Abstract

The effects of different transition metal halides (TiCl_3 , VCl_3 , ScCl_3 and NiCl_2) on the sorption properties of the 1:1 molar ratio of LiNH_2 to MgH_2 are investigated. The modified mixtures were found to contain LiNH_2 , MgH_2 and LiCl . TGA results showed that the hydrogen desorption temperature was reduced with the modifier addition in this order: $\text{TiCl}_3 > \text{ScCl}_3 > \text{VCl}_3 > \text{NiCl}_2$. Ammonia release was not significantly reduced resulting in a weight loss greater than the theoretical hydrogen storage capacity of the material. The isothermal sorption kinetics of the modified systems showed little improvement after the first dehydrogenation cycle over the unmodified system but showed drastic improvement in rehydrogenation cycles. X-ray diffraction and Raman spectroscopy identified the cycled material to be composed of LiH , MgH_2 , $\text{Mg}(\text{NH}_2)_2$ and Mg_3N_2 .

Key words: Hydrogen storage; Amides; Metal Hydrides; Kinetics; Raman; XRD

1 Introduction

In a study of more than 300 destabilization reactions using first principle density function theory (DFT), Alapati *et al.* predicted that the reaction between 1:1 MgH₂ and LiNH₂ was energetically favorable with an enthalpy of 31.9 kJ/molH₂ [1]. In 2007, Lu *et al.* showed that the reaction between MgH₂ and LiNH₂ in a 1:1 molar ratio a new binary light metal nitride, LiMgN, was created for hydrogen storage applications [2]. The initial dehydrogenation reaction pathway was identified as:

This 1:1 molar ratio of MgH₂ to LiNH₂ mixture has a theoretical hydrogen storage capacity of 8.2 wt%. The experimental heat of reaction was measured to be 33.5 kJ/mol H₂ [2], very close to the predicted enthalpy.

Through first-principle calculations of total energies and vibrations free energies, it was suggested that the initial decomposition of 1:1 LiNH₂: MgH₂ will proceed as in the following reaction steps [3]:

The first predicted decomposition step would be the exothermic formation of magnesium amide. In the next step, half of the MgH₂ and half of the Mg(NH₂)₂ would form Mg₃N₂ through the endothermic reaction, releasing H₂ with an enthalpy of 15 kJ/mol H₂ [3]. The third step is a decomposition reaction which produces a mixed Li-Mg imide with an enthalpy of 47 kJ/mol H₂ [3]. Finally, the ternary nitride is formed with an enthalpy of 80 kJ/mol H₂ at 227°C. However, the proposed rehydrogenation and subsequent dehydrogenation process of LiMgN produces LiH, Mg(NH₂)₂ and MgH₂, as [2]:

Transition metals have been shown to significantly improve kinetics and reduction of dehydrogenation temperatures in many hydrogen storage systems, including NaAlH₄ [4-8], MgH₂ [9-12], the 1:1 MgH₂:LiNH₂ [2, 13] and 2:1 LiNH₂:MgH₂ [14]. Through the electronic structure and total energy calculation using first principle calculations on the effect of titanium on MgH₂, Song *et al.* found that the bond between magnesium and hydrogen was weakened [15]. Liang *et al.* investigated the impact of transition metals on hydrogen desorption of MgH₂ at 300°C and found that the transition metal chemisorbs hydrogen and transfers it to the Mg matrix creating a nucleation site for the hydride phase [12]. Lu *et al.* observed an increase in hydrogen absorption kinetics of 1:1 LiNH₂:MgH₂ with the addition of 4 wt% TiCl₃ resulting in an increase in capacity from 5 wt% to 7.9 wt% [2]. For the 2:1 LiNH₂:MgH₂ system, through density of states analysis, Wang *et al.* found that the N-H bonds were weakened by a Ti atom substituted by a Li atom and the decreased energy value of Li vacancy formation indicated improvement in rehydrogenation of Li₂MgN₂H₂ with Ti additive [14].

One issue related to the application of metal-N-H storage systems is ammonia formation that takes place simultaneously with H₂ release [16, 17]. Through the use of Draeger tubes on the 2:1 LiNH₂:MgH₂ system, Luo *et al.* showed that ammonia concentration was strongly dependent on the desorption temperature with concentrations

of 180ppm measured at 180°C and 720ppm at 240°C [17]. In a separate analysis, the effect of milling duration on ammonia release from the 2:1 mixture during heating was investigated, resulting in over 30 ppm/mg for unmilled samples and under 10 ppm/mg for samples milled for 180 minutes using high-energy milling [18]. In a separate study on the effect of the variation of LiH composition in the $\text{Mg}(\text{NH}_2)_2 - \text{LiH}$ mixture, Hu *et al.* observed that if the molar ratio of LiH was below 2, ammonia evolution occurred during dehydrogenation reactions and if the molar ratio was above 2 a reduction in hydrogen storage efficiency was observed [19]. During hydrogen sorption of the 2:1 LiH: $\text{Mg}(\text{NH}_2)_2$ mixture, they observed a ternary imide with the composition of $\text{Li}_2\text{Mg}_2(\text{NH})_3$ as an intermediate [19, 20].

In this present article, we report the effects of different metal halide additions on the ammonia release and isothermal sorption kinetics of the 1:1 $\text{LiNH}_2:\text{MgH}_2$ system. The influence of these halides has been investigated using thermogravimetric analysis (TGA), isothermal kinetics, x-ray diffraction (XRD) and Raman spectroscopy.

2 Experimental Procedures

The starting materials, lithium amide (LiNH_2 , 95 % purity, Aldrich), magnesium hydride (MgH_2 , >97% purity, Gelest Inc), titanium chloride (TiCl_3 , 99%, Aldrich), nickel chloride (NiCl_2 , 99%, Aldrich), scandium chloride (ScCl_3 , 99 %, Aldrich) and vanadium chloride (VCl_3 , 99%, Aldrich) were purchased and used without alteration. Mixtures of LiNH_2 and MgH_2 with and without 1.5 mol% of the transition metal halides were prepared using Fritsch planetary milling technique. Three grams of mixtures were loaded into the milling jars in the argon glove box while maintaining a 30:1 ball to sample weight ratio. The powders were milled for 2 hours with 30 minute cycles at 500 rpm.

Desorption properties were monitored as a function of temperature and time using a thermogravimetric analyzer (TGA) coupled with a residual gas analyzer (RGA). The TGA was located inside an argon glove box to prevent the samples from oxidizing. Eight milligram samples were loaded into a stainless steel microbalance pan and heated from 30°C to 400°C with a heating rate of 5°C /min under a constant flow of argon gas. The effluent gases from the TGA were constantly monitored for H_2 , NH_3 , H_2O and O_2 using a Hiden Analytical residual gas analyzer (RGA).

Hydrogen desorption and absorption kinetics measurements were carried out using a Sievert's apparatus (PCTPro-2000, Setaram). Approximate 0.5 gram samples were loaded into a stainless steel reactor vial and sealed in a glovebox. Standard isothermal discharge procedure called for heating of the sample under 110 bar or greater, in order to prevent premature hydrogen release to occur while heating. Once the desired discharge temperature was reached, the sample was discharged into the largest reservoir, 1170 mL, into a backpressure of 1 bar. During subsequent recharging cycles, the sample was heated to 180°C under active vacuum and then exposed to 100 bar of H_2 pressure. During the dehydrogenation and hydrogenation cycles, the sample temperature and reservoir pressure were recorded. The amount of H_2 discharge and uptake was determined from the changes in pressure within the calibrated volume reservoirs. A

blank reactor vial was run under standard discharge conditions to identify the effects of gas thermal expansion during heating and volume expansion.

Powder x-ray diffraction (XRD) patterns of the as-milled, dehydrogenated and rehydrogenated materials were collected using a Rigaku Dmax/2100 (Cu K_{α} radiation). The samples were mounted on a glass slide and covered with Kapton[®] film while under argon. The XRD patterns were recorded at 2θ spanning 5 to 80° with a scanning rate of $0.02^{\circ}/\text{min}$.

Raman spectra were obtained with 532 nm excitation (Verdi-2W, Coherent, Inc.) in the backscattering mode, using an imaging probe (MultiRxn Probe, Kaiser Optical Systems) with a 5 mm working distance. Excitation powers were restricted to less than 20 mW at the sample, in a spot approximately 200 μm in diameter, to avoid sample degradation. No sample changes were visible after irradiation under these conditions. Scattered light was detected with a holographic spectrometer (Holospec VPH, Kaiser Optical Systems) and CCD camera (DV420A, Andor) electrically cooled to -55°C . Spectral resolution is $4\text{-}6\text{ cm}^{-1}$, with a shift accuracy of $\pm 1\text{ cm}^{-1}$. Spectra were measured at room temperature (approximately 20°C). Samples were contained in a sealed quartz vial; contributions of the vial to the spectra were subtracted. These samples exhibited a large background signal, probably due to scattering by metallic Mg (present in the MgH_2 source) and/or Ti (from TiCl_3 in the modified samples). The background was simulated by fitting to a polynomial and then subtracted. Despite this step, some of the weaker Raman bands presumed to be present (e.g. for MgH_2) could not be recovered.

3 Results and Discussion

3.1 Characterization of As-milled Systems

Figure 1 compares the XRD patterns of the unmodified, TiCl_3 and ScCl_3 modified mixtures after milling. Identification of LiCl peaks, shows clearly that the halide addition promoted initial decomposition of LiNH_2 . This was a typical observation for all the 1:1 $\text{LiNH}_2:\text{MgH}_2$ mixtures with transition metal halide modifiers. Furthermore, the unmodified mixture showed no indication of such a decomposition, which is in agreement with the results from Liu *et al.*, who observed the absence of gas evolution for milling times under 12 hours at 500 rpm [21].

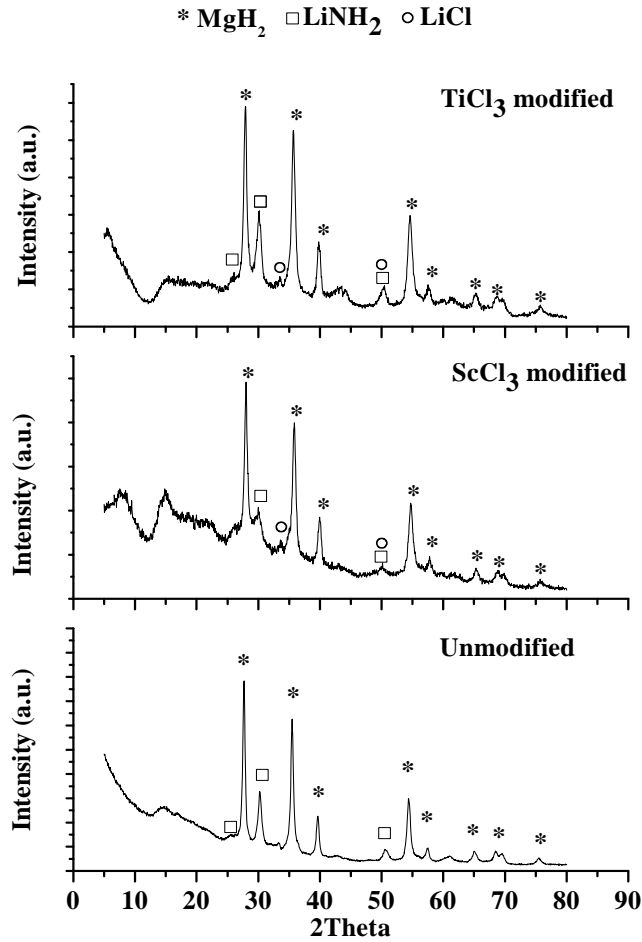

Figure 1. XRD analysis of unmodified (bottom), ScCl₃ (middle) and TiCl₃ (top) modified 1:1 LiNH₂:MgH₂ after 2 hours of Fritsch milling at 500rpm.

3.2 Decomposition of the modified and unmodified systems

The TGA curves of the unmodified and modified materials show that the weight loss of the modified mixture starts at lower temperatures than the unmodified, as seen in Figure 2. The slight increase in weight percent observed at the beginning of the TGA curves are attributed to a buoyancy effect as the carrier gas is heated.

Figure 2. TGA analysis of the decomposition of unmodified and modified 1:1 $\text{LiNH}_2\text{:MgH}_2$ mixture at a heating rate of $5^\circ\text{C}/\text{min}$.

By determining the derivative of weight change with time over a given time period, the initial hydrogen desorption temperature of the unmodified mixture was determined to be in the range of 135 to 145°C , which is slightly higher than the initial desorption temperature observed by Lu *et al.* of 120°C for samples synthesized using jar roll milling for 24 hours [2]. The ability of the metal halides to reduce the initial temperature of desorption follows the order: $\text{TiCl}_3 > \text{ScCl}_3 > \text{VCl}_3 > \text{NiCl}_2$. The approximate ranges for the modified samples are listed in Table 1.

The RGA results of hydrogen gas composition during the TGA experiments are given in Figure 3. This data show the unmodified material decomposition is comprised of three hydrogen releases steps. With the initial hydrogen release starting between 135 and 145°C and peaking at approximately 205°C , the sample lost $1\text{ wt}\%$. The second hydrogen release peaked at 260°C . During this time, a total of $6.48\text{ wt}\%$ was lost. It was during this step that NH_3 also peaked at 265°C , as illustrated in Figure 4. A similar ammonia emission temperature was observed by Liang, *et al.* for a 1:1 $\text{LiNH}_2\text{:MgH}_2$ milled for 2 hours [22]. The third hydrogen release peaked at 340°C . The unmodified mixture lost a total of $10.94\text{ wt}\%$ during decomposition, which is significantly higher than the theoretical hydrogen capacity of $8.14\text{ wt}\%$. This increase is attributed to release of ammonia from the decomposition of unreacted LiNH_2 and the slow reaction kinetics between MgH_2 and NH_3 [17, 18].

The total weight lost by the 1:1 $\text{LiNH}_2\text{:MgH}_2$ mixture with $1.5\text{ mol}\%$ TiCl_3 is $8.00\text{ wt}\%$, which is slightly higher than the theoretical hydrogen capacity of $7.85\text{ wt}\%$.

From Table 1, the range of initial hydrogen release is between 90 and 100°C, which is a significant reduction in temperature from the unmodified mixture. The other hydrogen releases were also shifted to lower temperatures indicating that the TiCl₃ promoted the dehydrogenation reaction, as depicted in Figure 3. Ammonia release peaked at approximately 245°C, as illustrated Figure 4, which is a 20°C reduction from the unmodified. The sample containing VCl₃, where initial H₂ release occurred between 110 and 120°C, showed very similar reduction in peak hydrogen and ammonia release temperatures. However, as seen in Table 1, the measured weight loss was significantly lower than the theoretical capacity indicating possible hydrogen release during milling.

The addition of ScCl₃ significantly impacted the 1:1 LiNH₂:MgH₂ mixture, resulting in the largest weight loss of the modified samples with 10.53 wt%, which is nearly 40 % larger than its theoretical H₂ capacity of 7.48 %. It also resulted in only 2 peak hydrogen releases, as shown in Figure 3. The first hydrogen release peaked at 270°C with a total of 8.3 wt% lost, which included both H₂ and NH₃ emission. The peak ammonia release temperature was at approximately 280°C, which is a 15°C increase from the unmodified sample. The second peak hydrogen release was at approximately 335°C where the remaining weight loss was attributed to hydrogen release.

From the addition of transition metal halides, the initial hydrogen desorption temperature of the 1:1 LiNH₂:MgH₂ system was reduced. As seen in Table 1, the initial hydrogen desorption for the modified systems began between 90°C and 120°C, which is lower than the release temperature of 135°C for the unmodified material, with TiCl₃ and ScCl₃ having the largest effect on temperature reduction. From literature, scandium has been shown to dissociate the Mg-H bonds since Sc has the lowest 3d orbital occupancy among the 3d transition metals which largely contributes to the donation of the electrons from the bonding orbitals to MgH₂ [23]. This suggests that Ti and Sc are more effective at allowing the conversion of LiNH₂ and MgH₂ to LiH, Mg(NH₂)₂ and H₂ to occur at a lower temperature by weakening the Mg-H bond. However, it is important to note that the NiCl₂ modified sample showed the largest hydrogen release prior to 300°C, which peaked at 275°C. This is also similar to the results reported by Tsuda et al., who showed that the high 3d orbital occupancy of Ni contributes to the back-donation of the electrons to the antibonding orbitals of MgH₂ allowing for easier Mg-H dissociation [23].

Additive compositions also greatly effected ammonia release. As seen in Figure 4, the mixtures with TiCl₃ and VCl₃ released ammonia at temperatures lower than the unmodified material, while the mixtures modified with ScCl₃ and NiCl₂ increased the temperature. As seen by the XRD pattern for the TiCl₃ and ScCl₃ samples, in **Error! Reference source not found.**, LiCl formed during milling via a metathesis reaction between LiNH₂ and the halide. It is possible that during decomposition, the metathesis reaction was promoted, resulting in the further formation of LiCl and release of NH₃. Also, as stated by Liang *et al.*, ammonia release could be the result from thermal self-decomposition of LiNH₂ due to its large particle size and uneven mixing with MgH₂ cause by the short milling time [22].

Figure 3. RGA curves of the hydrogen (Mass 2) release for the unmodified and modified 1:1 $\text{LiNH}_2:\text{MgH}_2$ mixtures after milling for 2 hours.

Figure 4. RGA curves of the ammonia release for the unmodified and modified 1:1 $\text{LiNH}_2:\text{MgH}_2$ mixtures after milling for 2 hours.

Table 1. Summary of TGA/RGA decomposition data of the as-milled 1:1 LiNH₂:MgH₂ samples with and without various modifiers while heating from RT to 400°C at 5°C/min.

Modification	Theoretical H ₂ Wt %	Total Wt % Released	Initial Onset Temperature (°C)	H ¹ (°C)	H ² (°C)	H ³ (°C)	Peak NH ₃ Release Temperature (°C)
Unmodified	8.14	10.94	135 - 145	205	260	340	260
1.5 mol% TiCl ₃	7.85	8.00	90-100	200	240	285	245
1.5 mol% VCl ₃	7.46	6.55	110-120	190	240	290	245
1.5 mol% ScCl ₃	7.48	10.53	110-115	-	270	335	280
1.5 mol% NiCl ₂ (by 300°C)	7.57	6.83	120-130	210	275	-	270

3.2.1 Effect of Modifiers on Isothermal Sorption Kinetics

The impact of the modifiers on the kinetic performance during the isothermal sorption of 1:1 LiNH₂:MgH₂ was also investigated. The overall sorption rate during the first 30 minutes (0.5 hours) of the first and fourth dehydrogenation cycles are shown in Figure 5. The sharp change in slope observed during the first desorption cycle indicates a change in reaction mechanisms and kinetics.

Figure 5. First (solid) and fourth (hollow) isothermal desorption curves at 260°C into 1 bar for the (black) unmodified and samples containing 1.5 mol% (blue) TiCl₃, (red) VCl₃, (green) NiCl₂ and (purple) ScCl₃ modifiers.

During the fourth desorption cycle, illustrated in Figure 5, a significant reduction in kinetics is observed for all samples. The addition of the modifiers lowered the initial desorption temperature but they did not enhance the kinetics of the isothermal desorption reaction past the first cycle, which is similar to the results observed by Lohstroh *et al.* for TiCl_3 with the 2:1 $\text{LiNH}_2:\text{MgH}_2$ [24]. Over four cycles, the samples desorbed 2.0 wt%, this is significantly lower than the theoretical hydrogen capacity for the system. Possible barriers preventing full capacity sorption are discussed below.

After each desorption cycles, vacuum was applied to the sample for 30 minutes while it cooled from 260°C to 180°C , providing a fully desorbed sample. During the absorption cycles at 180°C , the samples recharged between 4 and 6 wt%, with the ScCl_3 and NiCl_2 modified sample having the highest absorption capacity followed by the unmodified, VCl_3 and TiCl_3 samples respectively.

Figure 6. Overall bed discharge (A) and recharge (B) rates determined from isothermal dehydrogenation cycle at 260°C into 1 bar of back pressure and rehydrogenation cycle at 180°C under 100 bar hydrogen.

In order to compare the rates of charge and discharge to the DOE 2010 technical targets, the average sorption rate in grams of hydrogen per second per gram of media during the first 30 minutes of cycling was determined and reported here as $[\text{gH}_2/\text{s}]/\text{kg}_{\text{material}}$. This rate was then converted to bed discharge/charge rate using the estimated bed size, to hold 5 kg of H_2 . The US DOE has set the goal of minimum charging rates of 20 g/sec. and discharging rates of 5 g/sec. for a 5 kg capacity storage system [25]. The current rates of sorption are significantly below these goals, as seen in Figure 6. One possible cause for low sorption rates is the possible loss of nitrogen through NH_3 emission and the formation of magnesium nitride, Mg_3N_2 , which is the predominate product seen from XRD in Figure 7(A). Another cause could be the agglomeration of particle due to the high discharge temperature, as seen from the increase in average MgH_2 from 35 nm (as-milled) to 50 nm after cycling. Achievement of enhanced kinetics with minimal effect to capacity will be required to warrant further development and implementation of these materials.

3.2.2 Phase Identification

XRD analysis was performed after the second discharged at 260°C and the fourth rehydrogenation cycle at 180°C on the unmodified 1:1 LiNH₂:MgH₂. The XRD spectrum for the dehydrogenated sample shown Figure 7 in identifies cubic LiMgN and Mg₃N₂, similar to the results observed by Lu *et al.* [2, 13].

Figure 7. XRD pattern of 1:1 LiNH₂:MgH₂ without modifications (A) after 2nd desorption and (B) 4th absorption. The diffraction pattern of the dehydrogenated product is similar to that of cubic LiMgN identified by Lu *et al.* [2, 13] and Mg₃N₂ while the predominate components of the absorption pattern include MgH₂, LiH, Mg(NH₂)₂ and Mg₃N₂.

However, the Li₂Mg₂(NH)₃ observed by Osborn *et al.* after dehydrogenation at 210°C [25] was not observed. The XRD pattern of the hydrogenated sample after the 4th absorption cycle in Figure 7(B) shows that after the fourth rehydrogenation Mg₃N₂, MgH₂, LiH and Mg(NH₂)₂ are the dominant products. Here again, the Li₂Mg₂(NH)₃ phase seen by Lui *et al.* [21] in their rehydrogenated sample was not observed in the XRD pattern. The discrepancies with the reported literature were attributed different sample preparation techniques and cycling conditions.

Figure 8. The XRD spectra after the 1st complete cycle of 1:1 LiNH₂:MgH₂ modified with 1.5 mol% TiCl₃ or VCl₃ showing the predominant recharged species to be MgH₂, LiH, and Mg₃N₂. Since the sample was not annealed before x-ray examination, Mg(NH₂)₂ peaks were not clearly identified. The peaks associated with LiCl are indicative of the metathesis reaction between LiNH₂ and the transition metal chlorides.

The XRD spectra after one complete isothermal cycle given in Figure 8 further illustrates the formation of salts, predominately LiCl as a result of cycling. The metathesis reaction results in the loss of essential nitrogen due to ammonia release, as possibly:

thus preventing the reversible reaction from occurring. This metathesis reaction has been observed during the dry ball milling process of NaAlH₄ with TiCl₃, resulting in the reduction of TiCl₃ by the Na to form NaCl and metallic Ti [26]. Sandrock *et al.* went on to show that increasing the TiCl₃ loading resulted in an elimination of H-capacity with the formation of NaCl, Al and Ti, all of which do not store hydrogen [26].

To further identify the as-milled, dehydrogenated and hydrogenated phases, Raman spectroscopy was performed on the system modified with TiCl₃, with the results shown in Figure 9 (A) and (B). Raman spectra of the as-milled indicates the presence of unreacted LiNH₂ after milling. The vibrational bands observed at 3262 cm⁻¹ (N-H symmetric stretch) and 3323 cm⁻¹ (unresolved N-H asymmetric stretch doublet) match literature spectra of the pure material [11, 23]. Weak low-frequency (<500 cm⁻¹) bands associated with lattice translational and librational modes are not visible, most likely due to low measurement sensitivity against a large scattering background. A very weak peak observed at ~950 cm⁻¹ is consistent with the expected MgH₂ vibration at 954 cm⁻¹ [27], but is not definitive. However, no other peaks appear in this region of the spectrum that would suggest the presence of other reaction products.

The desorbed sample was taken after the second discharge cycle and the rehydrogenated sample was taken after the fourth recharge cycle. As expected for the dehydrided sample, there is little or no Raman activity observable in the H-N-H stretching regions. The low-frequency region shows the growth of a clear doublet at 379

(strong) cm^{-1} and 341 (weak) cm^{-1} . These peaks are not coincident with the reported spectrum for LiMgN in which a single broad peak is observed at 492 cm^{-1} [28].

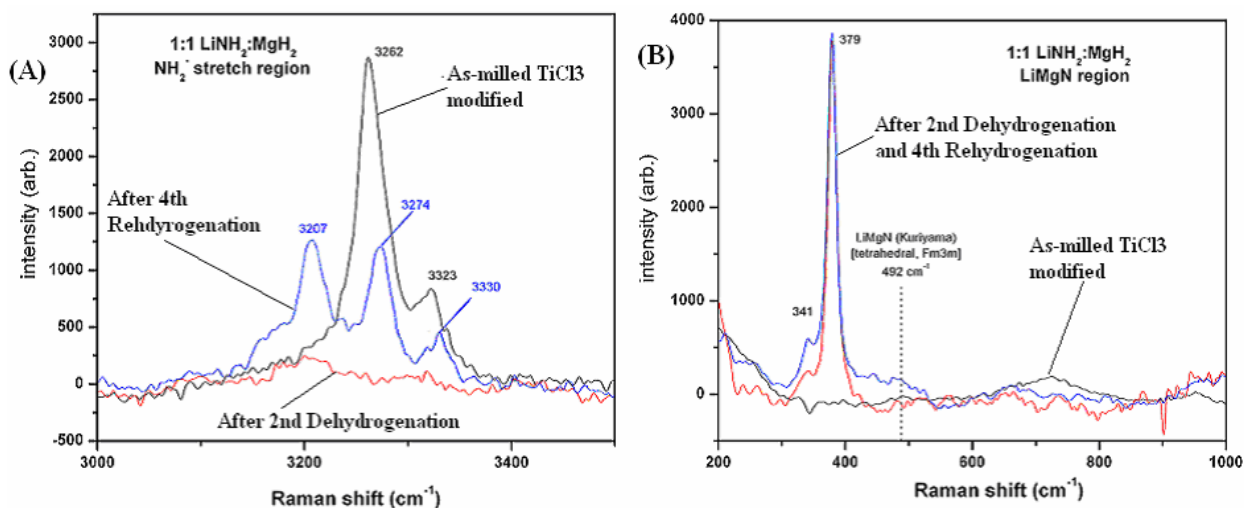

Figure 9. Raman spectra of the as-milled 1:1 $\text{LiNH}_2:\text{MgH}_2$ with TiCl_3 modifier in (A) the high-shift NH_2^- region and (B) the LiMgN region. The observed spectrum for the as-milled sample is consistent with high-shift stretches for LiNH_2 . However, the observed LiMgN spectrum for the desorption sample was not consistent with literature [28]. The high-shift NH_2^- region for the rehydrogenated sample is consistent with the formation of $\text{Mg}(\text{NH}_2)_2$ and there is no evidence that LiNH_2 has been reformed indicating that the desorption sample did not rehydrogenate to the starting material

It is worth noting that the spectrum observed doublet closely matches the strongest peaks in the reported spectrum of Mg_3N_2 [29]. The fate of the Li in the dehydrogenated sample is less clear. Yamane *et al.* noted that the insertion of Li into Mg_3N_2 to form $\text{Li}_{0.51}\text{Mg}_{2.49}\text{N}_{1.83}$ would reduce the space group from $Ia\bar{3}$ to $I213$ [30]. The expected Raman spectrum of such a material could have more peaks, due to the reduction of symmetry, and the frequencies of the strongest peaks could be shifted due to the presence of Li. Neither effect is observed for this material. Additionally, the peaks are sharp, suggesting that there is little disorder in the material as might be expected for the random inclusion of Li. Overall, the Raman spectrum for the dehydrogenated sample does not permit a definitive identification of the dehydrogenated product or the creation of a new material; however, they are not good enough to rule it out.

The low-shift region of the Raman spectrum for the rehydrogenated sample (seen in Figure 9(A)) is essentially identical to the dehydrogenated sample. The presence of the same doublet that is observed for the dehydrogenated material suggests that Mg_3N_2 and not LiMgN was formed during the dehydrogenation process. However, new peaks are observed in the N-H stretching region (Figure 9 (B)). The bands at 3274 cm^{-1} and 3330 cm^{-1} are consistent with the formation of $\text{Mg}(\text{NH}_2)_2$ [31] and echo the observation of that species in the XRD spectrum. There are no peaks that suggest the reformation of LiNH_2 (e.g. consistency with the spectrum of the as-mixed starting materials). As yet unidentified are the peak at 3207 cm^{-1} and the shoulder at $\sim 3170 \text{ cm}^{-1}$. The other products identified in the XRD spectrum – MgH_2 , LiH , and Mg_3N_2 – do not have Raman peaks in this region. Any candidate material(s) would have to be in an amorphous state or otherwise not be observable in the XRD spectrum. For example, the shoulder is coincident with a feature attributed to $\text{Li}_2\text{Mg}(\text{NH}_2)_2$ (3180 cm^{-1}) [31]. Also, discussion in

Heyns *et al.*[29] suggests the possibility that the 3207 cm^{-1} peak is consistent with the presence of physisorbed NH_3 , especially if the ammonia has some NH_4^+ character due to a hydrogen bonding interaction between the N lone pair and bound hydrogen. The observed position is intermediate between the range of “ NH_3 in amino complexes” (3115-3330 cm^{-1}) and NH_4^+ ion (3040 cm^{-1}). We note that we do not observe an accompanying bending mode expected near 1400-1600 cm^{-1} , but this mode would be less intense and may be unobservable against the large background. On the other hand, the ammonia would not be expected to be observed in XRD spectra. Also, as discussed previously, ammonia release occurs in the modified materials, so the presence of the gas in the sample is reasonable.

4 Conclusions

In this paper, we have compared the effect of compositional modifications on the dehydrogenation/rehydrogenation rates, the temperature of initial hydrogen release and the amount of ammonia released from unmodified and modified 1:1 MgH_2 and LiNH_2 . The decomposition steps observed in TGA-RGA data support the 3 step reactions listed in literature; however, further studies are needed to determine decomposition pathway. XRD studies indicate that after discharging at 260°C into 1 bar, the resulting mixtures consists of Mg_3N_2 , LiMgN . With the addition of TiCl_3 , VCl_3 , NiCl_2 or ScCl_3 , the temperature of initial hydrogen release was reduced; however, Ti and V chlorides also reduced the temperature of ammonia release by promoting a metathesis reaction between LiNH_2 and the chlorides. Ni and Sc modified samples showed the highest isothermal absorption capacity followed by unmodified, V and Ti modified samples. After cycling, no discernable kinetic effect remained from the additions. It is concluded that once the metathesis reaction is complete, the added metallic species are no longer active in the sorption cycle. This work has highlighted the requirement of cycling these materials to reach a steady state operating chemistry to evaluate the effectiveness of potential additives as kinetic aids.
