [15] use $2 \rightarrow 2$ leading order pQCD matrix elements matched with phenomenological parton-cascade models to simulate higher-order QCD effects. Such models have been successful at reproducing other QCD processes measured by the ATLAS Collaboration [7,16].

The ATLAS detector $[17,18]$ consists of an inner tracking system surrounded by a thin superconducting solenoid providing a 2 T magnetic field, electromagnetic and hadronic calorimeters, and a muon spectrometer based on
large superconducting toroids. Jet measurements depend most heavily on the calorimeters. The electromagnetic calorimeter is a lead liquid-argon (LAr) detector with an accordion geometry. Hadron calorimetry is based on two different detector technologies, with scintillator tiles or LAr as the active medium, and with either steel, copper, or tungsten as the absorber material. The pseudorapidity $(\eta)$ [8] and $\phi$ segmentations of the calorimeters are sufficiently fine to ensure that angular resolution uncertainties are negligible compared to other sources of systematic uncertainty.

A hardware-based calorimeter jet trigger identified events of interest; the decision was further refined in software $[17,18]$. Events with at least one jet that satisfied a minimum transverse energy $\left(E_{T}\right)$ requirement were recorded for further analysis. The events in each $p_{T}^{\max }$ range are selected by a single trigger with a given $E_{T}$ threshold, and the lower end of the range is chosen above the jet $p_{T}$ at which that trigger is $\approx 100 \%$ efficient. Three sets of triggered events with different integrated luminosity are considered: $2.3 \mathrm{pb}^{-1}$ for $110<p_{T}^{\max } \leq 160 \mathrm{GeV}, 9.6 \mathrm{pb}^{-1}$ for $160<p_{T}^{\max } \leq 260 \mathrm{GeV}$, and $36 \mathrm{pb}^{-1}$ for $p_{T}^{\max }>$ 260 GeV [2]. Events are also required to have a reconstructed primary vertex within 15 cm in $z$ of the center of the detector; each vertex had $\geq 5$ associated tracks. The inputs to the anti- $k_{t}$ jet algorithm are clusters of calorimeter cells seeded by cells with energy that is significantly above the measured noise [7]. Jets reconstructed in the detector, whether in data or the GEANT4-based simulation [19,20], are corrected for the effects of hadronic shower response and detector-material distributions using a $p_{T^{-}}$and $\eta$-dependent calibration [7] based on the detector simulation and validated with extensive test beam [18] and collision data [21] studies. Jets likely to have arisen from detector noise or cosmic rays are rejected [22].

The resulting $\Delta \phi$ distribution is shown in Fig. 1 for jets with $p_{T}>100 \mathrm{GeV}$. There are 146788 events in the data sample, 85 of which have at least five jets with $p_{T}>$ 100 GeV . Also shown is the PYTHIA sample with MRST 2007 LO* PDF [23] and ATLAS MC09 underlying event tune [24], processed through the full detector simulation and normalized to the number of events in the data sample. Two- and three-jet production primarily populates the region $2 \pi / 3<\Delta \phi<\pi$ while smaller values of $\Delta \phi$ require additional activity such as soft radiation or more jets in an event. Figure 1 illustrates that the decorrelation increases when a third high- $p_{T}$ jet is also required. Events with additional high- $p_{T}$ jets widen the overall distribution.

The measured differential $\Delta \phi$ distributions in data are corrected in a single step with a bin-by-bin unfolding method [7] to compensate for trigger and detector inefficiencies and the effects of finite experimental resolutions. These correction factors, evaluated using the PYTHIA sample, lie within $\pm 9 \%$ of unity. The leading sources of

FIG. 1 (color online). The $\Delta \phi$ distribution for $\geq 2, \geq 3, \geq 4$, and $\geq 5$ jets with $p_{T}>100 \mathrm{GeV}$. Overlaid on the calibrated but otherwise uncorrected data (points) are results from PYTHIA processed through the detector simulation (lines). All uncertainties are statistical only.
systematic uncertainty on the normalized cross section are the jet energy scale calibration ( $2 \%-17 \%$ ) [7], the bin-bybin unfolding method ( $1 \%-19 \%$ ), and the jet energy and position resolutions $(0.5 \%-5 \%)$. The ranges in parentheses represent the magnitude of the uncertainties near $\pi$ and $\pi / 2$, respectively, and correspond to the analysis region with the smallest statistical uncertainty $\left(160<p_{T}^{\max } \leq\right.$ 210 GeV ). Multiple $p p$ interactions in the same beam crossing that can increase the measured jet energy are included in the evaluation of the jet energy scale uncertainties $(<0.8 \%$ on the cross section for all analysis regions).

The normalized differential cross section is shown for each of the nine $p_{T}^{\max }$ analysis regions as a function of $\Delta \phi$ in Fig. 2. As $p_{T}^{\max }$ increases, and the probability for the emission of a hard third jet is reduced, the fraction of events near $\pi$ becomes larger. Overlaid on the data are the results from a NLO pQCD $\left[\mathcal{O}\left(\alpha_{s}^{4}\right)\right]$ calculation, NLOJET + + [10] with FASTNLO [25] and using the MSTW 2008 PDF [9]. The factorization and renormalization scales are set to $p_{T}^{\max }$ and are varied independently up and down by a factor of 2 to determine the scale uncertainties. The scale uncertainties are larger between $\pi / 2<$ $\Delta \phi<2 \pi / 3$ where the pQCD calculation is effectively leading order in four-parton production. The PDF uncertainties are treated as the envelope of the $68 \%$ C.L. uncertainties from MSTW 2008 [9], NNPDF 2.0 [26], and CTEQ 10 [27], and are combined with the uncertainties resulting from an $\alpha_{s}$ variation of $\pm 0.004$; the $\alpha_{s}$ contributions dominate. The calculation is corrected for nonperturbative effects due to hadronization and the underlying event [28]; the correction is smaller than $3 \%$. The fixedorder calculation fails near $\Delta \phi \rightarrow \pi$ where soft processes dominate and contributions from logarithmic terms are enhanced. Figure 3 displays the ratio of the cross section

FIG. 2 (color online). The differential cross section $(1 / \sigma) \times$ $(d \sigma / d \Delta \phi)$ binned in nine $p_{T}^{\max }$ regions. Overlaid on the data (points) are results from the NLO pQCD calculation. The error bars on the data points indicate the statistical (inner error bar) and systematic uncertainties added in quadrature in this and subsequent figures. The theory uncertainties are indicated by the hatched regions. Different bins in $p_{T}^{\max }$ are scaled by multiplicative factors of 10 for display purposes. The region near the divergence at $\Delta \phi \rightarrow \pi$ is excluded from the calculation.
with respect to the NLO calculation. In most regions, the theory is consistent with the data. However, the prediction in the range $110<p_{T}^{\max }<160 \mathrm{GeV}$ is relatively low in the central region of $\Delta \phi$ where the scale uncertainties are small.

The data are also compared with predictions [29] from sherpa, pythia, and herwig in Fig. 4. The leadinglogarithmic approximations used in these event generators' parton-shower models effectively regularize the divergence at $\Delta \phi \rightarrow \pi$; all three provide a good description of the data in this region. In the region $\pi / 2<\Delta \phi<5 \pi / 6$, where multijet contributions are significant, this observable distinguishes between the three generators. SHERPA, which explicitly includes higher-order tree-level diagrams, performs well in most $\Delta \phi$ and $p_{T}^{\max }$ regions. Having phenomenological parameters that have been adjusted to previous ATLAS measurements, PYTHIA [28] and HERWIG [24] also describe the data.

In summary, we present a measurement of dijet azimuthal decorrelations in events produced in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$. The normalized differential cross sections

FIG. 3 (color online). Ratio of the differential cross section $(1 / \sigma)(d \sigma / d \Delta \phi)$ measured in data with respect to expectations from NLO pQCD (points). The theory uncertainties are indicated by the hatched regions. The region near the divergence at $\Delta \phi \rightarrow \pi$ is excluded from the comparison.
are based on the full data set ( $\int \mathcal{L} d t=36 \mathrm{pb}^{-1}$ ) collected by the ATLAS Collaboration during the 2010 run of the LHC. Expectations from NLO pQCD $\left[\mathcal{O}\left(\alpha_{s}^{4}\right)\right]$ and those of

FIG. 4 (color online). Ratio of the differential cross section $(1 / \sigma)(d \sigma / d \Delta \phi)$ measured in data with respect to the result from SHERPA (points). The shaded region indicates the SHERPA statistical uncertainty. Predictions from PYTHIA and HERWIG, also in ratio to SHERPA, are displayed as lines.
several event generators successfully describe the general characteristics of our measurements, including the increasing slope of the $\Delta \phi$ distribution with $p_{T}^{\max }$ and the shape near $\Delta \phi \sim \pi / 2$ where events with multiple jets make a considerable contribution. Our data, which include jets with $p_{T}$ values that significantly exceed earlier measurements, explore QCD in a new kinematic region.

We wish to thank CERN for the efficient commissioning and operation of the LHC during this initial high-energy data-taking period as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNRF, DNSRC, and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG, and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP, and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society, and Leverhulme Trust, United Kingdom; DOE and NSF, U.S. The crucial computing support from all WLCG partners is gratefully acknowledged, in particular, from CERN and the ATLAS Tier- 1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (U.S.), and in the Tier-2 facilities worldwide.

[8] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point in the center of the detector. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam axis. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$. Rapidity is defined as $y=\frac{1}{2} \ln \left[\left(E+p_{z}\right) /\left(E-p_{z}\right)\right]$, where $E$ is the energy and $p_{z}$ is the longitudinal component of the momentum along the beam direction.

# Search for Dilepton Resonances in $p p$ Collisions at $\sqrt{s}=7 \mathrm{TeV}$ with the ATLAS Detector 

G. Aad et al.*<br>(ATLAS Collaboration)

(Received 7 August 2011; published 29 December 2011)

#### Abstract

This Letter reports on a search for narrow high-mass resonances decaying into dilepton final states. The data were recorded by the ATLAS experiment in $p p$ collisions at $\sqrt{s}=7 \mathrm{TeV}$ at the Large Hadron Collider and correspond to a total integrated luminosity of $1.08(1.21) \mathrm{fb}^{-1}$ in the $e^{+} e^{-}\left(\mu^{+} \mu^{-}\right)$channel. No statistically significant excess above the standard model expectation is observed and upper limits are set at the $95 \%$ C.L. on the cross section times branching fraction of $Z^{\prime}$ resonances and Randall-Sundrum gravitons decaying into dileptons as a function of the resonance mass. A lower mass limit of 1.83 TeV on the sequential standard model $Z^{\prime}$ boson is set. A Randall-Sundrum graviton with coupling $k / \bar{M}_{\mathrm{P} 1}=0.1$ is excluded at 95\% C.L. for masses below 1.63 TeV .

This Letter describes a search for narrow high-mass resonances decaying into $e^{+} e^{-}$or $\mu^{+} \mu^{-}$pairs using $7 \mathrm{TeV} p p$ collision data recorded with the ATLAS detector [1]. Such resonances, which are predicted by several extensions of the standard model (SM), include new heavy spin-1 neutral gauge bosons such as $Z^{\prime}[2-4]$ and $Z^{*}[5]$, technimesons [6-8], as well as spin-2 Randall-Sundrum (RS) gravitons $G^{*}$ [9].

The benchmark models considered for the $Z^{\prime}$ are the sequential standard model (SSM) [2], with the same couplings to fermions as the $Z$ boson, and the $E_{6}$ grand unified symmetry group [4], broken into $S U(5)$ and two additional $U(1)$ groups, leading to new neutral gauge fields $\psi$ and $\chi$. The particles associated with the additional fields can mix in a linear combination to form the $Z^{\prime}$ candidate: $Z^{\prime}\left(\theta_{E_{6}}\right)=$ $Z_{\psi}^{\prime} \cos \theta_{E_{6}}+Z_{\chi}^{\prime} \sin \theta_{E_{6}}$, where $\theta_{E_{6}}$ is the mixing angle between the two gauge bosons. The pattern of spontaneous symmetry breaking and the value of $\theta_{E_{6}}$ determine the $Z^{\prime}$ couplings to fermions; six well-motivated choices of $\theta_{E_{6}}$ $[2,4]$ lead to the specific $Z^{\prime}$ states named $Z_{\psi}^{\prime}, Z_{N}^{\prime}, Z_{\eta}^{\prime}, Z_{I}^{\prime}$, $Z_{S}^{\prime}$, and $Z_{\chi}^{\prime}$.

Other models predict additional spatial dimensions as a possible explanation for the gap between the electroweak symmetry breaking scale and the gravitational energy scale. The RS model [9] predicts excited Kaluza-Klein modes of the graviton, which appear as spin-2 resonances. These modes have a narrow intrinsic width when $k / \bar{M}_{\mathrm{PI}}<0.1$, where $k$ is the spacetime curvature in the extra dimension and $\bar{M}_{\mathrm{Pl}}=M_{\mathrm{Pl}} / \sqrt{8 \pi}$ is the reduced Planck scale.

Previous searches have set direct and indirect constraints on the mass of the $G^{*}$ and $Z^{\prime}$ resonances [10,11]. The

[^35]Tevatron $[12,13]$ experiments exclude a $Z_{\text {SSM }}^{\prime}$ with a mass lower than 1.071 TeV [13]. Recent measurements from the LHC experiments, based on $\approx 40 \mathrm{pb}^{-1}$ of data recorded in 2010, exclude a $Z_{\text {SSM }}^{\prime}$ with a mass lower than 1.042 TeV (ATLAS) [14] and 1.140 TeV (CMS) [15]. Indirect constraints from LEP [16-19] extend these limits to 1.787 TeV [11]. Constraints on the mass of the RS graviton have been set by the CMS [15], CDF [20], and D0 [21] Collaborations, excluding RS gravitons with mass below 1.079 TeV for $k / \bar{M}_{\mathrm{Pl}}=0.1[15]$.

The ATLAS detector consists of inner tracking devices surrounded by a 2 T superconducting solenoid, electromagnetic and hadronic calorimeters, and a muon spectrometer with a toroidal magnetic field. Charged particles in the pseudorapidity range $|\eta|<2.5$ [22] are reconstructed with the inner detector, which consists of silicon pixel, silicon strip, and transition radiation detectors. The superconducting solenoid is surrounded by a hermetic calorimeter that covers $|\eta|<4.9$. For $|\eta|<2.5$, the electromagnetic calorimeter is finely segmented and plays an important role in electron identification. Outside the calorimeter, air-core toroids provide the magnetic field for the muon spectrometer. Three sets of precision drift tubes and cathode strip chambers provide an accurate measurement of the muon track curvature in the region $|\eta|<2.7$. Resistive-plate and thin-gap chambers provide muon triggering capability up to $|\eta|<2.4$.

The data sample used in this analysis, recorded during the first half of 2011, corresponds to a total integrated luminosity of $1.08(1.21) \mathrm{fb}^{-1}$ in the $e^{+} e^{-}\left(\mu^{+} \mu^{-}\right)$channel. Events are required to pass single electron (muon) triggers with a transverse energy $E_{T}$ (transverse momentum $p_{T}$ ) threshold above $20(22) \mathrm{GeV}$. Collision candidates are selected by requiring a primary vertex with at least three associated charged particle tracks with $p_{T}>0.4 \mathrm{GeV}$.

In the $e^{+} e^{-}$channel, two electron candidates are required with transverse energy $E_{T}>25 \mathrm{GeV}$ and $|\eta|<2.47$; the transition region $1.37 \leq|\eta| \leq 1.52$
between the barrel and the end cap calorimeters is excluded. Electron candidates are formed from clusters of cells reconstructed in the electromagnetic calorimeter associated with a charged particle track in the inner detector. Criteria on the transverse shower shape, the longitudinal leakage into the hadronic calorimeter, and the association with an inner detector track are applied to the cluster to define a so-called medium electron [23,24]. The electron energy is obtained from the calorimeter measurement and its direction from the associated track. A hit in the first active pixel layer is required to suppress background from photon conversions. To further suppress background from QCD jet production, the higher $E_{T}$ electron is required to be isolated by demanding that $\Sigma E_{T}(\Delta R<0.2)<$ 7 GeV , where $\Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}$ and $\Sigma E_{T}(\Delta R<0.2)$ is the sum of the transverse energies around the electron direction. The core of the electron energy deposition is excluded and the sum is corrected for transverse shower leakage and pileup from additional $p p$ collisions. The two electron candidates are not required to have opposite charge to minimize the impact of possible charge misidentification. For these selection criteria, the total signal acceptance for a $Z^{\prime} \rightarrow e^{+} e^{-}\left(G^{*} \rightarrow e^{+} e^{-}\right)$of mass 1.5 TeV is $65 \%$ ( $69 \%$ ), and is approximately independent of mass above 600 GeV . These numbers include the acceptance of all selection cuts and efficiencies and reflect the lepton angular distributions due to spin.

In the $\mu^{+} \mu^{-}$channel, two muon candidates of opposite charge are required, each satisfying $p_{T}>25 \mathrm{GeV}$. Muon tracks are reconstructed independently in both the inner detector and muon spectrometer, and their momenta are determined from a combined fit to these two measurements. To optimize the momentum resolution, each muon candidate is required to pass quality cuts in the inner detector and to have at least three hits in each of the inner, middle, and outer layers of the muon system. Muons with hits in both the barrel and the end cap regions are discarded because of residual misalignment between these two parts of the muon spectrometer. The effects of misalignments and intrinsic position resolution are included in the simulation. The $p_{T}$ resolution at 1 TeV ranges from $15 \%$ (central) to $44 \%$ (for $|\eta|>2$ ).

To suppress background from cosmic rays, the muon tracks are required to have a transverse impact parameter $\left|d_{0}\right|<0.2 \mathrm{~mm}$, a distance along the beam line to the primary vertex below 1 mm , and the $z$ position of the primary vertex $|z(\mathrm{PV})|<200 \mathrm{~mm}$. To reduce background from QCD jets, each muon is required to be isolated such that $\Sigma p_{T}(\Delta R<0.3) / p_{T}(\mu)<0.05$, where only tracks with $p_{T}>1 \mathrm{GeV}$ enter the sum. The total signal acceptance is $40 \%(44 \%)$ for a $Z^{\prime} \rightarrow \mu^{+} \mu^{-}\left(G^{*} \rightarrow \mu^{+} \mu^{-}\right)$of mass 1.5 TeV . The lower acceptance compared to the electron channel is due to the stringent requirements on the muon selection criteria to improve $p_{T}$ resolution.

For both channels, the dominant and irreducible background is due to the $Z / \gamma^{*}$ (Drell-Yan) process, characterized by the same final state as the signal. Small contributions from $t \bar{t}$ and diboson ( $W W, W Z$, and $Z Z$ ) production are also present in both channels. Semileptonic decays of $b$ and $c$ quarks in the $\mu^{+} \mu^{-}$ sample and a mixture of photon conversions, semileptonic heavy quark decays, and hadrons faking electrons in the $e^{+} e^{-}$sample are backgrounds that are referred to below as QCD background. Jets accompanying $W$ bosons ( $W+$ jets) may similarly produce lepton candidates.
