Available for a processing fee to U.S. Department of Energy and its contractors, in paper, from:

U.S. Department of Energy
Office of Scientific and Technical Information
P.O. Box 62
Oak Ridge, TN 37831-0062
Phone: (865) 576-8401
Fax: (865) 576-5728
E-mail: mailto:reports@adonis.osti.gov

Available for sale to the public, in paper, from:

U.S. Department of Commerce
National Technical Information Service
5285 Port Royal Road
Springfield, VA 22161
Phone: (800) 553-6847
Fax: (703) 605-6900
E-mail: orders@ntis.fedworld.gov
Online ordering: http://www.ntis.gov/ordering.htm

Printed on paper containing at least 50% wastepaper, including 20% postconsumer waste
Table of Contents

I. Introduction ............................................................................................................. 1

II. Hydrogen Production .......................................................................................... 17
   II.0 Hydrogen Production Sub-Program Overview .................................................. 19
       II.A Distributed BDL Production ...................................................................... 23
   II.A.1 Ohio State University: Investigation of Reaction Networks and Active Sites in Bio-Ethanol Steam Reforming over Co-based Catalysts ..................................................... 23
   II.A.2 Pacific Northwest National Laboratory: Distributed Hydrogen Production from Biomass Reforming ................................................................................................. 29
   II.A.3 Argonne National Laboratory: Hydrogen from Glycerol: A Feasibility Study .... 34
   II.A.4 National Renewable Energy Laboratory: Distributed Bio-Oil Reforming ........ 38
   II.A.5 Argonne National Laboratory: Distributed Reforming of Renewable Liquids Using Oxygen Transport Membranes ...................................................... 42

       II.B Biomass Gasification .................................................................................... 46
   II.B.1 United Technologies Research Center: A Novel Slurry-Based Biomass Reforming Process .............................................................................................................. 46
   II.B.2 Los Alamos National Laboratory: Catalytic Solubilization and Conversion of Lignocellulosic Feedstocks .................................................................................. 50
   II.B.3 Gas Technology Institute: One Step Biomass Gas Reforming-Shift Separation Membrane Reactor ......................................................................................... 54

       II.C Separations ................................................................................................. 57
   II.C.1 Pall Corporation: High-Performance Palladium-Based Membrane for Hydrogen Separation and Purification ................................................................. 57
   II.C.2 Media and Process Technology Inc.: Development of Hydrogen Selective Membranes/Modules as Reactors/Separators for Distributed Hydrogen Production .... 62
   II.C.3 Arizona State University: Zeolite Membrane Reactor for Water-Gas Shift Reaction for Hydrogen Production ................................................................. 67

       II.D Hydrogen From Coal .................................................................................... 74
   II.D.1 Worcester Polytechnic Institute: Composite Pd and Alloy Porous Stainless Steel Membranes for Hydrogen Production and Process Intensification .................... 74
   II.D.2 National Energy Technology Laboratory: Development of Robust Hydrogen Separation Membranes ..................................................................................... 79
   II.D.3 Eltron Research Inc.: Scale Up of Hydrogen Transport Membranes for IGCC and FutureGen Plants .............................................................................................. 82
   II.D.4 Southwest Research Institute*: Amorphous Alloy Membranes for High Temperature Hydrogen Separation ................................................................. 86
   II.D.5 United Technologies Research Center: Experimental Demonstration of Advanced Palladium Membrane Separators for Central High-Purity Hydrogen Production ...... 90
   II.D.6 Worcester Polytechnic Institute: Supported Molten Metal Membrane (SMMM) for Hydrogen Separation ................................................................. 95

       II.E Electrolysis .................................................................................................. 99
   II.E.1 Avalence, LLC: High-Capacity, High-Pressure Electrolysis System with Renewable Power Sources ............................................................................................. 99
   II.E.2 Giner Electrochemical Systems, LLC: PEM Electrolyzer Incorporating an Advanced Low-Cost Membrane ................................................................. 103

FY 2010 Annual Progress Report iii DOE Hydrogen Program
## Table of Contents

### II. Hydrogen Production (Continued)

#### II.F Hi-Temp Thermochemical
- II.F.1 Argonne National Laboratory: R&D Status for the Cu-Cl Thermochemical Cycle-2010 ................................................................. 115
- II.F.2 Science Applications International Corporation: Solar High-Temperature Water-Splitting Cycle with Quantum Boost ............................... 120
- II.F.3 University of Colorado: Solar-Thermal Atomic Layer Deposition Ferrite-Based Water Splitting Cycles ............................................. 126

#### II.G Photoelectrochemical
- II.G.1 University of Hawaii at Manoa: Photoelectrochemical Hydrogen Production: DOE PEC Working Group Overview ........................................ 131
- II.G.3 University of California, Santa Barbara: Photoelectrochemical Hydrogen Production Using New Combinatorial Chemistry Derived Materials ................................. 145
- II.G.4 National Renewable Energy Laboratory: Semiconductor Materials for Photoelectrolysis ................................................................. 150
- II.G.5 University of Nevada, Las Vegas: Characterization of Materials for Photoelectrochemical Hydrogen Production ............................. 157
- II.G.7 MVSystems, Incorporated: Progress in the Study of Amorphous Silicon Carbide (a-SiC) as a Photoelectrode in Photoelectrochemical (PEC) Cells ................................................................. 167
- II.G.8 MVSystems, Incorporated: Progress in the Study of Tungsten Oxide Compounds as Photoelectrodes in Photoelectrochemical Cells ..................................................... 171
- II.G.9 MVSystems, Incorporated: Progress in the Study of Copper Chalcopyrites as Photoelectrodes in Photoelectrochemical Cells .................... 175
- II.G.10 Xunlight Corporation: Critical Research for Cost-Effective Photoelectrochemical Production of Hydrogen ........................................ 179
- II.G.11 University of Arkansas, Little Rock: Photoelectrochemical Generation of Hydrogen ............................................................. 182
- II.G.12 Lawrence Livermore National Laboratory: Characterization and Optimization of Photoelectrode Surfaces for Solar-to-Chemical Fuel Conversion ................................................................. 187
- II.G.13 University of Nevada, Reno: Photoelectrochemical Generation of Hydrogen from Water Using Visible Light Sensitive Ferro-Electric BiFeO$_3$ and Semiconductor Nanotubes ........................................ 191

#### II.H Biological
- II.H.1 University of California, Berkeley: Maximizing Light Utilization Efficiency and Hydrogen Production in Microalgal Cultures .................................. 195
- II.H.2 National Renewable Energy Laboratory: Biological Systems for Hydrogen Photoproduction .................................................... 198
- II.H.3 National Renewable Energy Laboratory: Fermentation and Electrohydrogenic Approaches to Hydrogen Production ......................... 203
- II.H.4 J. Craig Venter Institute: Hydrogen from Water in a Novel Recombinant Oxygen-Tolerant Cyanobacterial System .............................. 208

#### II.I Production
- II.I.1 Physical Optics Corporation: Photochemical System for Hydrogen Generation ................................................................. 212
- II.I.2 Synkera Technologies, Inc.: Nanotube Array Photoelectrochemical Hydrogen Production ................................................................. 216
- II.I.3 Directed Technologies, Inc.: Aqueous Phase Base-Facilitated Reforming (BFR) of Renewable Fuels ...................................................... 220
- II.I.4 ElectroChem, Inc.: Advanced PEM-Based Hydrogen Home Refueling Appliance ................................................................. 224
- II.I.5 Giner Electrochemical Systems, LLC: Unitized Design for Home Refueling Appliance for Hydrogen Generation to 5,000 psi ................................. 227
II. Hydrogen Production (Continued)

II.I Production (Continued)

II.I.6 Lynntech, Inc.: Design, Optimization and Fabrication of a Home Hydrogen Fueling System .................................................. 232
II.I.7 Proton Energy Systems: Hydrogen by Wire - Home Fueling System .................................................. 236
II.I.8 Materials and Systems Research, Inc.: Development of a Hydrogen Home Fueling System ......................... 240

II.J Cross-Cutting/Production .......................................................... 243

II.J.1 Edison Materials Technology Center: Developing Improved Materials to Support the Hydrogen Economy. .................. 243
II.J.2 Purdue University: Purdue Hydrogen Systems Laboratory: Hydrogen Production ............................... 245

III. Hydrogen Delivery ................................................................. 249

III.0 Hydrogen Delivery Sub-Program Overview .................................. 251
III.1 Argonne National Laboratory: Hydrogen Delivery Infrastructure Analysis ............................................. 255
III.2 National Renewable Energy Laboratory: H2A Delivery Analysis and H2A Delivery Components Model ................ 259
III.3 Mohawk Innovative Technologies, Inc.: Oil-Free Centrifugal Hydrogen Compression Technology Demonstration ....... 263
III.4 Concepts NREC: Development of a Centrifugal Hydrogen Pipeline Gas Compressor ................... 267
III.5 Praxair, Inc.: Advanced Hydrogen Liquefaction Process ................................................................. 274
III.6 Prometheus Energy: Active Magnetic Regenerative Liquefier ......................................................... 278
III.7 Lawrence Livermore National Laboratory: Inexpensive Delivery of Cold Hydrogen in High Performance Glass Fiber Pressure Vessels ........ 282
III.8 Lincoln Composites, Inc.: Development of High Pressure Hydrogen Storage Tank for Storage and Gaseous Truck Delivery ........................................ 290
III.9 Savannah River National Laboratory: Fiber Reinforced Composite Pipelines ................................. 293
III.10 University of Illinois at Urbana-Champaign: Hydrogen Embrittlement of Pipeline Steels: Fundamentals, Experiments, Modeling ......... 296
III.11 Oak Ridge National Laboratory: Composite Technology for Hydrogen Pipelines ........................... 302
III.12 Sandia National Laboratories: Hydrogen Embrittlement of Structural Steels ................................. 306
III.13 Gas Equipment Engineering Corporation: Innovative Hydrogen Liquefaction Cycle ......................... 310
III.14 Air Products and Chemicals, Inc.: Reversible Liquid Carriers for an Integrated Production, Storage and Delivery of Hydrogen ........................................ 314
III.15 Secat, Inc.: Materials Solutions for Hydrogen Delivery in Pipelines ............................................. 318
III.17 Oak Ridge National Laboratory: Hydrogen Permeability and Integrity of Steel Welds ......................... 326
III.18 Argonne National Laboratory: Hydrogen Pipeline Compressors .................................................. 333
III.19 Mohawk Innovative Technologies, Inc.: Advanced Sealing Technology for Hydrogen Compression ........ 337
III.20 Lawrence Livermore National Laboratory: Rapid Low-Loss Cryogenic Hydrogen Refueling .................. 341
III.21 Oak Ridge National Laboratory: Range Optimization for Fuel Cell Vehicles .............................. 344

IV. Hydrogen Storage ................................................................. 349

IV.0 Hydrogen Storage Sub-Program Overview .................................. 351
IV.A Metal Hydride CoE ............................................................... 361

IV.A.1a Sandia National Laboratories: Five-Year Review of Metal Hydride Center of Excellence ....................... 361
IV.A.1b University of Hawaii: Fundamental Studies of Advanced High-Capacity, Reversible Metal Hydrides .......... 364
IV. Hydrogen Storage (Continued)

IV.A Metal Hydride CoE (Continued)

IV.A.1c Ohio State University: Lightweight Metal Hydrides for Hydrogen Storage . 371
IV.A.1d Sandia National Laboratories: Development of Metal Hydrides at Sandia National Laboratories . 377
IV.A.1e Brookhaven National Laboratory: Aluminum Hydride Regeneration . 385
IV.A.1f University of Illinois at Urbana-Champaign: Reversible Hydrogen Storage Materials - Structure, Chemistry, and Electronic Structure . 389
IV.A.1g Savannah River National Laboratory: Electrochemical Reversible Formation of Alane . 394
IV.A.1h National Institute of Standards and Technology: Neutron Characterization and Calphad in Support of the Metal Hydride Center of Excellence . 399
IV.A.1i Oak Ridge National Laboratory: Metal Borohydrides, Ammines, and Aluminum Hydrides as Hydrogen Storage Materials . 404
IV.A.1j Jet Propulsion Laboratory: Development and Evaluation of Advanced Hydride Systems for Reversible Hydrogen Storage . 408
IV.A.1k Savannah River National Laboratory: Li-Mg-N Hydrogen Storage Materials . 413
IV.A.1l University of Nevada, Reno: Effect of Gaseous Impurities on Long-Term Thermal Cycling and Aging Properties of Complex Hydrides for Hydrogen Storage . 417
IV.A.3 Northwestern University: Efficient Discovery of Novel Multicomponent Mixtures for Hydrogen Storage: A Combined Computational/Experimental Approach . 428
IV.A.4 Delaware State University: Hydrogen Storage Materials for Fuel Cell-Powered Vehicles . 433

IV.B Chemical Hydrogen Storage CoE . 437

IV.B.1a Los Alamos National Laboratory: 2010 Overview and Wrapup: DOE Chemical Hydrogen Storage Center of Excellence (CHSCoE) . 437
IV.B.1b University of Oregon: Hydrogen Storage by Novel CBN Heterocycle Materials . 443
IV.B.1c Los Alamos National Laboratory: Chemical Hydrogen Storage R&D at Los Alamos National Laboratory . 447
IV.B.1d Pacific Northwest National Laboratory: Chemical Hydrogen Storage Research at PNNL . 453

IV.C Hydrogen Sorption CoE . 460

IV.C.1a National Renewable Energy Laboratory: Overview of the DOE Hydrogen Sorption Center of Excellence . 460
IV.C.1b Texas A&M University: A Biomimetic Approach to Metal-Organic Frameworks with High H$_2$ Uptake . 468
IV.C.1c University of Missouri: Multiply Surface-Functionalized Nanoporous Carbon for Vehicular Hydrogen Storage . 474
IV.C.1d National Institute of Standards and Technology: Neutron Characterization in Support of the Hydrogen Sorption Center of Excellence . 481
IV.C.1e National Renewable Energy Laboratory: NREL Research as Part of the Hydrogen Sorption Center of Excellence . 486
IV.C.1f Argonne National Laboratory: Hydrogen Storage through Nanostructured Porous Organic Polymers (POPs) . 495
IV.C.1g University of Michigan: Hydrogen Storage by Spillover . 499
IV.C.1h Lawrence Livermore National Laboratory: Carbon Aerogels for Hydrogen Storage . 502
IV.C.2 State University of New York, Syracuse: Nanostructured Activated Carbon for Hydrogen Storage . 506
IV.C.3 Gas Technology Institute: Electron Charged Graphite-Based Hydrogen Storage Material . 510
IV. Hydrogen Storage (Continued)

IV.D Hydrogen Storage Engineering CoE ................................................................. 514
  IV.D.1a Savannah River National Laboratory: Hydrogen Storage Engineering Center of Excellence ................................................................. 514
  IV.D.1b Pacific Northwest National Laboratory: Systems Engineering of Chemical Hydride, Pressure Vessel, and Balance of Plant for On-Board Hydrogen Storage ................................................................. 519
  IV.D.1c United Technologies Research Center: Advancement of Systems Designs and Key Engineering Technologies for Materials-Based Hydrogen Storage ................................................................. 524
  IV.D.1d Los Alamos National Laboratory: Chemical Hydride Rate Modeling, Validation, and System Demonstration ................................................................. 529
  IV.D.1f General Motors Company: System Design and Media Structuring for On-Board Hydrogen Storage Technologies ................................................................. 541
  IV.D.1g Ford Motor Company: Ford/BASF-SE/UM Activities in Support of the Hydrogen Storage Engineering Center of Excellence ................................................................. 546
  IV.D.1h Savannah River National Laboratory: SRNL Technical Work Scope for the Hydrogen Storage Engineering Center of Excellence ................................................................. 551
  IV.D.1i Jet Propulsion Laboratory: Key Technologies, Thermal Management, and Prototype Testing for Advanced Solid-State Hydrogen Storage Systems ................................................................. 556
  IV.D.1k Lincoln Composites, Inc.: Development of Improved Composite Pressure Vessels for Hydrogen Storage ................................................................. 563

IV.E Storage Testing, Safety and Analysis ................................................................. 566
  IV.E.1 Argonne National Laboratory: On-Board and Off-Board Analyses of Hydrogen Storage Options ................................................................. 566
  IV.E.2 TIAX, LLC: Analyses of Hydrogen Storage Materials and On-Board Systems ................................................................. 572
  IV.E.3 Savannah River National Laboratory: Fundamental Reactivity Testing and Analysis of Hydrogen Storage Materials ................................................................. 576
  IV.E.4 United Technologies Research Center: Quantifying and Addressing the DOE Material Reactivity Requirements with Analysis and Testing of Hydrogen Storage Materials and Systems ................................................................. 581

IV.F New Materials-Independent Projects ................................................................. 595
  IV.F.1 University of California, Los Angeles: A Joint Theory and Experimental Project in the Synthesis and Testing of Porous COFs for On-Board Vehicular Hydrogen Storage ................................................................. 595
  IV.F.2 Northwestern University: New Carbon-Based Porous Materials with Increased Heats of Adsorption for Hydrogen Storage ................................................................. 600
  IV.F.3 Pennsylvania State University: Hydrogen Trapping through Designer Hydrogen Spillover Molecules with Reversible Temperature and Pressure-Induced Switching ................................................................. 605
  IV.F.4 Los Alamos National Laboratory: Capacitive Hydrogen Storage Systems: Molecular Design of Structured Dielectrics ................................................................. 610

IV.G Tanks ................................................................. 615
  IV.G.1 Lawrence Livermore National Laboratory: Extended Dormancy, Vacuum Stability, and Para-Ortho Hydrogen Conversion in Cryogenic Pressure Vessels ................................................................. 615
  IV.G.2 Oak Ridge National Laboratory: Lifecycle Verification of Polymeric Storage Liners ................................................................. 619
  IV.G.3 Oak Ridge National Laboratory: High Strength Carbon Fibers ................................................................. 622
Table of Contents

IV. Hydrogen Storage (Continued)

IV.H Cross-Cutting ................................................................. 628
  IV.H.1 SiGNa: NaSi and Na-SG Powder Hydrogen Fuel Cells ............... 628
  IV.H.2 Purdue University: Purdue Hydrogen Systems Laboratory: Hydrogen Storage . 628
  IV.H.3 University of Nevada, Las Vegas: HGMS: Glasses and Nanocomposites for Hydrogen Storage ..................................................... 637
  IV.H.4 University of Arkansas, Little Rock: An Integrated Approach of Hydrogen Storage in Complex Hydrides of Transitional Elements ........... 639

IV.I Test/Analysis ................................................................. 647
  IV.I.1 Southwest Research Institute*: Standardized Testing Program for Solid-State Hydrogen Storage Technologies ........................................ 647

V. Fuel Cells ................................................................. 653

V.0 Fuel Cells Sub-Program Overview ....................................... 655

V.A Analysis/Characterization ............................................ 661
  V.A.1 Argonne National Laboratory: Fuel Cell Systems with Low Platinum Loadings .............. 661
  V.A.2 Directed Technologies, Inc.: Mass-Production Cost Estimation for Automotive Fuel Cell Systems ......................................................... 667
  V.A.3 TIAX, LLC: Cost Analyses of Fuel Cell Stacks/Systems ................. 672
  V.A.4 Oak Ridge National Laboratory: Characterization of Fuel Cell Materials............... 680
  V.A.5 National Institute of Standards and Technology: Neutron Imaging Study of the Water Transport in Operating Fuel Cells ......................... 686
  V.A.7 Argonne National Laboratory: Fuel Cell Testing at Argonne National Laboratory .... 699
  V.A.8 Los Alamos National Laboratory: Technical Assistance to Developers ........... 703

V.B Water Transport Studies ................................................. 706
  V.B.1 Los Alamos National Laboratory: Water Transport Exploratory Studies ............... 706
  V.B.2 CFD Research Corp.: Water Transport in PEM Fuel Cells: Advanced Modeling, Material Selection, Testing, and Design Optimization ....................... 711

V.C Impurities ................................................................. 722
  V.C.1 Los Alamos National Laboratory: Effects of Fuel and Air Impurities on PEM Fuel Cell Performance .................................................... 722
  V.C.2 Clemson University: Fundamental Effects of Impurities on Fuel Cell Performance and Durability .................................................... 727
  V.C.3 University of Connecticut: The Effects of Impurities on Fuel Cell Performance and Durability .................................................... 731
  V.C.4 National Renewable Energy Laboratory: Effect of System and Air Contaminants on PEMFC Performance and Durability .......................... 737

V.D Membranes ............................................................... 741
  V.D.1 Lawrence Livermore National Laboratory: New Polyelectrolyte Materials for High Temperature Fuel Cells ........................................ 741
  V.D.2 3M Company: Membranes and MEAs for Dry, Hot Operating Conditions ............ 748
  V.D.3 Giner Electrochemical Systems, LLC: Dimensionally Stable Membranes (DSMs) .... 754
  V.D.4 University of Central Florida: Lead Research and Development Activity for DOE's High Temperature, Low Relative Humidity Membrane Program .... 758
  V.D.5 Case Western Reserve University: Poly(p-Phenylenesulfonic Acids): PEMs with Frozen-In Free Volume ............................................. 761
  V.D.6 Vanderbilt University: NanoCapillary Network Proton Conducting Membranes for High Temperature Hydrogen/Air Fuel Cells ....................... 767
V. Fuel Cells (Continued)

V.D Membranes (Continued)

V.D.7 Colorado School of Mines: Novel Approaches to Immobilized Heteropoly Acid (HPA) Systems for High Temperature, Low Relative Humidity Polymer-Type Membranes ................................................................. 772
V.D.8 FuelCell Energy, Inc.: High Temperature Membrane with Humidification-Independent Cluster Structure ................................................................. 777
V.D.9 Arkema Inc.: Improved, Low-Cost, Durable Fuel Cell Membranes .................. 782
V.D.10 University of Arizona: Protonic Salt Polymer Membranes: High-Temperature Water-Free Proton-Conducting Membranes ........................................ 786

V.E Catalysts .............................................................................. 790

V.E.1 3M Company: Advanced Cathode Catalysts and Supports for PEM Fuel Cells ..... 790
V.E.2 UTC Power: Highly Dispersed Alloy Catalyst for Durability .......................... 799
V.E.3 Pacific Northwest National Laboratory: Development of Alternative and Durable High Performance Cathode Supports for PEM Fuel Cells ... 805
V.E.4 Argonne National Laboratory: Non-Platinum Bimetallic Cathode Electrocatalysts . 811
V.E.5 Los Alamos National Laboratory: Advanced Cathode Catalysts .................... 816
V.E.6 3M Company: Durable Catalysts for Fuel Cell Protection during Transient Conditions ................................................................................. 825
V.E.7 National Renewable Energy Laboratory: Extended, Continuous Pt Nanostructures in Thick, Dispersed Electrodes ............................................. 830
V.E.8 Argonne National Laboratory: Nanosegregated Cathode Alloy Catalysts with Ultra-Low Platinum Loading ......................................................... 835
V.E.9 Brookhaven National Laboratory: Contiguous Platinum Monolayer Oxygen Reduction Electrocatalysts on High-Stability Low-Cost Supports ............ 841
V.E.10 Los Alamos National Laboratory: The Science and Engineering of Durable Ultralow PGM Catalysts ................................................................. 845
V.E.11 Lawrence Livermore National Laboratory: Molecular-Scale, Three-Dimensional Non-Platinum Group Metal Electrodes for Catalysis of Fuel Cell Reactions ............. 850

V.F Water Management .................................................................. 857

V.F.1 Nuvera Fuel Cells, Inc.: CIRRUS: Cell Ice Regulation & Removal Upon Start-Up ... 857

V.G Distributed Energy ................................................................ 861

V.G.1 Intelligent Energy: Development and Demonstration of a New Generation High Efficiency 10-kW Stationary PEM Fuel Cell System ................. 861
V.G.2 Acumentrics Corporation: Development of a Low Cost 3-10 kW Tubular SOFC Power System ........................................................................ 866
V.G.3 Plug Power Inc.: Intergovernmental Stationary Fuel Cell System Demonstration ................................. 870
V.G.4 IdaTech, LLC: Research and Development for Off-Road Fuel Cell Applications ................................................................... 873

V.H Degradation Studies ................................................................. 876

V.H.1 Argonne National Laboratory: Polymer Electrolyte Fuel Cell Lifetime Limitations: The Role of Electrocatalyst Degradation ........................................ 876
V.H.2 Los Alamos National Laboratory: Durability Improvements through Degradation Mechanism Studies ......................................................... 881
V.H.3 Nuvera Fuel Cells, Inc.: Durability of Low Platinum Fuel Cells Operating at High Power Density ................................................................. 886
V.H.4 UTC Power: Improved Accelerated Stress Tests Based on Fuel Cell Vehicle Data . 890
V.H.5 Los Alamos National Laboratory: Accelerated Testing Validation ................... 895
V.H.6 Ballard Power Systems: Development of Micro-Structural Mitigation Strategies for PEM Fuel Cells: Morphological Simulations and Experimental Approaches ........................................................................ 899

V.I Auxiliary Power ................................................................. 903

V.I.1 Cummins Power Generation: Diesel-Fueled SOFC System for Class 7/Class 8 On-Highway Truck Auxiliary Power .................................................. 903
V. Fuel Cells (Continued)

V.I Auxiliary Power (Continued)

V.I.2 Delphi Corporation: Solid Oxide Fuel Cell Development for Auxiliary Power in Heavy Duty Vehicle Applications ................................................................. 907

V.J Portable Power ........................................................................................................... 911

V.J.1 National Renewable Energy Laboratory: Novel Approach to Advanced Direct Methanol Fuel Cell (DMFC) Anode Catalysts .............................................. 911

V.J.2 Arkema Inc.: Novel Materials for High Efficiency Direct Methanol Fuel Cells ........ 915

V.J.3 University of North Florida: New MEA Materials for Improved DMFC Performance, Durability, and Cost ............................................................. 917

V.K Balance of Plant ....................................................................................................... 919

V.K.1 Honeywell Aerospace: Development of Thermal and Water Management System for PEM Fuel Cell ................................................................. 919

V.K.2 W.L. Gore & Associates, Inc.: Materials and Modules for Low-Cost, High-Performance Fuel Cell Humidifiers ............................................................. 922

V.L Hardware .................................................................................................................. 925

V.L.1 Oak Ridge National Laboratory: Nitrided Metallic Bipolar Plates ......................... 925

V.L.2 TreadStone Technologies, Inc.: Low-Cost PEM Fuel Cell Metal Bipolar Plates ..... 930

V.L.3 Argonne National Laboratory: Metallic Bipolar Plates with Composite Coatings ... 934

V.L.4 UTC Power: Low-Cost Durable Seals for PEMFCs ............................................. 939

V.M Transport Studies .................................................................................................... 943

V.M.1 Plug Power Inc.: Air-Cooled Stack Freeze Tolerance ............................................. 943

V.M.2 Lawrence Livermore National Laboratory: Fuel Cell Fundamentals at Low and Subzero Temperatures ................................................................. 948

V.M.3 Sandia National Laboratories: Development and Validation of a Two-Phase, Three-dimensional Model for PEM Fuel Cells ........................................ 952

V.M.5 Giner Electrochemical Systems, LLC: Transport Studies and Modeling in PEM Fuel Cells ................................................................. 960

V.N Innovative Concepts ............................................................................................... 963

V.N.1 Versa Power Systems: Advanced Materials for RSOFC Dual Operation with Low Degradation ................................................................. 963

V.N.2 Los Alamos National Laboratory: Resonance-Stabilized Anion Exchange Polymer Electrolytes ................................................................................ 967

V.N.3 Los Alamos National Laboratory: Engineered Nano-Scale Ceramic Supports for PEM Fuel Cells ................................................................. 971

V.O Earmark .................................................................................................................... 978

V.O.1 Michigan Technological University: Center for Fundamental and Applied Research in Nanostructured and Lightweight Materials ......................................... 978

V.O.2 Colorado School of Mines: Renewable and Logistics Fuels for Fuel Cells at the Colorado School of Mines ........................................................................ 983

V.O.3 University of Akron: Development of Kilowatt-Scale Coal-Based Fuel Cell Technology ......................................................................................... 988

V.O.4 University of Southern Mississippi: Alternate Fuel Cell Membranes for Energy Independence ................................................................. 993

V.O.5 Rolls Royce Fuel Cell Systems Inc.: Extended Durability Testing of an External Fuel Processor for SOFC ................................................................. 997

V.O.6 University of South Carolina: Hydrogen Fuel Cell Development in Columbia (SC) ......................... 1001

V.O.7 Microcell Corporation: Martin County Hydrogen Fuel Cell Development ................. 1005

V.O.8 Stark State College of Technology: Fuel Cell Balance-of-Plant Reliability Testbed .... 1007

V.O.9 Colorado School of Mines: Biomass Fuel Cell Systems ........................................ 1011

I. INTRODUCTION
The DOE Hydrogen Program (the Program) has conducted comprehensive and focused efforts to enable the widespread commercialization of hydrogen and fuel cell technologies in diverse sectors of the economy. With emphasis on applications that will most effectively strengthen our nation’s energy security and improve our stewardship of the environment, the Program engages in research, development, and demonstration (RD&D) of critical improvements in the technologies, as well as diverse activities to overcome economic and institutional obstacles to commercialization. The Program addresses the full range of challenges facing the development and deployment of hydrogen and fuel cell technologies by integrating basic and applied research, technology development and demonstration, and other supporting activities. In addition to DOE’s Office of Energy Efficiency and Renewable Energy (EERE), the Program includes activities in the DOE Offices of Fossil Energy (FE), Nuclear Energy (NE), and Science (SC).

In Fiscal Year (FY) 2010, Congress appropriated approximately $244 million for the DOE Hydrogen Program. The Program is organized into distinct sub-programs focused on specific areas of RD&D, as well as other activities to address non-technical challenges. The goals, objectives, and targets of each of the applied research programs are identified in the multi-year program plans for EERE, FE, and NE; and the basic research areas addressed by the Office of Science are described in Basic Research Needs for the Hydrogen Economy—Report of the Basic Energy Sciences Workshop on Hydrogen Production, Storage, and Use. All of these documents are available at www.hydrogen.energy.gov/program_plans.html.

In the past year, the Program made substantial progress toward its goals and objectives. Highlights of the Program’s accomplishments are summarized below. More detail can be found in the sub-program chapters of this report.

PROGRAM PROGRESS AND ACCOMPLISHMENTS

Hydrogen Production

The FY 2010 Hydrogen Production activities continued to focus on developing technologies that enable the long-term viability of hydrogen as an energy carrier for a diverse range of end-use applications including portable power, stationary power, backup power, specialty vehicles, and transportation. The goal of the Program’s production portfolio is to develop low-cost, high-efficiency hydrogen production technologies from diverse, domestic sources, including renewable resources, coal (with carbon sequestration), and nuclear energy. The main objective is to reduce the cost of hydrogen dispensed at the pump to a cost competitive with gasoline. Important FY 2010 accomplishments in the major production technology pathways are summarized below:

**Biomass and Bio-Derived Liquids:** The National Renewable Energy Laboratory (NREL) demonstrated hydrogen production by auto-thermal reforming of bio-oil using a bench-scale reactor system and achieved hydrogen production of 7.3 g/100 g bio-oil (potentially 9.6 g/100 g bio-oil after water-gas shift) with 93% bio-oil to gas conversion. Argonne National Laboratory (ANL) completed an analysis of the economic feasibility of hydrogen production from glycerol derived as a byproduct of the biodiesel industry—estimating the cost of hydrogen for a base case set of conditions at $4.86/kg, where the price of glycerol was assumed to be $1.07/gallon. United Technologies Research Center demonstrated nearly 100% conversion of wood, using an inexpensive base metal catalyst, and completed a study to better understand the impact of base concentration on H₂ yield and selectivity.

**Electrolysis:** Giner Electrochemical Systems reduced hydrogen embrittlement in titanium/carbon cell-separators, demonstrated enhanced dimensionally stable membrane (DSMTM) performance, and projected a decrease in overall capital cost of their electrolyzer stack from >$2,500/kW in 2001 to $463/kW in 2010. In addition, NREL completed an independent review of wind electrolysis, estimating the levelized cost range for state-of-the-art electrolysis to be $4.90–$5.70 per gallon gasoline equivalent (gge) of hydrogen for forecourt refueling stations (including compression, storage and...
dispensing), and $2.70–3.50/gge for central electrolysis operations (at the plant gate, excluding all delivery and dispensing costs).

**Solar Thermochemical Hydrogen Production:** The University of Colorado optimized formulations for hercynite materials, which are more stable and generate hydrogen at lower temperature than the traditional ferrites; they also completed a techno-economic analysis indicating that atomic-layer-deposition of ferrite materials on 100 m²/g supports with an oxidation/reduction cycle every five minutes will meet the DOE 2015 cost targets. In addition, ANL initiated a development and testing project for new membrane materials for the CuCl electrolyzer in the hybrid copper chloride cycle, and demonstrated that a decrease in the reactor pressure reduces the amount of steam required (H₂O/CuCl₂ ratios reduced by more than 30%, from 20–23 to 11–15) for >90% yield of the desired Cu₂OCl₂ product.

**Photoelectrochemical and Biological Production:** Directed Technologies, Inc. (DTI) completed separate technoeconomic boundary analyses of photoelectrochemical (PEC) solar hydrogen production and biological hydrogen production, projecting cost ranges of $2.50–$10/gge H₂ for PEC and $3-$12/gge H₂ for biological production, based on the current state of these technologies. Stanford University achieved the first-ever demonstration of bandgap tailoring in photoactive MoS₂ nanoparticles—increasing the MoS₂ bulk bandgap from 1.2 eV up to 1.8 eV, a more optimal value for PEC water splitting. University of California, Berkeley, developed methods to minimize the size of chlorophyll antennae used in photosynthesis by decreasing the expression of the Truncated-Light-Antenna genes, thereby substantially improving solar light energy utilization efficiencies in plants and microalgal cultures from the 2000 baseline of 3% up to 25%. In addition, NREL, in collaboration with Pennsylvania State University, designed, constructed, and tested a 2.5-L bench-scale prototype microbial electrolysis cell that produced hydrogen gas at a rate up to 1,250 mL/d, demonstrating the usefulness of this design.

**Fossil Energy—Hydrogen from Coal:** Eltron Research Inc., Southwest Research Institute® (SwRI®), and Worcester Polytechnic Institute (WPI) developed membrane separation technologies that achieve a hydrogen recovery rate of 90% with nearly 100% H₂ purity, while simultaneously enabling 90–95% CO₂ capture at high pressure, minimizing CO₂ compression costs.

### Hydrogen Delivery

Hydrogen Delivery sub-program activities continued to focus on developing technologies to reduce the cost and increase the energy efficiency of hydrogen delivery, to enable the widespread use of hydrogen as an energy carrier. Three potential delivery pathways are being considered: gaseous hydrogen (trucks or pipelines), liquid hydrogen (trucks), and novel solid or liquid hydrogen carriers (trucks or pipeline). FY 2010 accomplishments in the major delivery activities are summarized below:

**Pipelines:** Savannah River National Laboratory (SRNL) completed a life-cycle management plan for fiber reinforced composite (FRC) pipelines, completed a review of existing FRC design specifications and standards and initiated environmental and flaw tolerance testing of FRC. Also, Sandia National Laboratories (SNL) examined the fracture properties of X52 pipeline steel in high-pressure hydrogen gas to evaluate the reliability of current pipeline steel for transmission.

**Tube Trailers and Bulk Storage:** Lincoln Composites completed an assembly that includes an International Organization for Standardization (ISO) frame, four pressure vessels, and relevant plumbing. The American Bureau of Shipping approved the entire ISO assembly for manufacture. In addition, Lawrence Livermore National Laboratory (LLNL) designed a pressure vessel that when incorporated into a trailer could deliver hydrogen at a cost below $1/gge (not including forecourt expenses).

**Compression and Liquefaction:** Concepts ETI Inc. completed a preliminary design of a six-stage H₂ pipeline compressor capable of delivering 240,000 kg H₂/day at 1,250 psig. In addition, five subsystems of a 290 K to 120 K active magnetic regenerative liquefier prototype were designed, fully assembled, and successfully tested by Prometheus Energy.

**Analysis:** ANL upgraded the Hydrogen Delivery Scenario Analysis Model to evaluate three new delivery pathways, two different station configurations for 700-bar dispensing, and an option permitting
user selection of station configuration. Also, NREL upgraded the Hydrogen Rail Components Model with 700-bar and cryo-compressed dispensing and higher tube-trailer delivery pressure, of up to 480 atm.

**Hydrogen Storage**

In FY 2010 the storage sub-program continued to make research and development (R&D) progress on advanced storage technologies for on-board vehicle applications.\(^1\) Investigations have continued to focus on development of materials within the three classes of hydrogen storage materials: hydrogen adsorbents, reversible metal hydrides and chemical hydrogen storage materials. There has also been an increased effort on advancing the state of the art in system engineering for materials-based vehicular storage systems through the Hydrogen Storage Engineering Center of Excellence (HSECoE). Progress has also continued on cryo-compressed physical storage.

**Metal Hydride Center of Excellence (MHCoE):** Over the five-year life of the MHCoE, more than 80 distinct materials have been investigated; work on about 75% of these has been discontinued, based on criteria developed by the MHCoE, such as reversible capacities, absorption thermodynamics, and kinetics. Work at the University of Hawaii and Sandia-Livermore National Laboratory has demonstrated 12 wt% reversibility from Mg(BH\(_4\)\(_2\))\(_2\), using severe re-hydrogenation conditions of 900+ bar H\(_2\) pressure and 400°C. The formation of the stable Mg(B\(_{12}\)H\(_{12}\)) intermediate has been found to be the reason that extreme hydrogenation pressures are needed. Under mild conditions, the group found they could obtain 2.4 wt% with partial cycling of Mg(BH\(_4\)\(_2\))\(_2\) without formation of the Mg(B\(_{12}\)H\(_{12}\)) intermediate. This preliminary work has been shown to extend to other metal borohydrides as well. Work has continued to progress at SRNL in developing a route for electrochemical formation of alanine (AlH\(_3\)) from aluminum metal and hydrogen gas in an electrolyte solution. In FY 2010, an electrocatalytic additive was found that increased the rate of alanine production approximately 1.8 times.

**Hydrogen Sorption Center of Excellence (HSCoE):** Through FY 2010, the HSCoE has identified approximately 210 materials, of which approximately 80% are no longer being investigated due to their failure to meet gravimetric or volumetric capacity targets. The Center has published its Materials Go/No-Go Recommendation Report (NREL), which is available through the DOE Web site at: http://www1.eere.energy.gov/hydrogenandfuelcells/pdfs/hscoe_recommendation_feb_10.pdf. Additionally, through collaborative center work, boron-substituted carbon materials were synthesized and demonstrated to have increased hydrogen binding energy (isosteric heats of 9–11 kJ/mol) as a function of coverage, agreeing with theory predictions. Several new sorbent materials were synthesized, including: Duke University’s polyether-etherketone (PEEK) material, which was found to have greater than 5 wt% excess hydrogen capacity; Texas A&M University’s PCN-68 framework material with 5,109 m\(^2\)/g surface area and 7.2 wt% excess hydrogen capacity; and Caltech’s Cs and Rb-intercalated graphite with narrow “slit-pore” geometries of 5.3 to 5.8 Å, which were shown to have a near constant isosteric heat of adsorption of 14 and 12 kJ/mol H\(_2\), respectively.

**Chemical Hydrogen Center of Excellence (CHCoE):** The CHCoE has investigated about 150 distinct chemical compositions over its five-year life. Research on approximately 95% of these has ended due to issues related to storage capacities, hydrogen release temperatures, kinetics, and spent fuel regeneration efficiency. FY 2010 advancements in chemical hydrogen storage materials included Los Alamos National Laboratory’s (LANL’s) development of a “one-pot” spent ammonia borane (AB) regeneration process with an overall yield of 90%; demonstration by Pacific Northwest National Laboratory (PNNL) of a new AB first-fill process with higher purity and yield and completion of a reactor scale-up capable of providing 100-gram batches of high purity AB to center partners; and the University of Pennsylvania achieving over 6x rate enhancements with reduced borazine formation and up to 11.4 wt% H\(_2\)-release from 80/20 (w/w)AB/ionic-liquid mixtures at 110°C. Additionally, high release rates for liquid AB at temperatures as low as 70°C with non-platinum group metal catalysts were demonstrated by LANL.

**Hydrogen Storage Engineering Center of Excellence (HSECoE):** FY 2010 was the first full year of effort for the HSECoE. The focus of FY 2010 was to develop preliminary complete system models for the three material classes using data for well-characterized representative materials from each class.

---

The Center also developed fuel cell power plant and vehicle models and coupled the models together so that on-board hydrogen storage system performance impacts on vehicle and power plant performance can be readily determined. The model development and coupling was carried out collaboratively primarily by Ford, General Motors, NREL, PNNL, SRNL, and United Technologies Research Center. LANL developed and demonstrated a novel acoustic fuel gauge sensor for use with materials-based storage systems.

In addition to the advancements made within the four Centers, the Storage sub-program continued to advance physical storage systems using compressed and cryo-compressed hydrogen. At Oak Ridge National Laboratory (ORNL), work was initiated to develop new melt-spin precursor preparation processes that could lead to projected cost savings of up to 50% of the carbon fiber precursor costs, potentially leading to a 25% reduction in final carbon fiber costs. ANL and TIAX LLC completed their technical assessments of compressed gas storage tank systems for automotive applications and their final report will be available through the DOE Web site. LLNL has continued progress on cryo-

**FIGURE 1.** Estimates of gravimetric and volumetric capacities projected for on-board storage systems that can supply 5.6 kg of usable hydrogen as compared to DOE targets (based upon engineering analyses). Note that the plotted data points are the average values for all systems analyzed during each year while the bars correspond to the range of maximum and minimum values obtained in each year. Also note that systems with predicted capacities exceeding the gravimetric or volumetric targets do not meet other targets.
compresses systems. An LLNL generation-3 tank design with 5.6 kg of usable H\textsubscript{2} has been projected by ANL to be capable of meeting the 2015 gravimetric and volumetric targets, with greater than 5.5 wt\% and 42 g/L capacities.

**Fuel Cells**

The Fuel Cells sub-program has made continued progress toward meeting 2010 and 2015 targets through advancements achieved in both catalysis and membrane R&D. Technological advances in several component areas have led to significant improvements in performance and durability, with decreased cost. Progress has also been demonstrated in the sub-program’s efforts to develop fuel cell systems for combined heat and power (CHP) applications.

The cost of a hydrogen-fueled 80-kW\textsubscript{e} fuel cell power system projected to high volume production (500,000 units/year) has been estimated to be $51/kW (assuming 2010 technology), as shown in Figure 2.\textsuperscript{2} Cost reduction was a result of simplified architecture and reduction in stack component costs through ongoing R&D efforts. The cost of the fuel cell stack has been estimated to be $25/kW (assuming 2010 technology).

In FY 2010, advancements in platinum group metal (PGM)-based catalysts resulted in significant progress toward improvement of fuel cell performance and reduction in cost through minimization of PGM loading. In FY 2010, 3M increased PtCoMn mass activity 30\%, reaching 0.24 A/mg\textsubscript{PGM} at 0.9 V, and demonstrated Pt\textsubscript{3}Ni\textsubscript{7} alloy with mass activity of 0.40 A/mg\textsubscript{PGM}.

3M operated a membrane over 5,000 hours with load cycling using a membrane electrode assembly (MEA) based on a non-stabilized 20-μm membrane and catalyst loading of 0.15 mg\textsubscript{PGM}/cm\textsuperscript{2}, meeting the DOE 2010/2015 durability target of 5,000 hours.\textsuperscript{3} (The 7,300 hours reported previously was with a higher PGM loading.) With the use of chemical stabilizers in the membrane, 3M exceeded the 200-hour DOE target for stability under open-circuit voltage hold in H\textsubscript{2}/air by more than 300\%.

In FY 2010, Brookhaven National Laboratory (BNL) improved its core-shell catalyst by using an interlayer of Au to separate the Pt shell from the PdCo core. Rotating disk electrode (RDE) testing of the new catalyst has demonstrated mass activity as high as 1.10 A/mg\textsubscript{PGM} and specific activity as high as 1,170 μA/cm\textsuperscript{2} at 0.9 V,\textsuperscript{4} suggesting a high probability of meeting DOE MEA-level and stack-level targets of 0.44 A/mg\textsubscript{PGM} and 720 μA/cm\textsuperscript{2}. RDE testing of an early Pt/Pd/C catalyst yielded 0.35 A/mg\textsubscript{Pt}. A Pt\textsubscript{3}ML/Pd/C core-shell catalyst delivered significantly better oxygen reduction reaction performance than a PtPd/C alloy with the same composition and identical performance as Pt/C, but with one fourth as much Pt at 0.90 V.

\textsuperscript{2} U.S. Department of Energy Hydrogen Program Record #10004, www.hydrogen.energy.gov/program_records.html; costs are based on projections to high-volume manufacturing (500,000 units/year).

Continued work at LANL on PGM-free catalysts yielded significant performance improvements in FY 2010, with current density as high as 60 A/cm² measured at 0.80 V (ir-free) during fuel cell testing with an Fe-cyanamide-C catalyst, representing a 64x improvement over the past two years. Progress also continues on PGM-free polyaniline-based catalysts at LANL, with activity as high as 31 A/cm² measured at 0.80 V, a 36x improvement over the past two years.\(^4\)

3M developed new polymer electrolyte membranes with higher proton conductivity and improved durability under hotter and drier conditions, compared with previously produced membranes, as shown in Figure 3.\(^5\) The new multi acid side-chain polymer membranes have better mechanical properties than conventional single acid side chain perfluorosulfonic acid membranes. In FY 2010, 3M developed innovative polymers in which side chains contain both sulfonic acid and sulfonamide groups.

The Fuel Cells sub-program also includes work on systems other than polymer electrolyte membrane (PEM) fuel cells, and progress is being made in these areas as well. For example, DOE is funding distributed energy and CHP systems based on several technologies. Acumentrics Corporation continues to develop micro-CHP systems based on tubular solid oxide fuel cell (SOFC) technology. In FY 2010, Acumentrics achieved a 24% increase in system power density, enabling a 33% reduction in stack volume and a 15% reduction in stack weight.\(^6\)

**Manufacturing R&D**

FY 2010 saw a number of cost and process advancements in the manufacturing of fuel cells and storage systems. W.L. Gore demonstrated, using their cost model, that a new 3-layer MEA process has the potential to reduce MEA cost by 25%. Quantum and Boeing demonstrated advanced filament winding and fiber placement processes that reduce storage system costs by 10%. BASF developed a predictive model and evaluated the impacts of electrode variation and defects on MEA performance using a new on-line X-ray fluorometer. Ballard developed a process model for controlling gas diffusion layer (GDL) coating conditions resulting in significant improvement in quality yields and GDL cost reduction of 53%. NREL developed and tested an ir-based test stand for defects such as pinholes, shorts, and variations in electrode thickness.

**Basic Research**

The Office of Basic Energy Sciences (BES) within the DOE Office of Science supports fundamental scientific research addressing critical challenges related to hydrogen storage, hydrogen production, and fuel cells. This basic research complements the applied R&D projects supported by other offices in the Program.

Progress in any one area of basic science is likely to spill over to other areas and bring advances on more than one front. The subjects of basic research most relevant to the Program’s key technologies are:

- **Hydrogen Storage:** Nanostructured materials; theory, modeling, and simulation to predict behavior and design new materials; and novel analytical and characterization tools.

---

Fuel Cells: Nanostructured catalysts and materials; integrated nanoscale architectures; novel fuel cell membranes; innovative synthetic techniques; theory, modeling, and simulation of catalytic pathways, membranes, and fuel cells; and novel characterization techniques.

Hydrogen Production: Longer-term approaches such as photobiological and direct photochemical production of hydrogen.

By maintaining close coordination between basic science research and applied R&D, the Program ensures that discoveries and related conceptual breakthroughs achieved in basic research programs will provide a foundation for the innovative design of materials and processes that will lead to improvements in the performance, cost, and reliability of fuel cell technologies and technologies for hydrogen production and storage. This is accomplished in various ways—for example, through monthly coordination meetings between the participating offices within DOE, and at the researcher level by having joint meetings with participation from principal investigators who are funded by the participating offices.

Technology Validation

The Technology Validation sub-program has been focused on conducting learning demonstrations that emphasize co-development and integration of hydrogen infrastructure with hydrogen fuel cell-powered vehicles to permit industry to assess progress towards technology readiness. These activities include fuel cell vehicle and infrastructure demonstrations, stationary power demonstrations, and projects that integrate renewable power generation and hydrogen production. The Controlled Hydrogen Fleet and Infrastructure Demonstration and Validation Project7 (also known as the “National Hydrogen Learning Demonstration”), launched in April 2004, brought together four teams of industry partners to operate fuel cell vehicles and all essential hydrogen infrastructure elements to evaluate progress and to identify challenges encountered when hydrogen and fuel cell technologies are operated in real-world environments. The teams were led by Chevron and Hyundai-Kia, Mercedes-Benz North America and BP, Ford and BP, and GM and Shell, with additional participation from hydrogen suppliers, fuel cell suppliers, utility or gas companies, fleet operators, system and component suppliers, small businesses, universities, and government entities.

Through the National Hydrogen Learning Demonstration, the Program has deployed 152 fuel cell vehicles and collected data from 24 hydrogen fueling stations. These vehicles have traveled over 2.8 million miles, and the fueling stations have produced or dispensed over 130,000 kg of hydrogen (not all of the hydrogen dispensed has been used in Learning Demonstration vehicles). Vehicles and infrastructure in these demonstrations have validated the status of several key technologies in integrated systems under real-world operating conditions, including vehicular fuel cell efficiency of 53 to 59 percent, projected durability of 2,500 hours (nearly 75,000 miles) for automotive fuel cell systems, and a range of more than 250 miles between refueling. The Technology Validation activity has collected and analyzed data from a total of nine fuel cell buses operated in revenue transit service at five sites in the United States. These buses have shown fuel economies 39 to 141 percent higher than conventional diesel buses and compressed natural gas buses, and they have traveled more than 395,000 miles.

In FY 2011 the final two National Learning Demonstration projects (GM and Mercedes-Benz North America) will conclude and publish final reports. In addition, the Hydrogen Energy Station at Fountain Valley, California, which will co-produce power, heat, and hydrogen, is expected to be fully operational in FY 2011. Data will be collected on power and heat generation, hydrogen production, and vehicle refueling.

Safety, Codes and Standards

The Safety, Codes and Standards sub-program continues to support critical R&D to establish key requirements and close knowledge gaps in safety, codes and standards to enable the commercialization of hydrogen and fuel cell technologies. Building on work from previous years, the sub-program continues to facilitate collaborative activities among relevant stakeholders in an effort to harmonize domestic and international regulations, codes, and standards.

7For more information on the Controlled Hydrogen Fleet and Infrastructure Demonstration and Validation Project, see: www1.eere.energy.gov/hydrogenandfuelcells/tech_validation/fleet_demonstration.html.
The sub-program developed a strong technical basis for a risk-informed approach to update bulk gas storage separation distances in the 2010 edition of National Fire Protection Association (NFPA) 55. Experimental and modeling studies were used to develop new, technically defensible separation distances, which were in some cases reduced by as much as 50%. The sub-program also completed testing to enable the deployment of 100-MPa stationary storage tanks. The sub-program facilitated the development of requirements for forklift tank life-cycle testing used by the Canadian Standards Association Hydrogen Powered Industrial Truck Committee. In cooperation with the Education sub-program, the Safety, Codes and Standards sub-program continued to deploy an advanced-level, prop-based course to support first-responder training; this course has successfully reached over 300 first responders in California.

The sub-program expanded its Web-based safety information tools in FY 2010 including the Technical Reference for Hydrogen Compatibility of Materials and Hydrogen Safety Training for Researchers, which highlights best practices for the safe use of hydrogen in a research setting.

Working with an international team of experts, the sub-program conducted an intensive testing, modeling, and analytical effort to provide data that established a scientific basis for hydrogen fuel quality specifications for PEM fuel cell road vehicles under the ISO and the Society of Automotive Engineers. This effort included a round-robin test of a single-cell PEM fuel cell among laboratories in Japan, the European Commission, and the United States to establish interchangeability of data among the laboratories.

**Education**

The Education sub-program facilitates hydrogen and fuel cell demonstrations and supports commercialization by providing technically accurate and objective information to key target audiences both directly and indirectly involved in the use of hydrogen and fuel cells.

To support early market outreach, the Education sub-program implemented several end-user, state and local government, and safety and code official education activities in FY 2010. Carolina Tractor and Equipment Inc. conducted hydrogen education sessions with hands-on forklift demonstrations at material handling dealerships, customer sites, community colleges, and regional green business expos to educate potential end-users about the benefits of fuel cell forklifts. As evidence of the project’s success, one site has decided to acquire over 100 fuel cell forklifts as a result of their experience with the demonstration units. Seven state and local government outreach projects focused on states with an active hydrogen and fuel cell presence to develop case studies, best practices, and technical assistance resources; these will be used to help decision-makers identify and assess opportunities for future deployment. Many groups have been using these education resources to work directly with state agencies to implement policies, programs, and best practices that can support the growth of hydrogen and fuel cell markets in the local economy. PNNL expanded first responder education by hosting several sessions of an advanced-level, hands-on prop course for firefighters and registering the Web-based “Introduction to Hydrogen Safety for First Responders” on the Training Finder Realtime Affiliate Network (TRAIN) Web site, a central repository for health training courses.

University and secondary education projects introduced future scientists, engineers, technicians, and end-users to hydrogen and fuel cell technologies. Five university projects—at California State University, Los Angeles; Michigan Technological University; the University of North Dakota; Humboldt State University; and the University of Central Florida—targeted a broad student audience through general education courses, specialized science and engineering courses, minor and concentration programs, curriculum modules, internships, labs, lab kits, and textbook chapters. In their second year, these projects are finalizing development of curricula and have moved into teaching, reviewing, and refining the course materials. “H2 Educate!” a set of lesson plans and activities for middle school teachers and students, continued to be disseminated through one-day teacher training workshops across the country. The companion effort for high schools, “HyTEC,” deployed a six-unit science curriculum and laboratory kit on hydrogen and fuel cells through professional development workshops and science teacher conferences across the country.
Market Transformation

To ensure that the benefits of its efforts are realized in the marketplace, the Program continues to facilitate the growth of early markets for fuel cells used in portable, stationary, and specialty-vehicle applications. Market transformation activities are helping to reduce the cost of fuel cells by enabling economies of scale through early market deployments and by overcoming a number of barriers, including the lack of operating performance data, the need for applicable codes and standards, and the need for user acceptance.

The development of niche-market applications for hydrogen fuel cells has been identified as the quickest way to achieve early market penetration. A study conducted for the Program by the Battelle Memorial Institute, Identification and Characterization of Near-Term Direct Hydrogen PEM Fuel Cell Markets, identifies fuel cells to power forklifts and to provide backup power for telecommunications and emergency response communications as promising near-term opportunities.

In FY 2010, the Program provided approximately $15 million for market transformation activities, to accelerate the deployment of fuel cells in early market applications. Specific FY 2010 projects included the deployment of nearly 100 lift trucks and a primary power system at Department of Defense sites and 14 hydrogen fuel buses at federal facilities across the country. These projects provide valuable data on the status of the technologies in real-world operation and information that will be used to validate the benefits of the technologies and potential needs for further R&D.

Systems Analysis and Integration

Systems Analysis supports decision-making by providing a greater understanding of technology gaps, options, and risks. Analysis is also conducted to assess cross-cutting issues, such as integration with the electrical sector and use of renewable fuels. Particular emphasis is given to assessing stationary fuel cell applications, fuel quality impacts on fuel cell performance, resource needs, and potential infrastructure options.

Accomplishments in FY 2010 included an update of the Macro-System Model (MSM) to include infrastructure and resource analysis for various regions and a variety of hydrogen production pathways. The Fuel Cell Power Model was upgraded to include business and financial analysis useful to multiple entities such as building owners, fuel cell vendors, station owners, utilities, and fleet operators.

Infrastructure analysis identified potential synergies between fuel cells for stationary power generation and transportation applications, particularly in the early phases of market adoption of hydrogen for light-duty fuel cell vehicles. Widespread deployment of combined heat, hydrogen, and power (CHHP) could address the problem of hydrogen availability in the early stages of transition to fuel cell vehicles. Analyses have indicated that the practice of producing hydrogen from CHHP systems could give rise to smaller stations with higher capital utilization and lower hydrogen cost, supplementing the supply of hydrogen from distributed natural gas–based steam methane reforming (SMR). Analysis conducted by NREL with the Fuel Cell Power model predicts that hydrogen produced from a stationary fuel cell would have a lower cost than hydrogen produced from an SMR system at low volumes, as shown in Figure 4.

ANL enhanced well-to-wheels analysis capabilities by modifying the Greenhouse gases, Regulated Emissions and Energy use in Transportation model to include analysis of criteria pollutant emissions from stationary fuel cells for combined heat, power and/or hydrogen generation (CHP/CHHP). The analysis estimates that fuel cell systems for CHP and CHHP emit significantly less carbon monoxide, particulate matter, and nitrogen oxides (NOx) than conventional generation technologies. For example, phosphoric acid fuel cells and molten carbonate fuel cells (MCFCs) emit at least 80% less NOx than other conventional generation technologies without after treatment.

8 For a brief summary of early market opportunities for PEM fuel cells, see the Program’s fact sheets on forklifts and backup power: www1.eere.energy.gov/hydrogenandfuelcells/education/pdfs/early_markets_forklifts.pdf and www1.eere.energy.gov/hydrogenandfuelcells/education/pdfs/early_markets_backup_power.pdf; for the full report by the Battelle Memorial Institute, see: www1.eere.energy.gov/hydrogenandfuelcells/pdfs/pemfc_econ_2006_report_final_0407.pdf.
I. Introduction

American Recovery and Reinvestment Act Projects

The American Recovery and Reinvestment Act (Recovery Act or ARRA) has been a critical component of the Program’s efforts to accelerate the commercialization and deployment of fuel cells in the market. With approximately $41.9 million from the Recovery Act and $54 million in cost-share funding from industry participants—for a total of nearly $96 million—this funding is supporting the deployment of nearly 1,000 fuel cell systems in emergency backup power, material handling, and CHP applications. Twelve projects were competitively selected to develop and deploy a variety of fuel cell technologies including polymer electrolyte, solid oxide, and direct-methanol fuel cells in stationary, portable, and specialty vehicle applications. To date, a total of at least 36 direct jobs have been created or retained as a result of these projects. The Program exceeded its 2010 target by deploying 206 fuel cell-powered lift trucks and installing fuel cells for backup power at 24 cell tower sites. An additional 75 portable fuel cells—handheld power generators for consumer electronics—are being sent to users as test units.

These projects will help build a competitive domestic supply base, decrease costs, and demonstrate the economic and performance benefits of fuel cells as competitive options for stationary, portable, and specialty vehicle applications. These advances will lead to reductions in carbon emissions, the creation of jobs, and a broadening of the nation’s clean energy technology portfolio.

Tracking the Commercialization of Technologies

One indicator of the robustness and innovative vitality of an R&D program is the number of patents applied for and granted, and the number of technologies commercialized. The Program continued to assess the commercial benefits of EERE’s Fuel Cell Technologies (FCT) Program by tracking the commercial products and technologies developed with the support of the Program. The FY 2010 Pathways to Commercial Success Report shows that 198 patents have been issued and 28 products have been commercialized as a result of research funded by the FCT Program in the areas of fuel cells and hydrogen production, delivery, and storage (Figure 5).

These advances will lead to reductions in carbon emissions, the creation of jobs, and a broadening of the nation’s clean energy technology portfolio.
International Partnership for Hydrogen and Fuel Cells in the Economy

The United States is a founding member of the International Partnership for Hydrogen and Fuel Cells in the Economy (IPHE), which includes 17 member countries (Australia, Brazil, Canada, China, France, Germany, Iceland, India, Italy, Japan, New Zealand, Norway, the Republic of Korea, the Russian Federation, South Africa, the United Kingdom, and the United States) and the European Commission. The IPHE is a forum for governments to work together to advance worldwide progress in hydrogen and fuel cell technologies. IPHE also offers a mechanism for international R&D managers, researchers, and policymakers to share program strategies.

In FY 2010, DOE hosted the IPHE Steering Committee meeting in Washington, D.C., at which the secretariat was transferred from Canada to Germany. Germany and China also hosted two additional joint Steering Committee and Implementation & Liaison Committee meetings. In November 2010, the IPHE released an overview of the global technical and commercialization progress of hydrogen and fuel cell technologies titled, 2010 Hydrogen and Fuel Cell Global Commercialization and Development Update.

IPHE—in collaboration with DOE, the California Fuel Cell Partnership (CaFCP), and NREL—coordinated the IPHE Infrastructure Workshop on February 25–26, 2010, to examine the key drivers and gaps to early market infrastructure development for light-duty vehicles. This interactive workshop engaged more than 80 professionals—representing a wide variety of stakeholders and expertise—in developing creative and practical solutions for establishing hydrogen infrastructure in the near term. Responding to the strategic issues and information gaps discussed during the workshop, the Program plans to conduct a rigorous assessment of challenges and needs—both from an R&D and business case perspective—to develop the appropriate strategy for vehicle and infrastructure rollout. For more information on the IPHE, visit www.iphe.net.

International Energy Agency

The United States is also involved in international collaboration on hydrogen and fuel cell R&D through participation in the International Energy Agency (IEA) implementing agreements, where it is a member of both the Advanced Fuel Cells Implementing Agreement (AFCIA) and the Hydrogen Implementing Agreement (HIA). These agreements provide a mechanism for member countries to share the results of research, development, and analysis activities in their respective areas.
The AFCIA currently comprises six annexes: Molten Carbonate Fuel Cells, Polymer Electrolyte Fuel Cells, Solid Oxide Fuel Cells, Fuel Cells for Stationary Applications, Fuel Cells for Transportation, and Fuel Cells for Portable Power. The participating countries are Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Italy, Japan, South Korea, the Netherlands, Mexico, Sweden, Switzerland, Turkey, and the United States. The implementing agreement was recently extended from 2009 to 2013. Information about the IEA AFCIA is available at www.ieafuelcell.com.

The IEA HIA is focused on RD&D and analysis of hydrogen technologies. It includes ten tasks covering safety, hydrogen production, hydrogen storage materials, hydrogen delivery, and systems analysis including: Hydrogen Safety, Biohydrogen, Fundamental and Applied Hydrogen Storage Materials Development, Small-Scale Reformers for On-Site Hydrogen Supply, Wind Energy and Hydrogen Integration, High-Temperature Production of Hydrogen, Water photolysis, Near-Market Routes to Hydrogen by Co-Utilization of Biomass with Fossil Fuel, and Large Scale Hydrogen Delivery Infrastructure and Global Hydrogen Systems Analysis. The United States participates in all of these tasks. Members of the HIA are Australia, Canada, Denmark, the European Commission, Finland, France, Germany, Greece, Iceland, Italy, Japan, South Korea, Lithuania, the Netherlands, New Zealand, Norway, Spain, Sweden, Switzerland, Turkey, United Nations Industrial Development Organization-International Center for Hydrogen Energy Technologies, and the United States. In the past year, new tasks or annexes in hydrogen delivery infrastructure and global systems analysis have been initiated. A new task, Distributed and Community Hydrogen for Remote Communities, is under definition and is expected to start in FY 2011. Information about the IEA HIA is available at www.ieahia.org.

EXTERNAL COORDINATION, INPUT, AND ASSESSMENT

Hydrogen and Fuel Cell Technical Advisory Committee (HTAC)

HTAC was created in 2006 to advise the Secretary of Energy on issues related to the development of hydrogen and fuel cell technologies and to provide recommendations regarding DOE’s programs, plans, and activities, as well as on the safety, economic, and environmental issues related to hydrogen and fuel cells. HTAC members include representatives of domestic industry, academia, professional societies, government agencies, financial organizations, and environmental groups, as well as experts in the area of hydrogen safety.

HTAC met three times between August 2009 and August 2010. In March 2010, HTAC released its second annual report, which summarizes hydrogen and fuel cell technology domestic and international progress in RD&D projects; commercialization activities; and policy initiatives. More information about HTAC, including the annual reports, is available at: http://www.hydrogen.energy.gov/advisory_htac.html

Federal Agency Coordination—the Interagency Task Force and the Interagency Working Group

The Hydrogen and Fuel Cell Interagency Working Group (IWG), co-chaired by DOE and the White House Office of Science and Technology Policy, meets monthly to share expertise and information about ongoing programs and results, to coordinate the activities of federal entities involved in hydrogen and fuel cell RD&D, and to ensure efficient use of taxpayer resources.

In August 2010, the IWG launched an updated Web portal, www.hydrogen.gov. The site serves as an information and government news source on hydrogen and fuel cells and a portal to participating agency activities. The IWG also completed a draft Interagency Action Plan with an expected release in FY 2011 in preparation for the reconvening of the Interagency Task Force.

National Academy of Sciences

The National Research Council (NRC) of the National Academies provides ongoing technical and programmatic reviews and input to the Hydrogen Program. The NRC has conducted independent
reviews of both the Program\textsuperscript{11} and the R&D activities of the FreedomCAR and Fuel Partnership.\textsuperscript{12,13} In 2010, the NRC completed its Phase III review of the Partnership. Key outcomes of the review are documented in the report, \textit{Review of the Research Program of the FreedomCAR and Fuel Partnership: Third Report},\textsuperscript{14} in which the committee expressed an overall opinion that the Partnership “is effective in progressing toward its goals,” and that “there is evidence of solid progress in essentially all areas, even though substantial barriers remain.” In this report, the committee also recognized “three primary alternative pathways” for reducing petroleum consumption and greenhouse gas emissions in the transportation sector: (1) improved internal combustion engine vehicles coupled with greater use of biofuels, (2) expanded use of plug-in electric vehicles and battery electric vehicles, and (3) hydrogen fuel cell vehicles.

In 2010, the NRC’s Committee on Assessment of Resource Needs for Fuel Cell and Hydrogen Technologies released the report, \textit{Transitions to Alternative Transportation Technologies—Plug-In Hybrid Electric Vehicles.}\textsuperscript{15} This report followed the committee’s 2008 report, \textit{Transitions to Alternative Transportation Technologies—A Focus on Hydrogen}. These reports were required by the Energy Policy Act section 1825 to compare hydrogen fuel cell vehicles to alternate advanced vehicle technologies. A key conclusion of the latest report is that a diverse approach to RD&D and market transformation—comprising a portfolio of efforts in hydrogen, batteries, and biofuels—will “enable the greatest reduction in oil use.”

\textbf{FY 2010 Annual Merit Review and Peer Evaluation}

The Annual Merit Review (AMR) took place June 7–11, 2010, providing an opportunity for the Program to obtain an expert peer review of the projects it supports and to report its accomplishments and progress. For the second time, this meeting was held in conjunction with the annual review of DOE’s Vehicle Technologies Program. During the AMR, reviewers evaluate the Program’s projects and make recommendations; DOE uses these evaluations, along with other review processes, to make project funding decisions for the upcoming fiscal year. The review also provides a forum for promoting collaborations, the exchange of ideas, and technology transfer. This year, over 1,700 people attended the review and 349 projects were presented, of which 216 were peer-reviewed. There were 198 contributing reviewers; the report compiling their comments is available at http://www.hydrogen.energy.gov/annual_review.html. In 2011, the AMR will be held May 9–13 in Arlington, Virginia.

\textbf{IN CLOSING…}

The Program will continue to pursue a broad portfolio of RD&D activities for fuel cell applications across multiple sectors. Efforts will span the full spectrum of technology readiness, including: early market applications that are already viable or are expected to become viable in the next few years, such as forklifts, backup power, and portable power applications; mid-term markets that are expected to emerge in the 2012–2015 timeframe, such as residential combined-heat-and-power systems, auxiliary power units, fleet vehicles, and buses; and longer-term markets that are expected to emerge in the 2015–2020 timeframe, including light-duty passenger vehicles and other transportation applications. The Program will also continue to pursue activities to enable commercialization and stimulate the markets for hydrogen and fuel cells as they achieve technology readiness. Supporting these markets will not only help to achieve the economic, environmental, and energy security benefits that fuel

\textsuperscript{14} The full report is available from: http://www.nap.edu/catalog.php?record_id=12939.

\textsuperscript{15} The full report is available from: http://books.nap.edu/catalog.php?record_id=12826.
cells provide in those specific applications, but it will complement the Program’s longer-term R&D efforts by helping to increase current sales and manufacturing volumes, providing essential cost reductions—through economies of scale—for many of the same technologies that will be used in longer-term applications. Supporting earlier markets can also reduce many non-technological barriers to the deployment of hydrogen and fuel cell technologies and lay the groundwork for the larger infrastructure and supply base that will be needed for fuel cell vehicles. The Program released its draft strategic plan in October 2010 (www.eere.energy.gov/hydrogenandfuelcells/pdfs/program_plan2010.pdf); the final version will be released in FY 2011.

We are pleased to present the U.S. Department of Energy’s 2010 Hydrogen Program Annual Progress Report. The report is divided into chapters and is organized by technology area (e.g., fuel cells, hydrogen storage, etc.). Each chapter opens with an overview written by a DOE technology development manager that summarizes the progress and accomplishments of the previous fiscal year. The projects outlined in this document represent the work of the many innovative scientists and engineers supported by DOE. They are the ones responsible for the progress and technical accomplishments reported this year’s Annual Progress Report. We would like to recognize them for their hard work, commitment, and continued progress.

II. HYDROGEN PRODUCTION
II.0 Hydrogen Production Sub-Program Overview

Introduction

Fiscal Year (FY) 2010 Hydrogen Production activities focus on developing technologies that enable the long-term viability of hydrogen as an energy carrier for a diverse range of end-use applications, including portable power, stationary power, backup power, specialty vehicles, and transportation. A variety of feedstocks and technologies are being pursued.

Four DOE offices have been engaged in research and development (R&D) relevant to hydrogen production:

- Energy Efficiency and Renewable Energy (EERE) is developing technologies for distributed production of hydrogen from bio-derived renewable liquids and by electrolysis of water, as well as centralized renewable production options that include water electrolysis integrated with renewable power (e.g., wind, solar, hydroelectric, and geothermal), biomass gasification, solar-driven high-temperature thermochemical water splitting cycles, direct photoelectrochemical (PEC) water splitting, and biological processes.

- Fossil Energy (FE) is advancing the technologies needed to produce hydrogen from coal-derived synthesis gas, including carbon sequestration and co-production of hydrogen and electricity.

- The Office of Basic Energy Sciences, within the Office of Science, conducts basic research to develop a fundamental understanding of biological and biomimetic hydrogen production, PEC water splitting, catalysis, and membranes for gas separation.

- In Nuclear Energy (NE), the Nuclear Hydrogen Initiative was discontinued as a separate program in FY 2009, after the selection of steam electrolysis as being the hydrogen production pathway most compatible with the Next Generation Nuclear Plant (NGNP). Limited development of high-temperature electrolysis is continuing under the NGNP project, which also includes evaluations of other end-user applications and energy transport systems.

Goal

The goal of the Program’s hydrogen production portfolio is to research and develop low-cost, highly-efficient hydrogen production technologies from diverse, domestic sources, including coal (with sequestration), nuclear, and renewable resources.

Objective

The objective of the Program’s hydrogen production portfolio is to reduce the cost of hydrogen dispensed at the pump to a cost that is competitive with gasoline, on a cents-per-mile basis. This goal applies to all production technology pathways. Specific targets—for when the various technologies will achieve this goal—are based on the technologies’ current states of development.

FY 2010 Technology Status

Recent independent reviews of production pathway costs are summarized in Table 1. The report, Distributed Hydrogen Production from Natural Gas (National Renewable Energy Laboratory [NREL], 2006) provided the basis for DOE to discontinue R&D in steam methane reforming for hydrogen production—it verified that the cost target could be met from distributed reforming of natural gas. Other reports shown in Table 1 reflect the H2A cost projections and cost and performance targets for the Hydrogen Production sub-program’s chapter of the Multi-Year Program Plan, which is currently being updated.

Interim and ultimate pathway-specific targets consistent with the overall targets established for the Program are being revised. These will include verification of the competitive feasibility of hydrogen production from non-ethanol bio-derived liquids by 2015, and of hydrogen production using advanced
renewable technologies (including PEC and biological hydrogen generation, as well as high-temperature thermochemical cycles driven by concentrated solar energy) by 2020.

The goals and objectives of FE’s efforts in hydrogen production are documented in the *Hydrogen from Coal Program Research, Development and Demonstration Plan* (September 2009). They include proving the feasibility of a near-zero emissions, high-efficiency plant that will produce both hydrogen and electricity from coal and reduce the cost of hydrogen from coal by 25 percent compared with current technology, by 2016.

**FY 2010 Accomplishments**

**Biomass, Bio-Derived Liquids, Coal and Separations Processes**

- NREL demonstrated hydrogen production by auto-thermal reforming of bio-oil using the bench-scale reactor system and achieved hydrogen production of 7.5 g/100 g bio-oil (potentially 9.6 g/100 g bio-oil after water-gas shift) with 93% bio-oil to gas conversion.
- Argonne National Laboratory (ANL) completed an analysis of the economic feasibility of hydrogen production from glycerol derived as a byproduct of the biodiesel industry. The cost of hydrogen for a base case set of conditions was estimated at $4.86 per kg, where the price of glycerol was assumed to be $1.07/gallon. The cost of feedstock (crude glycerol) represented 44% of the cost of hydrogen.
- United Technologies Research Center demonstrated nearly 100% conversion of wood, using an inexpensive base metal catalyst, and completed a study to better understand the impact of base concentration on hydrogen yield and selectivity.
- Eltron Research Inc., Southwest Research Institute®, and Worcester Polytechnic Institute have developed membrane separation technologies that achieve a hydrogen recovery rate of 90% with essentially 100% hydrogen purity, while simultaneously enabling 90–95% CO₂ capture at high pressure, minimizing CO₂ compression costs. (FE project)

**Electrolysis**

- Giner Electrochemical Systems reduced hydrogen embrittlement in titanium/carbon cell-separators, demonstrated enhanced dimensionally stable membrane (DSM™) performance, and projected a decrease in overall capital cost of their electrolyzer stack from >$2,500/kW in 2001 to $463/kW in 2010.
NREL completed an independent review of wind electrolysis, estimating the levelized cost range for state-of-the-art electrolysis to be $4.90–$5.70/gge of hydrogen for forecourt refueling stations (including compression, storage and dispensing), and $2.70–3.50/gge for central electrolysis operations (at the plant-gate, excluding all delivery and dispensing costs).

Solar Thermochemical Hydrogen Production

- The University of Colorado at Boulder optimized formulations for hercynite materials, which are more stable and generate hydrogen at lower temperature than the traditional ferrites; they also completed a techno-economic analysis indicating that atomic-layer-deposition of ferrite materials on 100 m²/g supports with an oxidation/reduction cycle every five minutes will meet the 2015 DOE cost targets.
- ANL initiated a development and testing project for new membrane materials for the CuCl electrolyzer in the hybrid copper chloride cycle, and demonstrated that a decrease in the reactor pressure reduces the amount of steam required (H₂O/CuCl₂ ratios reduced by more than 30%, from 20–23 to 11–15) for >90% yield of the desired Cu₂OCl₂ product.

PEC and Biological Production

- Stanford University achieved the first-ever demonstration of bandgap tailoring in photoactive MoS₂ nanoparticles. The bulk MoS₂ bandgap of 1.2 eV was increased to 1.8 eV, a more optimal value for PEC water splitting, by quantum confinement effects in 5-nm diameter nanoparticles.
- Directed Technologies Inc. completed separate techno-economic boundary analyses of PEC solar hydrogen production and biological hydrogen production, projecting cost ranges of $2.50–$10/gge H₂ for PEC and $3–$12/gge H₂ for biological production, based on the assumption of technology readiness for the PEC materials and biological organisms being developed.
- University of California, Berkeley, developed methods to minimize the size of chlorophyll antennae used in photosynthesis by decreasing the expression of the Truncated-Light-Antenna genes, thereby substantially improving solar light energy utilization efficiencies in plants and microalgal cultures from the 2000 baseline of 3% up to 25%.
- NREL, in collaboration with Pennsylvania State University, designed, constructed, and tested a 2.5-L bench-scale prototype microbial electrolysis cell that produced hydrogen gas at a rate up to 1,250 mL/d, demonstrating the usefulness of this design.

Budget

The FY 2010 appropriation for hydrogen production provided $41 million for continued hydrogen production research. FE received $26.4 million, NE $5 million, and EERE $9.6 million to continue research efforts in FY 2010.

The President’s FY 2011 budget request for EERE includes $40 million for hydrogen fuel R&D, of which $12.8 million is planned for hydrogen production, with an emphasis on materials and processes for hydrogen from renewable resources. The request for FE is $12 million.
II. Hydrogen Production / Overview

FY 2011 Plans

- Continued emphasis on addressing major challenges in hydrogen production. In particular, the sub-program will focus on cost reduction, including the cost of materials and capital equipment. Performance enhancement will remain a priority as cost reductions are expected to result through process optimizations for all production pathways and technologies.
- Completion of an Independent Panel Review of costs for hydrogen production from biomass gasification and an analysis of near-term markets for hydrogen from biomass gasification.
- Update H2A cost projections for hydrogen production pathways.
- Update the Hydrogen Production chapter of EERE’s Multi-Year Program Plan.
- Continue EERE coordination with the Office of Science, which plans up to $50 million in basic research related to hydrogen and fuel cell technologies. Through basic science activities, a fundamental understanding of issues related to hydrogen production, particularly in the longer term R&D areas of PEC and biological processes, can help address the challenges of hydrogen production.
- Deployment projects funded by the American Recovery and Reinvestment Act will provide lessons-learned related to hydrogen production technologies.
- The National Energy Technology Laboratory will continue to support implementation of the membrane separation test protocols.
- Eltron Research Inc. plans to perform slipstream tests of a 12 lb/day hydrogen separation membrane at Eastman Chemicals’ coal gasification facility.
- Projects will complete 150 hours of laboratory-scale testing of non-precious-metal hydrogen separation membranes to show potential toward cost goals.

II.A.1 Investigation of Reaction Networks and Active Sites in Bio-Ethanol Steam Reforming over Co-Based Catalysts

Objectives

To develop precious metal-free catalysts that can operate at lower temperatures with high yields and selectivities for hydrogen steam reforming from bio-ethanol; acquire a fundamental understanding of the reaction networks, active sites and deactivation mechanisms of potential bio-ethanol steam reforming catalysts. More specifically:

- Determine the effect of catalyst synthesis methods on oxidation state, structure, metal dispersion, and particle size of cobalt-based bio-ethanol reforming catalysts using the following techniques:
  - Aqueous or organic impregnation
  - Co-precipitation
  - Sol-gel synthesis
  - Organometallic synthesis
  - Colloidal templating
  - Control of calcination and reduction conditions
- Determine oxidation states and chemical structures that are present in active catalysts that are exposed to:
  - Varying pre-treatment protocols
  - Differing levels of steam-to-carbon ratio during reaction
- Oxidative and auto thermal operation
- Different space velocities
- To study how the observed catalyst characteristics influence the reaction pathways for:
  - Oxygenate formation
  - Reverse water-gas shift
  - Alkane and olefine formation
  - Coke deposition
  - Steam reforming
- Determine how the chosen support material can influence metal dispersion and structure, and how it participates in:
  - Alcohol and water adsorption
  - Spillover of species
  - Intermediate and product formation
- Determine methods that can tailor the catalyst surface for optimum selectivity and activity by:
  - Surface acidity control
  - Chemical promotion
  - Active site density control
- Determine factors that degrade catalyst stability and optimize regeneration methods:
  - Pathways and active sites for coke formation
  - Loss of surface area under reaction
  - Metal-support interaction
  - Sintering

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Reformer Capital Costs
(C) Operation and Maintenance (O&M)
(D) Feedstock Issues

Technical Targets

This is a university project, which involves a systematic and detailed study aimed to provide fundamental answers to questions that are not readily solved in an industrial setting. The approach is an iterative one that combines catalyst synthesis, characterization and reaction engineering studies. The results of this study will prevent interpreting erroneous information resulting from the screening of a large
catalyst matrix by characterizing the parameters that lead to or inhibit the formation of active sites for reforming. The information obtained from this study will address many common problems associated with catalyst development, such as choice of materials, pretreatment conditions, and factors controlling active site distribution, stability, and selectivity. Insights gained from these studies will be applied toward the design and synthesis of cost-effective and efficient reforming technologies that meet the DOE 2012 technical targets for hydrogen from bio-derived renewable liquids. Specific technical targets that would benefit from this study are the following:

- Production Energy Efficiency: 72.0%
- Contribution of Production to Capital Cost: 0.45 ($/gasoline gallon equivalent, gge)
- Total Hydrogen Cost from bio-derived liquids: 3.80 ($/gge)

Accomplishments (most recent)

- An advanced X-ray spectroscopy technique, X-ray absorption fine structure spectroscopy (XAFS), that allows monitoring of the transformation of cobalt species during ethanol steam reforming was added to the arsenal of techniques that are being utilized to characterize the developed catalyst formulations under real working conditions.
- In situ XAFS studies provided insight to the changes in the oxidation state and local coordination environment of cobalt species during ethanol steam reforming which would, in turn, result in ease of operation with the elimination catalyst pretreatment step.
- The use of in situ infrared spectroscopy led to the identification of reaction intermediates under actual reaction conditions of ethanol steam reforming which solidified the understanding of the reaction mechanism.

Introduction

For hydrogen energy to fulfill its potential for protecting the environment, providing more efficient energy sources, and decreasing our nation’s dependence on foreign oil, we need economical and efficient technologies for hydrogen production from renewable energy sources. Hydrogen production from ethanol through steam reforming lends itself very well to a distributed hydrogen production strategy and hence has the potential to offer solutions to problems associated with hydrogen storage and infrastructure. The bio-ethanol produced by fermentation of biomass can yield an ethanol-water mixture already ideal for reforming without additional distillation steps. A review of the ethanol steam reforming literature shows that there is no consensus about an optimal catalyst, and a fundamental understanding of the relationships between catalytic properties and how these properties are affecting various reaction steps involved in this complex network is lacking.

The development of non-precious metal catalysts in this project will reduce the catalyst cost, while the lower operation temperatures will reduce the material cost for reactor systems and will also reduce the energy requirement for heating the feed mixture to high reaction temperatures. The catalyst will have high steam reforming activity, while being non-selective for various undesired side reactions, such as methanation, dehydration, dehydrogenation, coking, and reverse water-gas shift reaction. The high yields to be achieved will help increase the production energy efficiency. The catalytic system will have high stability and well-understood regeneration mechanisms. High stability will reduce catalyst cost by prolonging the active life span of the catalyst. The regeneration mechanisms will be useful in reactivating the catalyst, rather than discarding the deactivated catalyst. The design of such catalysts will not be possible without a thorough understanding of the relationships between the catalyst preparation parameters, their structural and molecular characteristics and their reaction performance. The understanding acquired through this study will eliminate the need for costly trial-and-error efforts and will enable design of catalytic systems with the desired characteristics.

Approach

The project encompasses examination of the cobalt-based catalyst system at every stage of its life history, from precursor stage to activation, deactivation and regeneration steps. The techniques used include catalyst synthesis studies, transient and steady-state reaction tests, and characterization using surface, bulk and molecular analysis techniques (both ex situ and in situ) such as X-ray photoelectron spectroscopy, laser Raman spectroscopy, diffuse reflectance infra-red Fourier transform spectroscopy (DRIFTS), transmission electron microscopy, X-ray diffraction, thermal gravimetric analysis, differential scanning calorimetry, temperature-programmed reduction, temperature-programmed oxidation, temperature-programmed desorption (TPD) and most recently, XAFS. The approach taken is not a consecutive execution of the tasks or steps in each task, but rather an iterative approach where the findings in one aspect of the study are utilized in a feedback mechanism to plan and modify the steps taken in another task. Understanding gained through molecular simulations is utilized in tailoring the catalyst surfaces for better performance.
Results

The activities during this reporting period focused on determination of the local coordination environment and oxidation state of cobalt-based catalyst formulations via XAFS spectroscopy. The project had multiple sessions of beam time at the Dow-Northwestern-DuPont Collaborative Access Team bending magnet beam line (5BM-D) at the Advanced Photon Source of Argonne National Laboratory. The primary focus of the XAFS studies was investigation of the effect of pretreatment conditions on the nature of cobalt species in efforts to improve the ease of operation and to shed light to the ongoing debate on the nature of the cobalt active sites in the bio-ethanol steam reforming literature.

XAFS spectra of Co/CeO₂ catalyst following oxidation and reduction pretreatment is shown in Figure 1 together with the XAFS spectra for cobalt (II) oxide and cobalt (II, III) oxide used as standards. Figure 1 clearly shows that the coordination environment of cobalt species in Co/CeO₂ catalyst closely resembles that of cobalt (II, III) oxide following oxidation treatment. Following reduction treatment cobalt species were reduced to a lower oxidation state that closely resembles cobalt (II) oxide. Figure 1 also shows the XANES fit for oxidized and pre-reduced Co/CeO₂ catalysts which have undergone ethanol steam reforming (ESR) for 1-hour at the designated temperature. A comparison of the oxidation states of cobalt species following ESR over the pre-oxidized and pre-reduced samples clearly showed that regardless of the pretreatment procedure the same type of cobalt species were present in almost the same proportions over both of the catalysts.

In addition to the XAFS technique for studying the active cobalt species during reaction conditions, the interactions of ESR reactants, intermediates and products were studied under ESR conditions using in situ DRIFT spectroscopy. Although DRIFTS technique has been used extensively in the project to investigate the thermal evolution of surface species following the room-temperature adsorption of reactants and reaction intermediates (DRIFTS-TPD), these in situ reaction DRIFTS experiments allowed monitoring of the transformation of reactants and especially less stable surface intermediates under reaction conditions. The DRIFTS data collected during reaction were combined with spectra collected during purging for a detailed identification of surface species. Figure 2 shows such a pair of DRIFTS data as a function of temperature for a 10% Co/CeO₂ catalyst during ESR and subsequent purge steps. The 1,731 cm⁻¹ band observed in the spectra collected in situ during ESR above 150°C is of particular
importance since it signifies adsorbed acetaldehyde [1-7]. Although in our steady-state reaction experiments, acetaldehyde was observed as a reaction product, it was not detected in the transient experiments or in the TPD experiment. It is highly likely that these species interact weakly with the surface and get flushed away during the purge, and therefore, the DRIFTS-TPD profiles failed to show the presence of aldehyde species on the surface. Along with the ethoxy groups detected on the surface, this finding provided further evidence for the previously proposed ethanol steam reforming reaction mechanism where an ethanol-to-ethoxy-to-acetaldehyde pathway was proposed to be the initial steps for hydrogen production in bio-ethanol steam reforming (Figure 3).

This year’s work also involved preliminary studies with different feedstocks such as dimethylether (DME). DME is an inert, non-carcinogenic, non-corrosive, non-mutagenic and virtually non-toxic alternative to ethanol. Moreover, it is possible to liquefy DME at 0°C and 6 psig which makes it a versatile feedstock for industrial applications. The DRIFTS spectra presented in Figure 4 shows operando DME steam reforming over a 10% Co/CeO$_2$ catalyst. Strong bands associated with methoxide species, which persisted throughout the investigated temperature range of 25-400°C were observed. Furthermore, the presence absorption bands in the 1,250-1,100 cm$^{-1}$ region pointed to the presence of formates [8]. Co/CeO$_2$ catalyst showed strong single carbon adsorption bands on the surface, which were observed throughout the temperature program in steam reforming conditions.

Conclusions and Future Directions

- New collaboration was initiated with the Argonne National Laboratory.
- Local coordination environment and oxidation state of cobalt over the cobalt-based ESR catalysts were determined via XAFS.
- The role of catalyst pre-treatment was examined by XAFS.
- Operando vibrational spectroscopy techniques were shown to provide new insights into the reaction mechanism.
- Alternative feedstocks such as DME were introduced.
- Collaborative molecular simulation work using density functional theory calculations will be performed and used to guide rational catalyst design.

II.A.2 Distributed Hydrogen Production from Biomass Reforming

Objectives

- Evaluate and develop bio-derived liquid aqueous phase reforming (APR) technology for hydrogen production that can meet the DOE 2017 cost target of <$3.00/gasoline gallon equivalent (gge).
- Identify and control the catalyst composition, reaction pathways, and catalyst preparation methods to enhance hydrogen selectivity, productivity, and catalyst life.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Reformer Capital Cost
(C) Operation & Maintenance
(D) Feedstock Issues
(E) Greenhouse Gas Emissions

Technical Targets

For production of hydrogen from bio-derived liquids, the primary target is the cost of delivered hydrogen (non-compressed). This target is $3.80/gge in 2012 and $3.00 in 2017 ($3.00/kg H₂). For APR, the cost targets remain the primary drivers. We have been focusing on identifying the specific role of the catalyst components, delineating the mechanistic pathways leading to desired and undesired products, and understanding the causes of catalyst deactivation. This improved understanding is aimed at reducing operating costs, which will lower cost of hydrogen production.

Accomplishments

- Found evidence for dual-functionality of Pt-Re/C under a hydrothermal APR environment:
  - Pt-Re alloy formation provides increased activity toward H₂ production.
  - Acidic ReOₓ facilitates competitive dehydration pathways.
- Advanced the understanding of glycerol APR over Pt-Re/C:
  - Addition of Re increases conversion of glycerol, but also provides additional reaction pathways competing with the H₂-generating C-C cleavage pathway.
  - ReOₓ formed under APR conditions facilitates C-O scission, which consumes H₂ and leads to higher selectivity to alcohols and C₂₊ alkanes.
  - H₂ productivity increases with addition of Re at expense of H₂ selectivity.
  - Addition of KOH to glycerol feed over Pt-Re/C neutralizes acidity of ReOₓ and depresses C-O scission pathways, resulting in increased H₂ productivity via C-C cleavage.
- Preliminary results from APR of sorbitol have been obtained, providing comparative behavior between APR of sorbitol and glycerol, indicating that maintaining selectivity toward C-C bond cleavage vs. C-O bond cleavage is even more challenging.

Introduction

The conversion of biomass-derived liquids to hydrogen is attractive because of their near carbon-neutral footprint and their availability in many regions of the U.S. We target sugars and sugar alcohols, along with other polyols such as glycerol, for distributed production of hydrogen. These sugars and sugar alcohols are thermally unstable if vaporized to reforming temperatures; therefore aqueous phase reforming is the technology of choice. Currently, many researchers are investigating the conversion of sugars and sugar alcohols to liquid products that are infrastructure compatible, with less attention being paid to hydrogen production from these same molecules. Our project focuses on this latter aspect, hydrogen production, which has perhaps a longer time horizon, but over the long-term is an
important approach to meeting the energy needs through the application of fuel cells.

**Approach**

APR is becoming a recognized technology for the production of hydrogen from thermally unstable bio-derived sugars and sugar alcohols. Operation is at relatively low temperatures (225-265°C), placing a significant demand on catalytic activity. The standard catalyst is platinum on carbon (Pt/C), which shows modest activity but high hydrogen selectivity. Much development effort has been on catalyst modification to increase activity while preserving the good hydrogen selectivity. Addition of Re to Pt/C has been established as the leading candidate for enhanced APR performance. Our approach has included:

- Detailed study of Pt-Re/C catalyst:
  - Compare catalytic performance with Pt/C for glycerol feedstock.
  - Quantify the effect of Re addition on Pt/C performance.

- Develop advanced catalyst characterization methods to understand interactions between the Pt, Re, and C components: X-ray photoelectron spectroscopy, X-ray absorption near-edge spectroscopy, transmission electron microscopy.

- Examine and quantify effect of base addition on catalyst performance.

- Evaluate options for co-production of hydrogen with CH₄ for compatibility with solid oxide fuel cells (SOFC) for power generation.

**Results**

Our APR work has focused on correlating catalyst structure with performance, and delineating competing reaction pathways with the intention to maximize the H₂ production pathway. Work has progressed this year from glycerol to sorbitol feedstock.

**Affect of Re Addition on Activity and Selectivity**

Figure 1 compares the activity of 3%Pt/C, 3%Pt-1%Re/C and 3%Pt-3%Re/C catalysts. The figure provides this information on a turnover frequency basis, meaning moles (of glycerol converted or product formed) per active Pt metal site (based on CO chemisorption) per minute. It can be seen that the addition of Re dramatically increases turnover frequencies for both glycerol conversion and all products formed, indicating that Re addition more affects activity than selectivity. Figure 2 compares the product selectivity in greater detail for the 3%Pt/C and 3%Pt-3%Re/C catalysts. In this case, the space velocity (flow rate) of the 3%Pt/C catalyst was substantially decreased in order to allow a comparison of performance over the two catalysts to be made at comparable glycerol conversion levels. The figure shows that the catalyst without Re addition is more selective toward H₂, CO₂, and diol formation, whereas addition of Re to the catalyst increases formation of alkanes, mono-alcohols, and carboxylic acids. We believe that the increase in alcohols and alkanes is the result of facilitating a dehydration pathway via the addition of Re, probably present as ReOₓ, in which diols are converted to mono-alcohols, and mono-alcohols converted to alkanes via successive dehydration/hydrogenation pathways. The reason for the increased formation of carboxylic acids is less clear.
Effect of Base Addition to 3%Pt-3%Re/C Catalyst

With the operating assumption being that the increase of mono-alcohols and alkanes was due to acidity present on the catalyst, we have explored the addition of 0.1% KOH base to neutralize the acidity of the catalyst. The net effect is a small increase in hydrogen selectivity, as shown in Figure 3, accompanied by a decrease in alkanes production, the result of significantly removing the dehydration pathway from mono-alcohols to alkanes. On the other hand, the addition of base results in the generation of more liquid phase product. We conclude that although base addition can have some positive effects in controlling reaction pathways, the amount of base added must be carefully controlled to maximize overall hydrogen productivity and minimize accumulation of liquid phase product.

Co-Production of Methane with H₂

This past year, we examined adjusting pH and operating conditions in an effort to maximize the combined production of H₂ and CH₄. The purpose for this was the potential utilization of the APR product with an SOFC, which is capable of processing CH₄. Figures 4 and 5 show that it is possible to maximize both H₂ and CH₄ through a combination of increased residence time and base addition.

Comparison of APR of Glycerol with Sorbitol

We examined the effect of changing feedstock from glycerol to sorbitol on the conversion and product selectivity, keeping the same operating parameters for both. The comparative results are shown in Figure 6a. It can be seen that for the larger (sorbitol) molecule, the hydrogen selectivity is significantly lower. However,
addition of base appears to be quite beneficial in terms of increasing the hydrogen selectivity from sorbitol, as seen in Figure 6b. The relative selectivity of methane vs. other alkanes is also increased on addition of base, pointing toward the possible realistic application of coupling the APR reformer with an SOFC.

Economic Benefits of Coupling APR with an SOFC

Based on a combination of Aspen modeling and H2A analysis, a qualitative assessment of the potential benefits of combining APR of sorbitol with an SOFC was made. These results are summarized in Table 1.

Two conclusions can be drawn from the economic analysis:
- The use of fuel cell waste heat to drive the endothermic APR reaction provides a significant saving on cost of delivered H2.
- The overall production cost for hydrogen is significantly impacted by the cost of the feedstock.

Conclusions

- We have quantified the effect of the addition of Re to Pt/C catalyst in terms of catalyst activity and selectivity. Re addition increases overall catalyst activity, but at a loss of hydrogen selectivity relative to alkanes.
- Addition of KOH base to an aqueous 10% glycerol feed increases hydrogen productivity modestly with 3%Pt-3%Re/C catalyst, primarily through shutting down the production of light alkanes. However, more liquid products are also seen.
- Residence time is important in glycerol APR with the Pt-Re/C catalysts. Longer residence time increases gas phase products, hydrogen, and methane (relative to light alkanes).
- Hydrogen productivity with sorbitol declines relative to glycerol, primarily because more pathways are available, predominantly via dehydration/hydrogenation pathways. This can be ameliorated by employing longer residence times and adding base to the aqueous feed.

Future Directions

We will focus on the following:
- Catalyst synthesis and characterization, focusing on a number of synthesis variables including support characteristics, metal loading, and pretreatment conditions.
- Long-term testing to assess catalyst life.
- Screen catalysts to identify possible replacements for Re as a promoter for Pt, due to the undesired dehydration selectivity associated with Re addition.
- Explore alternate feedstocks, including less pure sorbitol and the effects of impurities on catalyst performance. Also identify purification needs with the raw feed material, as needed.

Project Start Date:  October, 2009
Project End Date: Project continuation and direction determined annually by DOE

Objectives

Evaluate the economic feasibility of distributed hydrogen production from glycerol derived as a byproduct of the biodiesel industry.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:
(D) Feedstock Issues
(E) Greenhouse Gas Emissions

Technical Targets

The project is conducting the analysis to determine the feasibility of meeting the efficiency and cost targets for producing hydrogen from glycerol at distributed production centers with a capacity of 1,500 kg of hydrogen per day and operating at 85% of capacity.

Accomplishments

- Completed the study using systems analysis followed by H2A to estimate the cost of hydrogen.
- Defined the process conditions needed to produce hydrogen from glycerol with an efficiency of 72%.
- The cost of hydrogen for a base case set of conditions was estimated at $4.86 per kg, where the price of glycerol was assumed to be $1.07/gal (10 cents/lb). The current price of crude glycerol ranges between 3-10 cents per pound.
- The cost of feedstock (crude glycerol) represents 44% of the cost of hydrogen.

Introduction

Glycerol is a biomass-derived liquid that is being generated by the biodiesel industry as a byproduct (waste stream) in quantities that exceed current demands. As a byproduct of the biodiesel industry the crude glycerol (80–88% pure) contains methanol, water, and salts (soaps). The presence of methanol requires that the crude glycerol be treated as a hazardous waste, which adds to the cost of biodiesel production. A preferred alternative is to convert the waste glycerol to secondary products within the bio-refinery (which has a very limited potential at this time), or to sell the glycerol, either as the crude glycerol as is, or after refining it to commodity grade. Table 2 summarizes some information on the supply, demand, and the price of glycerol.

*Each pound of biodiesel produced generates approximately 0.1 pound of crude glycerol byproduct
The burgeoning demand for hydrogen, preferably produced from renewable sources, and the growing availability of glycerol has attracted attention as a potential pathway for the distributed production of hydrogen from glycerol. A distributed hydrogen refueling infrastructure can potentially use this surplus renewable resource to produce hydrogen. This approach would simultaneously help manage a waste/surplus stream (to reduce the cost of biodiesel production costs) and produce hydrogen from a renewable resource. The economic viability of this pathway will be determined, in part, by the availability and cost of glycerol, and the cost of producing hydrogen from it.

Approach

The project reviewed the availability of glycerol which was then used to estimate the amount of hydrogen that can be produced annually in the U.S.

The process was based on the steam reforming of glycerol followed by purification using pressure swing adsorption. The model was set up, along with a set of assumptions, to determine the process conditions that would be needed to meet DOE’s efficiency target. The inputs and results from the base case were used to estimate the cost of hydrogen and the cost contributors.

Results

Glycerol can be steam reformed to produce up to 7 mol of hydrogen per mol of glycerol, according to the reaction,

\[
C_3H_8O_3 + 3H_2O \rightarrow 3CO_2 + 7H_2, \quad \Delta H_1 = +347 \text{ kJ} \quad (1)
\]

The reaction is strongly endothermic and requires a combination of catalysts, excess steam, and temperatures greater than 500°C to achieve high conversions of glycerol to hydrogen and carbon oxides. The actual reaction mechanism is complex, beginning with the decomposition of glycerol to intermediates including CO and H₂, followed by steam reforming of the intermediate carbonaceous species (Eqn.(2)) and water-gas shift (WGS) reaction (Eqn.(3)).

\[
C_{n}H_{m}O_{p} + H_2O \rightarrow CO + H_2, \quad \Delta H_2 > 0 \quad (2)
\]

\[
CO + H_2O = CO_2 + H_2, \quad \Delta H_3 = -41 \text{ kJ} \quad (3)
\]

Figure 1 shows the process schematic where hydrogen is produced at 72\%\(^1\) efficiency in the base case scenario for the production of 1,500 kg of H₂/day. The reforming process is based on 20 atm (~300 psi) steam-reforming/WGS reaction followed by a pressure-swing adsorption (PSA) unit for hydrogen purification. The steam reformer is operated with a molar steam-to-carbon ratio (S/C) of 3. The product stream leaving the reformer (reformate at chemical equilibrium at 800°C) is cooled and then processed in a high-temperature WGS reactor at 400°C. The reformate, composition is shown

\(^1\)Energy efficiency is defined as the energy of the hydrogen (lower heating value, LHV) out of the production unit divided by the sum of energy inputs into the process, i.e., \(\Sigma\) (Feedstock (LHV) + Natural Gas (LHV) + electricity). Electrical energy utilized does not include efficiency losses from the production and the transmission of electricity.
in Table 3, then enters the PSA unit where high purity hydrogen is extracted with 80% recovery, exiting the production unit at 20 atm.

The PSA off-gas containing the carbon oxides and methane, along with the un-recovered hydrogen is combusted in the burner to generate heat for the reforming process. Additional fuel (natural gas) is used in the burner, if needed.

For the base case, the cost of hydrogen (untaxed) from the steam-reforming of glycerol was calculated to be $4.86/kg-H₂. For this set of (base case) conditions, the estimated cost is 27% higher than the 2012 DOE target of 3.8/kg-H₂ from bio-derived liquids. The contributions of various elements to the cost of hydrogen are shown in Figure 2. The production unit accounts for ~60% ($2.97/kg) of the hydrogen cost, with feedstock being the main cost contributor. The refueling station part accounts for almost 40% ($1.88/kg) of the delivered hydrogen cost, where the majority of that cost is due to the required capital investment. Overall, the highest cost contributors for the delivered hydrogen are the feedstock costs (44%) and the combined capital investment costs for the production unit and refueling station (37%).

The production unit efficiency, affecting feedstock utilization, influences the cost of the delivered hydrogen. Figure 3 shows the cost of hydrogen as a function of production efficiency for four different feedstock prices. When the price of glycerol is high (>10 cents/lb), efficiency has a significant impact on hydrogen cost. At such a high feedstock price, however, the cost of delivered hydrogen exceeds the target by over 50%, even at 72% efficiency. The targeted cost of hydrogen for 2012 ($3.80) can be met with the glycerol price at 5 cents/lb. At this price, the efficiency has only a marginal impact on the hydrogen cost. At the low feedstock prices (2.4 cents/lb), efficiencies above 68% actually increase the cost of the delivered hydrogen, since the cost of the natural gas which is assumed to provide supplemental heat to the reformer is more expensive (LHV basis) than the glycerol feedstock.

**Conclusions**

- Glycerol supply is outpacing its demand as a result of the biodiesel industry.
Glycerol is renewable and can be efficiently converted to hydrogen.

With glycerol at $1.07/gal (10¢/lb) the estimated cost of H₂ is $4.86/kg.

The cost of hydrogen is highly sensitive to the price of the feedstock.

The U.S. biodiesel plants (capacity in 2008) can produce sufficient crude glycerol to enable 200,000 kg/day of hydrogen.

Project Start Date:  October 1, 2004  
Projected End Date:  September 30, 2012

Objectives

- By 2012, develop and demonstrate distributed reforming technology for producing hydrogen from bio-oil at $3.80/kilogram (kg) purified hydrogen.
- By 2011, develop a prototype that incorporates the key operations: bio-oil injection, catalytic auto-thermal reforming, water-gas shift, and hydrogen isolation.
- Develop the necessary understanding of process chemistry, bio-oil compositional effects, catalyst chemistry, and deactivation and regeneration strategy to form a basis for process definition for automated distributed reforming to meet the DOE targets.
- In Fiscal Year (FY) 2010, demonstrate the process of auto-thermal reforming of bio-oil including a long-term catalyst performance, yields of hydrogen, and mass balances.
- Using a bench-scale reactor system, demonstrate catalytic conversion consistent with $3.80/kg hydrogen.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Fuel Processor Capital

Accomplishments

- Demonstrated hydrogen production by auto-thermal reforming of bio-oil using the bench-scale reactor system.
- Achieved hydrogen production of 7.3 g/100 g bio-oil (potentially 9.6 g/100 g bio-oil after water-gas shift) with 93% bio-oil to gas conversion.
- Demonstrated 60 hours of steady performance of a research catalyst in several reforming/regeneration cycles.
- Achieved similar performance data for a commercial catalyst.

Introduction

Renewable biomass is an attractive near-term alternative to fossil resources because it has near-zero life-cycle CO₂ impact. Recent assessments have shown that more than 1 billion tons of biomass could be available in the United States each year at less than $50/ton [1]. This biomass could be converted to 100 million tons of hydrogen, enough to supply the light-duty transportation needs of the United States. This work addresses the challenge of distributed hydrogen production with the target of hydrogen cost of $3.80/kg by 2012 [2]. Pyrolysis is used to convert biomass to a liquid that can be transported more efficiently and has the potential for automated operation of the conversion system [3,4]. “Bio-oil” can then be converted to hydrogen and CO₂ in a distributed manner at fueling stations.
The thermally reactive compounds in bio-oil tend to decompose thermally and may form carbonaceous deposits and/or aromatic hydrocarbons, which are more difficult to convert to hydrogen. Thus, conventional fixed-bed reformers have not been proven efficient for this highly reactive feedstock. Reactors that fluidize or circulate the catalyst are much more suited for this application [5] but are not the optimal choice for small-scale and unattended operation. The objective of this project is to develop a system that will provide distributed production of hydrogen from bio-oil at filling stations. To accomplish this we are developing a simple fixed-bed reactor suitable for unsupervised automated operation.

Approach

Research is focused on developing a compact, low capital cost, low/no maintenance reforming system to enable achievement of the cost and energy efficiency targets for distributed reforming of renewable liquids. In this project, we are evaluating the following steps in the process:

- Bio-oil volatilization using ultrasonic atomization. We need to control physical and chemical properties of the liquid (viscosity), so blending with alcohol may be necessary.
- Heterogeneous auto-thermal reforming of bio-oil derived gas and vapor. Non-nickel reforming catalysts, including precious metal and potential cheaper oxides and other metals that remain active, need to be examined in application to bio-oil and its partial oxidation products.

Initial experiments were carried out using a micro-scale continuous flow tubular reactor coupled with a molecular-beam mass-spectrometer for analyzing the product gas composition. This year, we conducted a series of tests using a bench-scale reactor system that allowed for a longer-duration steady-state operation and provided more reliable data for mass balance calculations.

Results

The bench-scale auto-thermal reforming tests were carried out in the systems shown in Figure 1. Poplar pyrolysis bio-oil diluted with 10 wt% methanol was fed at 60 g/h using a membrane pump to the top of the 34 mm internal diameter, 45 cm long tubular quartz reactor. The bottom section of the reactor contained a fixed bed comprising 38 g of catalyst (1 wt% Rh, 1 wt% Ce on alumina) prepared at University of Minnesota mixed with 62 g of α-alumina. In the freeboard, the liquid in the form of a very fine mist produced by a 60 KHz ultrasonic nozzle (Sono-Tek) contacted air and steam; steam was produced by a home-made micro-generator. The non-catalytic oxidation was followed...
by the reactions in the catalytic bed. The optimum conditions that assured a smooth operation, high hydrogen yields and high bio-oil to gas conversion were process temperature of 800-850°C, oxygen-to-carbon ratio O/C=1.5, molar steam-to-carbon ratio S/C=1.6, and methane-equivalent volumetric hourly space velocity equal to 5,200 h⁻¹. The steam excess and some organics were collected in two condensers. The outlet gas flow rate was measured by a dry test meter. The concentrations of CO₂, CO, and CH₄ in the product gas were monitored by a non-dispersive infra-red analyzer (NDIR Model 300 from California Analytical Instruments); the hydrogen concentration was tracked by a thermal conductivity monitor TCM4. In addition, the gas was analyzed every 4 minutes by an on-line Varian (Model 4900) micro gas chromatograph, which provided concentrations of H₂, CO, CO₂, CH₄, C₂H₄, O₂, and N₂. The temperatures in the system, as well as the flows, were recorded and controlled by an OPTO 22 data acquisition and control system. Based on the flows and compositions of the process streams, mass balances as well as the yields of hydrogen generated from the feed were calculated.

A series of auto-thermal reforming tests included several production and regeneration cycles. After each hydrogen production test, the catalyst was regenerated by air oxidation and reused in the subsequent tests carried out at the same process conditions. The catalyst performance gradually decreased during the reforming cycle but was restored after every regeneration cycle. Gas composition as a function of time is shown in Figure 2. The average hydrogen production during this time span was 7.3 g/100 g bio-oil. This yield could increase to 9.6 g/100 g bio-oil if CO in the gas were further converted by water-gas shift. The carbon-to-gas conversion was 91-93% with the remaining carbon recovered mostly in the form of solid cenospheres (very light weight hollow spheres). These carbon deposits caused pressure drop increase during the tests and had to be removed by burn-off.

The next step in our research on the process development was the application of a commercial catalyst similar to that prepared by University of Minnesota. Previously, noble metal catalysts provided by Engelhard showed significantly lower performance than the University catalyst in micro-scale tests. This year, we obtained new rhodium and platinum catalysts that are being developed by BASF for commercial applications. These were alumina-based catalysts with a noble metal content of only 0.5 wt% compared to 1 wt% for the University of Minnesota catalysts. The gas composition from reforming bio-oil using BASF rhodium catalyst is shown in Figure 3. This figure shows combined results of two reforming experiments separated by the catalyst regeneration after five hours on stream. Remarkably, the system operation was even more stable than during previous tests using the University of Minnesota catalyst. The catalyst did not show any deactivation during tests but similarly to the experiments described above, the pressure drop due to the carbon deposits was observed. The hydrogen production was 7.4 g/100 g bio-oil with the potential to increase to 10.3 g/100 g bio-oil after completing water-gas shift. The carbon-to-gas conversion was 93% with the remaining carbon forming cenospheres. Though the BASF catalyst was tested for only 11 hours compared to 60 hours for the University catalyst, the results allow us to expect that its performance will remain at the same level.

Conclusions and Future Directions

- Bench-scale reactor tests of catalytic auto-thermal reforming of bio-oil performed using 90 wt% bio-oil/10 wt% methanol mixtures produced hydrogen...
yields of 7.3-7.4 g/100 g bio-oil with 91-95% of carbon-to-gas conversion.

- Rh/Ce catalyst prepared at University of Minnesota performed satisfactorily during 60 hours of operation that included reforming and regeneration cycles. Noble metal catalysts produced by BASF also showed very promising performance and will be used extensively in further tests.
- Tests will continue with bio-oil containing more inorganic impurities to assess their impact on the catalyst performance.
- A prototype system including catalytic reformer, water-gas shift reactor, and electrochemical hydrogen separator will be constructed and operated to demonstrate the integrated process performance.

Subcontractor: Directed Technologies, Inc. (DTI), Arlington, VA
Project Start Date:  May, 2005
Project End Date:  Project continuation and direction determined annually by DOE

Objectives

Develop a compact ceramic membrane reactor that meets the DOE 2017 cost target for producing hydrogen by reforming renewable liquids. Specific objectives for Fiscal Year (FY) 2010 were:

• Use oxygen transport membrane (OTM) to reform ethanol (EtOH) at ≤700°C.
• Generate data for detailed analysis to assess benefits of approach.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Reformer Capital Costs
(B) Reformer Manufacturing
(C) Operation and Maintenance (O&M)
(N) Hydrogen Selectivity
(P) Flux
(R) Cost

Technical Targets

This project is developing compact dense ceramic membranes that transport pure oxygen to efficiently and cost-effectively produce hydrogen by reforming renewable liquid fuels such as EtOH and bio-oil. Cost-effective small-scale reformer technology will be developed to integrate process steps, thereby minimizing unit size, capital cost, energy use, and operating cost and helping to meet DOE technical targets:

• Production Unit Energy Efficiency:
  – 72% (lower heating value, LHV) by 2012
  – 65-75% (LHV) by 2017
• Production Unit Capital Cost (un-installed):
  – $1.0M by 2012
  – $600K by 2017
• Total Hydrogen Cost:
  – $3.80/gasoline gallon equivalent (gge) (delivered) at the pump by 2012
  – <$3.00/gge (delivered) at the pump by 2017

A preliminary techno-economic analysis estimated a cost of ≈$3.40/gge for producing hydrogen by reforming EtOH with an OTM. DOE's hydrogen cost target is being revised at the present.

Accomplishments

• Significantly increased EtOH conversion with a new OTM, but analysis of the products of reforming indicated that a suitable catalyst is needed in order to increase hydrogen production during reforming.
• Enhanced H₂ production rate by increasing EtOH concentration and H₂O/EtOH in feed during EtOH reforming with OTM.
• Developed BFZ1 (BaFe₀.₉Zr₀.₁Oₓ) a new OTM whose significantly higher oxygen flux might enhance EtOH conversion at low temperature (∼500°C).
• Provided data to Directed Technologies, Inc. (DTI), whose preliminary analysis indicated a hydrogen production cost of ≈$3.40/gge for a station capacity of 1,500 kg H₂/day.

☆ ☆ ☆ ☆ ☆
Introduction

Previous study has shown that supplying oxygen with an OTM reduced the costs of methane reforming by ≈30–40% and energy consumption by ≈50%. Similarly, it has been shown that supplying oxygen during EtOH reforming increases EtOH conversion and enhances catalyst performance by preventing coke formation [1]. An OTM can supply high-purity oxygen for EtOH reforming by separating it from air without using a separate gas separation unit. Because the OTM is a mixed conductor, the oxygen transport requires neither electrodes nor external power circuitry, i.e., the process is non-galvanic. The oxygen flux through the membrane depends on the membrane's electron and oxygen-ion conductivities, its surface oxygen exchange kinetics, and the oxygen partial pressure (pO₂) gradient across the membrane.

The goal of this subtask is to develop a dense OTM that provides oxygen for efficiently and economically producing hydrogen through the reforming of renewable liquid fuels such as EtOH and bio-oil. Using an OTM to supply high-purity oxygen from air can reduce the cost and energy consumption associated with EtOH reforming, but a detailed system analysis must be done to determine the cost and energy benefits. In this project, we are generating data for the system analysis. While generating the necessary data, we are also developing OTMs that transport oxygen at an industrially significant rate at low temperature (≈500°C) and possess sufficient mechanical and chemical stability to withstand the large stresses that develop from having air on one side of the OTM and carbonaceous fuels on the other side.

Approach

In order for our approach to be cost-effective in reforming renewable liquids, an OTM must efficiently transport oxygen. In order to efficiently transport oxygen, an OTM must have an appropriate combination of electronic and ionic conductivity; therefore, we use conductivity measurements to identify promising membrane materials. If a material has sufficient conductivity (>10⁻¹ ohm⁻¹·cm⁻¹), we measure its hydrogen production rate, which is directly related to its oxygen transport rate. In order to increase the oxygen transport rate, we adjust the OTM’s composition, decrease its thickness, coat it with porous layers to increase its active area, and modify its microstructure to overcome limitations from surface reaction kinetics. Catalysts will be used to promote reforming reactions. We measure the hydrogen production rate under various reaction conditions for periods up to ≈1,000 h to evaluate the chemical stability of OTMs, because OTMs must be stable for extended periods to cost-effectively produce hydrogen. Because OTMs must be available in a shape with a large surface area, e.g. tubes, we fabricate small tubular OTMs and test their performance. In order to evaluate the expected cost and energy benefits of reforming renewable liquids with an OTM, we are generating the necessary data for an independent party, Directed Technologies, Inc., to conduct a detailed system analysis.

Results

OTMs made of La₀.₇Sr₀.₃Cu₀.₂Fe₀.₈Oₓ (LSCF), Sr₀.₆Fe₀.₉Ti₀.₁Oₓ (SFT1), BaFe₀.₉7₅Zr₀.₀₂₅O₃ (BFZ0), and BFZ1 were tested. Powders for the OTMs were prepared by conventional solid state reaction between the constituent oxides. Dense OTMs were prepared in the shape of disks, tubes, or OTM thin films on porous disks or tubes. Before measuring an OTM’s oxygen flux or its hydrogen production during EtOH reforming, the OTM was tested for interconnected porosity and/or microcracks by checking if isopropyl alcohol (IPA) penetrated it. Penetration of the OTM by even a small amount of IPA was easily seen as darkening of its surface and indicated that the OTM contains cracks or interconnected porosity.

If IPA did not penetrate an OTM, it was tested on a fixture that allowed separate gases to be flowed over opposite faces of the OTM. The oxygen flux was measured while air flowed on the “feed” side of the OTM and ultra-high purity He on the “sweep” side, both gases flowing at a rate of 150 ml/min. The oxygen concentration in the sweep gas was measured with a Hewlett-Packard 6890 gas chromatograph (GC); the nitrogen concentration in the sweep gas was measured to correct for minor oxygen leakage through the gas seal. EtOH reforming was studied while feed with a steam/EtOH ratio ranging from 0/1 to 5/1 flowed on one side of the OTM, while air flowed on the opposite side. As a reference, EtOH reforming was also done with a dense, oxygen-impermeable Al₂O₃ cap instead of an OTM. The concentrations of EtOH reforming products were measured during the tests with the GC.

Figure 1 compares the compositions of the product streams during EtOH reforming at 550°C with a thin-film OTM tube (LSCF, thickness ≈30 μm) and with a dense, oxygen-impermeable Al₂O₃ “blank.” Steam was not added to the feed during these tests. The hydrogen formation rate with the OTM, although not large in this experiment without a catalyst, was more than twice that with the Al₂O₃ blank. Whereas the formation rates of CO, H₂O, and CO₂ were negligible with the blank, they all increased significantly when an OTM was used. The amount of un-reacted EtOH decreased by >50% with an OTM, giving an EtOH conversion of ≈63% as compared to the EtOH conversion of ≈47% that was reported in FY 2009.

The higher formation rates for products and the smaller concentration of un-reacted EtOH clearly show
that oxygen supplied by the OTM enhanced EtOH reforming. The high formation rate of H\textsubscript{2}O indicates that much of the hydrogen formed by reforming reacts with the oxygen supplied by the OTM. The high H\textsubscript{2}O formation rate demonstrates that a catalyst is needed to promote preferential oxidation of carbon-containing products. Although the formation rate of ethylene formed by dehydration of EtOH was not high, its presence is highly undesirable because ethylene is a precursor of coke formation, and may lead to catalyst deactivation [2].

EtOH reforming with an LSCF tube (thickness ≈1.5 mm) was studied using steam/EtOH ratios up to 5/1. As before, reforming experiments were also done with oxygen-impermeable Al\textsubscript{2}O\textsubscript{3} as a reference. Steam/EtOH mixtures were prepared by mixing two gas streams (N\textsubscript{2} or He), one saturated with EtOH at room temperature (23°C), giving P\textsubscript{EtOH}=0.067 atm, and the other saturated with water at a controlled temperature (38.5-72.1°C).

Figure 2 shows the effect of steam/EtOH ratio on the hydrogen formation rate. The hydrogen formation rate increased as the steam/EtOH ratio increased in both experiments. In the blank experiment, the hydrogen formation rate increased the most as the steam/EtOH ratio increased to 3/1 and only slightly more as the steam/EtOH ratio increased to 5/1. With P\textsubscript{EtOH}=0.067 atm, the hydrogen formation rate with the OTM tube was measured only for steam/EtOH ratios of 0/1 and 3/1. Under both conditions, the hydrogen formation rate with the OTM tube was about twice as high as that measured in blank experiments. When P\textsubscript{EtOH} was increased to 0.135 atm (with a steam/EtOH ratio of 0/1), the hydrogen formation rate increased to ≈1.7 cm\textsuperscript{3}/min. A blank experiment was not done with the higher P\textsubscript{EtOH}.

Figure 3 shows the oxygen flux (normalized for thickness of 1.0 mm) of BF20, BFZ1, SFT1, and LSCF disks.
appears promising for use during EtOH reforming at low temperature, provided that it exhibits good chemical stability during reforming.

DTI is performing a detailed techno-economic analysis of EtOH reforming with an OTM to evaluate its cost- and energy-benefits. For the analysis, Argonne is providing oxygen flux and EtOH conversion data for promising OTMs. A preliminary analysis shows that the cost of the EtOH feedstock comprises a major fraction (~70%) of the cost of producing hydrogen by EtOH reforming with an OTM. Figure 4 shows the cost of producing hydrogen by EtOH reforming with an OTM is $3.10-$3.60/kg H₂, depending on the EtOH fuel efficiency. A more detailed analysis is underway.

Conclusions and Future Directions

Significant progress has been made in demonstrating that a dense OTM can enhance the reforming of renewable liquids. In order to further evaluate the benefits of this approach, we will:

- Reform EtOH with OTM in presence of catalyst(s).
- Generate key data for performing a detailed economic analysis of our approach.
- Continue testing the performance of OTMs during EtOH reforming at ~500°C.
- Study effect of EtOH concentration, gas flow rates, and OTM thickness.
- Evaluate chemical stability of OTM during reforming of EtOH.
- Work with DTI to perform a detailed cost and energy analysis to judge the merits of using OTM to enhance H₂ production by EtOH reforming.
- Compare the cost of hydrogen production by OTM-assisted EtOH reforming with conventional steam reforming.

II.B.1  A Novel Slurry-Based Biomass Reforming Process

Technical Targets

This project consists of three key elements: plant and system design, catalyst research, and a proof-of-concept demonstration. The information obtained from all three efforts will be used to demonstrate that the proposed H₂ production system will meet the DOE’s 2012 Biomass Gasification/Pyrolysis Hydrogen Production energy efficiency and total H₂ cost targets of 43% (based on feedstock LHV) and $1.60/kg H₂, respectively. The current progress toward achieving the DOE’s technical targets based on the preliminary plant and system design is shown in Table 1.

Table 1. Technical progress for the project as measured against the DOE’s technical targets for biomass gasification/pyrolysis hydrogen production.

Accomplishments

- Demonstrated 100% conversion of wood using an inexpensive base metal catalyst.
- Examined the effect of base concentration on liquid phase reforming H₂ selectivity.
- Developed a promoted nickel (Ni) catalyst that maintains a high selectivity to H₂ with minimal base.
- Elucidated the liquid phase reforming reaction pathways for ethylene glycol via atomistic modeling.
- Demonstrated palladium (Pd) membrane integration with a liquid phase reforming flow reactor.

Introduction

This project is focused on developing a catalytic means of producing H₂ from raw, ground biomass, such as fast growing poplar trees, willow trees, or switch grass. The use of a renewable, biomass feedstock with minimal processing can enable a carbon-neutral means of producing H₂ in that the carbon dioxide produced from the process can be used in the environment to produce additional biomass. For economically viable production of H₂, the biomass is hydrolyzed and then reformed without any additional purification steps. Any unreacted...
biomass and other byproduct streams are burned to provide process energy. Thus, the development of a catalyst that can operate in the demanding corrosive environment and presence of potential poisons is vital to this approach.

**Approach**

The concept for this project is shown in Figure 1. The initial feed is assumed to be a >5 wt% slurry of ground poplar wood in dilute base. Potassium carbonate, derived from wood ash, is an effective base. Base hydrolysis of the wood is carried out at high, but sub-critical, pressures and temperatures in the presence of a solid catalyst. A Pd alloy membrane allows the continuous removal of pure H\textsubscript{2}, while the retentate, including methane, is used as fuel in the proposed plant.

**Results**

Following the successful demonstration of the near 100% conversion of wood to hydrogen-containing gas using liquid-phase reforming (LPR), the project efforts were focused on further understanding the durability and kinetics of the process in a plug flow reactor system. Model compounds, such as ethanol, 1,4-butanediol, and ethylene glycol, were used to study a fixed bed reactor system using UTRC’s Pt-Re based catalyst. Tests showed that the catalyst could reform the model compounds for periods greater than 250 hours without signs of degradation.

During the model compound study, the coupling of the flow reactor with a Pd alloy H\textsubscript{2} separation membrane was also demonstrated. A 10% ethanol in 0.1M K\textsubscript{2}CO\textsubscript{3} solution was flowed through the reactor bed at 310°C at 3 mL/min. The effluent gas stream from the reforming reactor was approximated 213 mL/min and composed of approximately 64% H\textsubscript{2}. The effluent gas stream was fed to a palladium-copper alloy membrane held at 450°C at a pressure of 193 psig. The system was allowed to run for 45 minutes to stabilize and collect data. The data from the experiment is given in Figure 2. The system behaved as expected, with a 93% H\textsubscript{2} recovery, indicating maximum recovery of the H\textsubscript{2} from the reformate gas stream.

As part of the goal of reducing catalyst costs, and thus capital costs, the project focused on transitioning from a precious metal-based catalyst to one with base metal as the active component. At the same time, a study was performed to better understand the impact of base concentration on H\textsubscript{2} yield and selectivity. It was determined that for a commercially available Raney Ni catalyst, the selectivity toward H\textsubscript{2} could be adjusted by changing base concentration. By increasing base concentration, methane generation could be significantly suppressed, but at the expense of a reduced H\textsubscript{2} yield due to the formation of high levels of intractable organic acids. Figure 3 shows the impact of H\textsubscript{2} selectivity as a function of residence time and base concentration for a 5% ethylene glycol feed.

First principles atomistic modeling was used to gain an insight into the factors that control the activity and selectivity toward H\textsubscript{2} production by ethylene glycol reforming on Ni catalysts. The schematic diagram of reforming pathways is depicted in Figure 4. For ethylene glycol on a Ni surface, the first step after adsorption is hydroxyl bond breaking to form an ethylenedioxy intermediate. At the surface coverage considered, the activation of the C-O bond in ethylenedioxy and rearrangement to form the acetaldehyde intermediate and adsorbed oxygen are thermodynamically favorable. Subsequent dehydrogenation and C-C bond scission...
of acetaldehyde yields the CO and CH₃ as final decomposition intermediates. CO is shifted in water to CO₂ and H₂ while the methyl is hydrogenated into methane. In a basic environment, CO can also be converted to a formate ion in solution through hydrophilic attack, consistent with the experimental observation of formic acid in the spent liquor.

As the reaction pathway for LPR on Ni consists of three major paths toward either H₂, methane, or organic acid, modifications were performed to standard Raney Ni catalysts to adjust their selectivity. As a result, a modified Raney Ni catalyst was developed that enabled the use of dilute carbonate bases while still maintaining high selectivity as well as high H₂ yield. Figure 5 shows the impact of H₂ selectivity as a function of residence time and base concentration for a 2.5% ethylene glycol feed. This performance was also reproduced using yellow poplar in a batch reactor.

Conclusions and Future Directions

Based on the successful work with base metal catalysts, the next step of the project is to construct a demonstration unit for H₂ production. The demonstrator shall integrate a liquid phase reformer with a Pd membrane separator and show the integration...
of the major process components into a small system. Construction of a 12 L/min H₂ generation demonstrator fed by wood slurry has begun and shall be in operation later in 2010.

Phone: (202) 586-1623
E-mail: Richard.Farmer@ee.doe.gov

Project Start Date: October 2007
Project End Date: October 2008

Objectives

Develop novel chemical routes and catalysts to produce hydrogen/syngas from lignocellulosic feedstocks.

Technical Barriers

Feedstock Cost and Availability

Feedstock costs are high. Improved feedstock/agriculture technology (higher yields per acre, etc.), lower cost feedstock collection, and improved feedstock preparation are needed. Because biomass feedstocks are seasonal in nature, feedstock-flexible processes and cost-effective feedstock storage are needed.

Capital Cost and Efficiency of Biomass Gasification/Pyrolysis Technology

The capital cost for biomass gasification/pyrolysis needs to be reduced. Process intensification by combining unit operations can significantly reduce capital costs. This could range from combining the current two step water-gas shift and pressure swing adsorption separation to a one step water-gas shift with integrated separation, to integrating gasification, reforming, water-gas shift and separation all in one unit operation. Improved process efficiency and higher hydrogen yields and selectivities through catalyst research, better heat integration, and alternative gas clean-up approaches are needed. Improved catalysts or engineering approaches for tar cracking are also needed.

This project addresses the following technical barriers from the Biomass Gasification/Pyrolysis Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(T) Capital Cost and Efficiency of Biomass Gasification/Pyrolysis Technology

Technical Targets

LANL is conducting applied research that will increase the research knowledge base on biomass solubilization/depolymerization and hydrogen producing reaction pathways from biomass. LANL’s research is anticipated to provide alternative routes to hydrogen production from biomass that are aimed at meeting or exceeding the DOE targets (Table 1).

Accomplishments

- Conversion of cellobiose to glucose is feasible, but rates currently too low.
- Recent results of low-temperature catalyzed pyrolysis of lignin shows potential.
- Demonstrated heterogeneous catalysis of glucose and cellobiose:
  - Relatively high conversions during batch reaction (~60–90%).
  - Major products appear to be gas phase for heterogeneous catalysis.
- Demonstrated homogeneous catalysis of cellobiose hydrolysis to glucose without significant decomposition and/or caramelization:
  - Aqueous cellulose suspension marginally hydrolyzed to free glucose.
- Solid conversion of lignin and pine increased by Lewis Acid catalysis.
Gas phase products tend to syngas rather than alkanes.

- Minimal structural change of remaining lignin:
  - Some change in vibrational structure with La Triflate.
  - Lignin/Gd Triflate demonstrates different decomposition mechanism

- Demonstrated catalytically enhanced decarboxylation of lignin.

Introduction

Aqueous-phase reforming (APR) at low temperature has been successfully demonstrated for simple sugars, sugar alcohols, and glycols. In these instances, the simple sugars are derived from cellulosic feedstocks via acid or base hydrolysis via batch processing followed by neutralization of the sugar solutions to near-neutral pH. Successful approaches to the direct utilization of lignocellulosic feedstocks using APR to convert the carbon-hydrogen bonds of polymeric or oligomeric cellulosics into hydrogen have not been demonstrated. We propose to seek out direct or tandem routes from lignocellulosic feedstocks to hydrogen, gaining a significant advantage in feedstock cost reduction while maintaining the low-pressure, low-temperature capital cost advantages of aqueous phase reforming that have been demonstrated by others.

Utilization of lignocellulosic biomass to generate CO₂-neutral, renewable hydrogen is an attractive pathway to meet the DOE goal of producing hydrogen at a cost of $2-3/gge. Existing technology based on glucose or sorbitol results in approximately twice the target cost given current estimates. In addition, utilization of more of the biomass by being able to process lignin, which represents up to 50% of many sources of biomass, is anticipated to yield additional hydrogen per unit of biomass. Catalytic approaches to solubilization and depolymerization of lignocellulose also offer the advantage that they eliminate the use of stoichiometric dilute acid or base to hydrolyze the cellulose to sugars, and obviate the need to deal with the large mass of salt that results from eventual neutralization of the acid or base solutions.

Approach

In general terms, LANL is in search of novel hydrogen production routes from lignocellulosics. Two approaches will be explored: 1) catalytic solubilization of cellulosics to generate a sugar feedstock stream for downstream APR, and 2) solubilization of lignocellulosics followed by aqueous phase reaction (APRxn) of oligomeric, soluble cellulose.

LANL will conduct screening experiments for evidence of direct APRxg of cellulose to hydrogen through the use of catalysts designed to cleave carbon-carbon bonds of the cellulose backbone. Tandem catalysis approaches, where two catalysts or processes are linked together in a single reaction vessel, will be explored to demonstrate “one-pot” cellulose solubilization followed by aqueous phase catalytic reforming to generate hydrogen. This is important in that if catalysts can be found that will generate hydrogen directly from soluble cellulose oligomers, this provides a ‘one-pot’ approach and offers potential for cost reductions both in feedstock and in capital equipment. LANL’s approach to producing hydrogen from lignocellulosics (i.e., middle and bottom routes) is represented by the chemical routes shown in Figure 1.

Results: Hydrolysis of Cellobiose to Glucose

For a complete summary of our research, please refer to our 2009 DOE Annual Merit Review presentation (project ID: pdp_12_semelsberger). LANL has investigated catalytic routes of glucose production (which then can be reformed to bio-syngas) from cellobiose (i.e., oligomers of glucose). Depicted in Figure 2 is the reaction of cellobiose to glucose reaction that is being investigated.

LANL has demonstrated the feasibility of converting cellobiose to glucose via catalytic hydrolysis routes. Figure 3 shows the nuclear magnetic resonance results of the uncatalyzed thermal treatment of cellobiose and the results of a catalyzed treatment of cellobiose (the carbon color coding correlate to those in Figure 2). The uncatalyzed reaction of cellobiose does produce trace amounts of glucose. In contrast, the catalyzed reaction of cellobiose produces greater quantities of glucose as compared to the control experiment. These results are promising in that the low temperature catalyzed
hydrolysis of cellobiose is feasible. Although the results are feasible, the rates are still too low. Further research on improving catalyst performance (i.e., rates) is necessary.

**Results: Low-Temperature, Catalytic Pyrolysis of Lignin**

Recent LANL results has shown the low temperature catalytic pyrolysis of lignin (Aldrich). Shown in Figure 4 and Figure 5 are the thermogravimetric mass spectrometry results of the uncatalyzed and catalyzed pyrolysis of lignin. In the uncatalyzed pyrolysis of lignin, lignin was the only reactant. In the catalyzed reaction, lignin was physically mixed with a catalyst forming a solid-phase homogeneous mixture. On the industrial scale, the solid-phase catalytic reaction of lignin is not most likely an unviable process, but the primary objective is to uncover the reaction mechanism. Understanding the reaction mechanism allows for catalyst optimization and novel industrial-scale catalytic processes.

The pyrolysis products for both cases (catalyzed and uncatalyzed) are carbon dioxide, methane, and hydrogen. The uncatalyzed pyrolysis of lignin produces hydrogen around 700°C, while the catalyzed pyrolysis of lignin produces hydrogen around 400°C. In both
cases, the observed weight loss percentage is the same. The observation of similar weight loss percentages are a coincidence because the added mass of the catalyst is also included in the weight loss percentage. The result of the catalyzed pyrolysis of lignin are encouraging because not only is hydrogen produced at a lower temperature, but the selectivity has also changed.

**Conclusions**

- Conversion of cellobiose to glucose is feasible, but rates currently too low.
- Lignin hydrophobicity is a critical challenge for APRxn processes.
- Recent results of low temperature catalyzed pyrolysis of lignin shows potential:
  - Mechanism of the low-temperature catalyzed pyrolysis of lignin currently unknown.
- Heterogeneous catalysis of glucose and cellobiose:
  - Relatively high conversions during batch reaction (~60–90%).
  - Major products appear to be gas phase for heterogeneous catalysis.
- Homogeneous catalysis of cellobiose hydrolysis to glucose without significant decomposition and/or caramelization:
  - Aqueous cellulose suspension marginally hydrolyzed to free glucose
- Solid conversion of lignin and pine increased by Lewis Acid catalysis:
  - Gas phase products tend to syngas rather than alkanes.
  - Minimal structural change of remaining Lignin:
  - Some change in vibrational structure with La Triflate.
  - Lignin/Gd Triflate demonstrates different decomposition mechanism.

**Future Directions**

- Continue screening for novel hydrogen production catalysts.
- Explore conversion chemistry of model monolignols:
  - Develop heterogeneous catalyst for aqueous phase reactions.
- Focus on chemistry and catalyst development for cellulosic conversion.
II.B.3 One Step Biomass Gas Reforming-Shift Separation Membrane Reactor

Objectives

GTI together with its partners, NETL, Schott North America and ATI Wah Chang are working to determine the technical and economic feasibility of using the membrane gasifier to produce hydrogen from biomass. Specifically, the team plans to:

- Reduce the cost of hydrogen from biomass to $1.60/kg \( \text{H}_2 \) (excluding delivery).\(^1\)
- Develop an efficient membrane reactor that combines biomass gasification, reforming, shift reaction and \( \text{H}_2 \) separation in one step.
- Develop hydrogen-selective membrane materials compatible with the biomass gasification conditions.
- Demonstrate the feasibility of the concept in a bench-scale biomass gasifier.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- Impurities
- Hydrogen Selectivity
- Operating Temperature
- Flux

Technical Targets

This project is directed at developing a membrane reactor that can be closely-coupled with a gasification reactor while having a sufficiently high hydrogen flux to achieve a hydrogen production cost of $1.60/kg (without delivery) per the DOE 2012 technical target.

Accomplishments

- Project was restarted (February 2010) after 1 year hiatus. Selected team members completed contractual activities with GTI.
- Development of metallic, glass-ceramic membranes is in progress.
- Process development and economic analysis with initial candidate membrane is in progress.
- Membrane module design with initial candidate membrane is in progress.

Introduction

GTI has developed a novel concept of membrane reactor for clean, efficient, and low cost production of hydrogen from biomass-derived syngas. Our approach is presented in Figure 1 and shows a hydrogen-selective membrane closely coupled with a reforming or gasification reactor for direct extraction of hydrogen from the syngas. The specific objective of the project is to develop high temperature metallic or glass membranes that can be used closely-coupled with a biomass gasifier. The technical feasibility of using the membrane reactor to produce hydrogen from a biomass gasifier will be evaluated. GTI with its project team (SCHOTT North America, NETL, and ATI Wah Chang) has been evaluating potential membranes (metal, ceramic and glass) suitable for high temperature, high pressure, and the harsh environment of a biomass gasifier. The project team has been screening and testing each type of material, investigating its thermal and chemical stability, and conducting durability tests.

\(^1\) From 2007 H2 Production technical plan. During the 2010 Annual Merit Review, the need to rebaseline costs was stated.
Approach

To conduct commercially successful research, GTI has developed a plan where efforts are concentrated in four major areas: membrane material development, membrane module development, membrane process development and membrane gasifier scale up. The initial focus of the project has been concentrated on membrane material development. Metallic and glass-based membranes have been identified as hydrogen selective membranes under the conditions of the biomass gasification, temperatures above 700°C and pressures up to 30 atmospheres. Membranes are synthesized by arc-rolling for metallic type membranes and incorporating Pd into a glass matrix for glass membranes. Testing for hydrogen permeability properties have been completed and the effects of hydrogen sulfide and carbon monoxide were investigated for perspective membranes. The initial candidate membrane chosen in 2008 was selected for preliminary reactor design and cost estimates. The overall economics of hydrogen production from this new process will be assessed and compared with traditional hydrogen production technologies from biomass. The final deliverable of the project will be a gasification membrane reactor system that is expected to meet or exceed the DOE’s cost target for hydrogen production from biomass. This will be demonstrated by a bench scale gasification membrane reactor that can process approximately 2~10 kg/hr of woody biomass for hydrogen production.

Results

The project was restarted after a one year hiatus. The Arizona State University work on ceramic membranes was discontinued due to an inability to show sufficient promise for flux improvement to compete with the metallic or glass/ceramic membrane work during the project’s timeframe.

NETL is pursuing a new approach for stabilizing Pd alloys for high temperature use. This approach is modeled on a strategy that has been used to strengthen and stabilize certain high performance alloys such as Ni-based super alloys for high temperature applications. This approach utilizes a two-phase microstructure for stabilization. Unlike previous approaches where the additive is concentrated at grain boundaries, the two phases in the system under consideration can form a uniform dispersion of grains rather than be concentrated at grain boundaries. In this scenario, the primary phase transports hydrogen while the secondary phase improves the high temperature strength. NETL has fabricated new alloy combinations and hydrogen permeability tests were subsequently conducted. A 55 wt% Ni-Pt alloy was successfully rolled. Figure 2 shows permeability of the alloy at 600, 700 and 800°C. Permeability of a Pd,Pt,Al alloy is also shown. A Pd,Pt,Al alloy was synthesized and oxidized in an attempt to convert the Al to oxide for grain boundaries stabilization. Pt was added to this alloy to possibly improve the strength and sulfur resistance of the membrane. Due to failure of the membrane at 700°C, there is no data of hydrogen permeability at higher temperatures to determine a potential Pt effect on alloy characteristics. Scanning electron microscopy shows that the Al is located along the grain boundaries. So, Al incorporation into an alloy with subsequent oxidation of Al to Al,2O3 allows us to have Al located along the grain boundaries. The hydrogen permeability of synthesized alloys is lower than the permeability of the initial candidate membrane (Pd-Cu).

Glass membranes were obtained from SCHOTT and tested for hydrogen permeation. Table 1 summarizes results obtained for membranes synthesized by SCHOTT. Membranes with Pd have palladium content of about 0.05 wt%. At T=850°C, hydrogen flux was 0.02 SCFH/ft² at pressure difference 7.3 psi for membrane containing palladium. Pure glass synthesized at the same conditions with no palladium has no hydrogen permeation. From these results, one deduces that hydrogen transports only through the metal network in the glass.

SCHOTT has focused to synthesize metal-glass-ceramic membranes using a reducing agent. Addition of a reducing agent
agent (sugar) may assist hydrogen permeation by further reduction of Pd incorporated in the matrix. A few formulations with sugar additions were completed and total conductivity was measured. Also, a new melting protocol has nearly been completed this quarter that should enable SCHOTT to produce larger quantities of higher homogeneity material for permeability testing.

GTI continued to test membranes fabricated by GTI and other team members as they become available. Testing of the initial candidate membrane for 50 hours with a gas containing H₂S to try and duplicate NETL results for grain boundary failure is in progress.

GTI has resumed work on HYSYS modeling of downstream processes and variations; some modifications were implemented into three schemes for downstream processes after the biomass reactor. Different variations of process systems for producing hydrogen from biomass are being evaluated and are shown in Figure 3. Construction of HYSYS process schemes for downstream processes after biomass gasification is completed. Input data for UGAS software based on gasifier sizing, biomass types and operational conditions were selected: feedstock feed rate, temperature and pressure of gasifier, oxygen/carbon molar ratio, types of feedstock, etc. Based on gasifier design, diameters of lower and upper sections of gasifier were specified. Preliminary results were obtained to be used in HYSYS modeling. A detailed gasifier reactor drawing is in the final stage of development. A planar design for the hydrogen membrane module based on initial candidate membrane has been selected.

Conclusions and Future Directions

GTI selected Pd_{80}Cu_{20} as an initial candidate membrane for integrated testing with a biomass gasifier:
- GTI and partners will continue to pursue development of membranes with greater flux and higher resistance to contaminants for the best candidate membrane.
- GTI will continue development of the membrane gasifier process and an economic analysis will be performed.
- GTI will utilize a biomass gasifier currently under construction for future membrane integration.

II.C.1 High-Performance Palladium-Based Membrane for Hydrogen Separation and Purification

Objectives

- The overall project objective is the development, demonstration and economic analysis of a Pd-alloy membrane that enables the production of 99.99% pure H₂ from reformed natural gas as well as reformed bio-derived liquid fuels such as ethanol at a cost of $2-3/gge by 2011.
- The objectives for the past year were to improve the membrane fabrication process to retain high flux and purity in water-gas shift (WGS) reaction environment and gas streams.
- An objective for last year was to extend the testing of Pd-Au alloy membranes to include H₂S-containing WGS streams.
- Another objective was to incorporate a potential end user on the program that will provide the system economic and energy analysis/assessment of the membrane technology and compare it to current state-of-the art hydrogen production processes.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan and the technical targets indicated in Table 1:
- (K) Durability
- (L) Tolerance to Impurities
- (M) Membrane defects
- (N) Hydrogen selectivity

*Maximum observed flux. Average flux over more than 20 samples ~190 scfh/ft². Economic analysis indicates separation factor rather than flux to be stronger determinant of cost of hydrogen production.
** Measured on a 50%H₂/21%H₂O/up to 3.5% CO/balance CO₂ mixed gas stream. Hydrogen flux and recovery measurements are planned with other impurities starting in mid-2009. The experimentally observed recovery is determined by chosen operating conditions and is not necessarily a limit of the membrane performance.
*** Projected purity based on H₂/N₂ ideal selectivity.

Accomplishments To-Date with Specific Barriers Addressed

- Increased operating capabilities to 400 psi at 550°C through use of 310SC stainless steel tubular substrate.
- Optimized and scaled up the diffusion barrier coating process to 12-inch lengths with the manufacturing capability of producing up to 1 m length substrate tubes. A commercial welding process has been developed for welding non-porous fittings to porous tube (N, R).
- Developed additional sequential steps in the membrane synthesis process (air oxidation...
II.C Hydrogen Production / Separations

Introduction

This project is focused on optimizing the overall composition of the Pd alloy, intermediate layers and tubular support, as well as on the manufacturing methods required to produce a very thin, high-flux, cost effective membrane for H₂ separation and purification on a robust, porous, inorganic substrate. The substrate used is Pall's AccuSep® inorganic media which is readily scalable to high-volume production as it is manufactured in long lengths. Robust high-area modules can be made by welding multiple tubes into a pressure vessel, eliminating low-temperature seal materials.

Approach

The approach is to further develop and optimize the performance of Pd-alloy membranes that have been shown to have both high flux rate and high separation factor for H₂ from reformate. This is being accomplished by design of a composite membrane based on robust, tubular, porous metal media as a substrate. The substrate is modified by the addition of a uniform, fine pore size diffusion barrier layer. The deposition methods are modified to produce a thin, uniform, functional gas separation Pd-alloy membrane layer. The project plan includes commercial scale up of the high quality porous metal substrate and diffusion barrier layer that enables the development of a technically and economically viable composite membrane. Membrane alloy composition and thickness will be optimized for assuring high hydrogen flux and selectivity as well as long-term durability with tolerance to contaminants. The membrane performance will be determined under operating conditions in a typical reformed natural gas or bio-derived liquid fuels stream. The H₂A model, modified to incorporate a membrane reactor design, will be used to verify economic viability. Our plan is to confirm an increase in the overall energy efficiency of a H₂ reforming system through the use of membrane technology for process intensification. Economic modeling will be conducted to determine the cost benefit of an integrated membrane reactor that results from fewer pressure vessels and reduced catalyst volumes. An end-user will be conducting system economic and energy analyses and comparing the results to pressure swing adsorption (PSA) and amine-based systems.

Results

1. Membrane Development and Testing

Optimization and characterization continued on the membrane formation process with emphasis being placed on developing a technique with a sequence of multiple thin layers and treatments to maximize performance over extended time periods in WGS streams. Some mechanical issues have been observed.
with regard to bonding between the membrane layers. Positive results were obtained with membrane #286 fabricated using the multi-layer process as shown in Figure 1. The hydrogen flux remained constant at 70 scfh/ft² and the hydrogen permeate purity varied between 99.98 and 99.99% with methane as the only detected impurity until ~175 hours of test time. Membrane #286 is 8.4 micron thick and has the following alloy composition Pd₈₃Au₁₇. Additionally, there was no observed downward trend in the permeate hydrogen purity over the duration of the test that included shutdown cycles.

Scale up of the membrane process to deposit 10-inch long Pd-Au alloy membrane on a 12-inch long diffusion barrier coated AccuSep substrate tube has been initiated.

2. Membrane Durability in Pure Gas Streams

In order to test the ΔP capability of the membrane, ORNL determined the maximum operating pressure of the Pd-alloy membrane at room temperature. The membrane tube didn’t collapse even with external pressure of up to 4,000 psia.

The membrane housing is rated for 1,596 psi at 537°C exceeding the 400 psi and 400°C DOE target goal.

3. Membrane Durability in WGS Streams

Effect of WGS Environment on the Hydrogen Flux of Pd and Pd-Alloy Membranes

A primary goal of this project is to determine the performance trends as a function of Au level and membrane thickness in WGS streams. One test series was completed. As shown in Figure 2, Pd-Au alloy membranes exhibited a 10% flux reduction, whereas a pure Pd membrane exhibited a 30% flux reduction in a WGS atmosphere. The pure Pd membrane showed a sharp decrease in H₂ purity indicating leaks. Additional tests are in progress.

Effect of WGS Environment on Stability of Membrane Hydrogen Flux with Time

A Pd-Au alloy membrane was tested in WGS environment to determine the stability of H₂ flux with time up to 500 hours. As shown in Figure 3, flux remained constant at 65 scfh/ft² for 460 hours after an initial decline (consistent with the acclimatization of the membrane to the syngas composition) from 73 scfh/ft² in the first 40 hours. H₂ flux remained constant at 65 scfh/ft² through 500 hrs H₂. The H₂ recovery was 56% and the purity was 99.8%.

At a high feed pressure of 170 psig and 6 l/min WGS feed flow rate in a 2” single membrane tube module, the
H₂ flux was 285 scfh/ft² for >100 hours tested and the H₂ purity was 99.997% with a H₂ recovery of 78%.

**Effect of WGS Environment on Membrane Performance as a Function of Feed Flow Rate**

H₂ flux increased by 20% as the feed flow rate was increased from 2 to 6 l/min. This was attributed to a reduction in the concentration polarization effect. Hydrogen purity remained high.

**Effect of WGS on the Performance of Pd-Au Alloy Membranes as a Function of Steam/CO Ratio**

The membrane performed well at steam/CO ratios above 1.5.

**Effect of Various Concentrations of H₂S in WGS on Membrane Hydrogen Flux**

As shown in the Figure 4, the H₂ flux decreased with increasing H₂S content, however, the flux was almost fully recovered when the H₂S was removed from the feed stream. The membrane was a Pd₉₀Au₁₀ alloy, 2.8 microns thick with a 2-inch active length. The WGS composition was 51% H₂, 26% CO₂, 2% CO, 21% H₂O plus up to 25 ppm H₂S. The feed flow rate was 2 l/min, feed pressure was 50 psig and the temperature was 450ºC.

4. System Economic and Energy Analysis

Agreement was reached with an end-user to work with Pall on this project. The end-user will carry out system economic and energy analyses at no cost to the project but with certain restrictions on confidentiality. The end-user will provide the results of a confidential report that they will prepare on a cost comparison between Pall’s membrane system, an amine-based solvent system and a PSA system. They will compare the cost of producing H₂ and the cost of carbon capture for all three processes. The cost for the membrane system capital equipment will be based on performance and cost figures provided by Pall Corporation to the end-user, based on our test performance results in WGS atmospheres.

**Conclusions**

- Improvements were made in membrane synthesis process and membranes were evaluated for their performance in a synthesis gas environment in the presence of contaminants.
- High hydrogen purity was demonstrated in high pressure WGS environments.
- The membrane cost and economic analysis indicated hydrogen recovery to be more influential than hydrogen flux with a slightly favorable tradeoff for a little thicker membrane. The membrane synthesis process is capable of producing membranes in the appropriate thickness range.
- An end-user has agreed to work with Pall Corporation to provide information on the system economic and energy analysis task.

**Future plans**

- Improvements in the membrane synthesis process will be verified and scaled up for manufacturability.
- The optimum alloy composition and membrane thickness with respect to performance and durability in WGS streams will be determined.
- Mixed gas testing of the membranes will be conducted using the two test stands to determine long term membrane performance at various operating conditions of feed pressure, permeate pressure, gas composition, contaminant composition (especially H₂S) and hydrogen recovery. The membrane performance data collected from these tests will be used for system economic and energy modeling analysis.
- System analysis and energy analyses will be conducted by an end user. It will include the cost of producing H₂ and the cost of carbon capture for Pall’s membrane system, an amine-based solvent system and a PSA system.

**FY 2010 Publications/Presentations**

II.C.2 Development of Hydrogen Selective Membranes/Modules as Reactors/Separators for Distributed Hydrogen Production

Project Objective

The water-gas shift (WGS) reaction becomes less efficient when the high CO conversion is required, such as for the distributed hydrogen production applications. Our project objective includes:

- Develop a highly efficient and low-temperature membrane-based WGS reaction process in a bench scale first, then tested in a pilot scale and finally demonstrated in a field test unit.
- Screen our existing membranes and then tailor them specifically for the proposed process and reactor.
- Determine hydrogen production cost and define the system integration requirement for commercialization.
- Reduce the capital and operating cost for distributed hydrogen production applications.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Reformer Capital Costs
(B) Reformer Manufacturing
(C) Operation and Maintenance (O&M)
(D) Feedstock Issues
(E) Greenhouse Gas Emissions
(F) Control and Safety

Technical Targets

Technical targets for dense metallic membranes for 2010 are listed below:

- Flux Rate - 250 scfh/sq foot at 20 psig pressure
- Membrane Material and all Module Costs - $1,000/sq. foot of membrane
- Durability – 2,680 hours of testing has been completed
- Operating Capability - 400 psi
- Hydrogen Recovery - >80% (of total gas)
- Hydrogen Quality - 99.99%

Accomplishments

- **Balanced Performance vs. Cost for our H₂ Selective Membrane.** Through evaluation of a range of ceramic membrane substrates with various permeances, we have been successful in developing our H₂-selective membrane product to meet the low cost feature requested by our commercialization partner.

- **Corrected Leakage Issue of the 1st Generation Module and Ready for the Field Test.** Our first field test failed due to module leakage. The leakage of the 1st generation module has been corrected and the module is now ready for the field test scheduled in the second quarter.

- **Designed and Fabricated the 2nd Generation Module using Ceramic Membrane Bundles.** We have successfully developed the membrane bundle for our tubular H₂-selective membrane. This bundle approach can minimize module leak and reduce the module cost, and will be used for our field test in Phase II.

- **Conducted Membrane Reactor Test using our Full-Scale Membrane Tubes.** The WGS-membrane reactor process we developed from a bench-scale unit previously has been verified experimentally using a full-scale tubular membrane. Approximately 99% CO conversion, >85% H₂ recovery and >99.9% purity H₂ were achieved with this full-scale membrane reactor module.

Contract Number: DE-FG36-05GO15092
Subcontractor:
University of Southern California, Los Angeles, CA

Project Start Date: July 1, 2005
Project End Date: June 30, 2010
Introduction

Membrane separation has been traditionally considered to be a simple, low cost and compact process. Thus, the membrane process has been considered under this project as a WGS reactor/separator for enhancing the hydrogen production efficiency for distributed hydrogen production. In this project, we have focused on the development of the technology components required for integrating a membrane reactor process for distributed hydrogen production. During 2009-2010, we have completed the first field test using our full-scale Pd membrane bundle/module. In addition, we have generated the WGS membrane reactor database using our full-scale Pd membrane and a commercial catalyst for the design and construction of the full-scale membrane reactor module for Phase II study.

Approach

Our overall technical approach includes three steps as follows:

1. Bench-Scale Verification
   - Evaluate membrane reactor: use existing membrane and catalyst via math simulation.
   - Experimental verification: use upgraded membrane and existing catalyst via bench unit.
   - Validate membrane and membrane reactor performance and economics.

2. Pilot-Scale Testing
   - Prepare membranes, module, and housing for pilot testing.
   - Perform pilot-scale testing.
   - Perform economic analysis and technical evaluation.
   - Prepare field testing.

3. Field Demonstration
   - Fabricate membranes and membrane reactors and prepare catalysts.
   - Prepare site and install reactor.
   - Perform field test.
   - Conduct system integration study.
   - Finalize economic analysis and refine performance simulation.

Results

1. Successfully Prepared an 11-tube 24” Length Full Pd Membrane Bundle as Our 2nd Generation Pd Membrane Module
   a. Excellent pure gas permeation characteristics consistent with our single-tube membrane performance. The H₂ permeance of our Pd Bundle #2 is ca. 7.3 m³/m²/hr/bar. Single-tube permeances typically range from ca. 8 to 11 m³/m²/hr/bar.

2. Excellent pure gas selectivity. Pure component N₂ permeance is ca. 0.006 m³/m²/hr/bar, yielding selectivities on the order of 1,200 which is typical of our single-tube results.

3. Excellent mixed gas performance in a H₂/CO₂ blend. A blend of H₂/CO₂ (80/20 vol%) was also tested. Mixed gas H₂ permeance was ca. 7.5 m³/m²/hr/bar and H₂/CO₂ selectivity was ~1,200, consistent with the single tube results.

4. Additional bundle in production. Pd Bundles #3 and #4 have been produced and are ready for testing.

2. Pilot and Field tests of the 1st Generation Pd Membrane Module

The 1st generation full-scale module was field tested last year; however, severe module leaks were encountered. During this year, we have redesigned the module seal to overcome this problem. Since leaking from the individual tubes after thermal cycling does not follow the sequence of thermal cycles for most tubes, we concluded that the tube seal was stable through multiple thermal cycles. Further, N₂ measurement of ~0.08 m³/m²/hr/bar in average is equivalent to ~0.006 m³/m²/hr/bar at 350°C based upon Knudsen diffusion, which is consistent with the measurement on the module basis. The selectivity of about 1,000 for H₂ over N₂ was obtained. The field test at our end user site using the actual reformate delivered performance consistent the laboratory using synthetic reformate.

3. Effect of Substrate on Permeance and Selectivity of Pd Membranes

A wide range of commercial and experimental ceramic membranes, with permeances ranging from 50 to 800 m³/m²/hr/bar in N₂ at room temperature, were selected to study the Pd membrane performance and permeate quality. Hydrogen permeances of up to 25 m³/m²/hr/bar at 350°C and H₂/N₂ selectivities ranging from 350 to >10,000 were obtained. Although the higher permeance substrates delivered higher H₂ permeances as a result of the reduced resistance, the selectivities, as expected, decreased because of the surface topography. As a result, an intermediate substrate has been selected for commercial product development, with hydrogen permeance of 15 to 25 m³/m²/hr/bar and the selectivity of 1,000 to 3,000 at 350°C as presented in Figure 1.

4. Cost vs. Performance Evaluation with Regard to Our End-User Application

As shown in Figure 1, our cost vs. performance relationship is 2-10 times lower than the relationship target set by DOE for 2010. However, our end-user cost target is much more stringent than the DOE target.

**FIGURE 1.** Cost analysis of our Pd membranes for stationary power generators and the cost target set by our end-user participant.

**FIGURE 2.** Experimental results from the membrane reactor operation at 50 psig with no sweep using a full-scale H₂ selective membrane.
Based upon the input from our end user, for a 5 kW genset, about $400 at 121 scfh H₂ at 20 psig pressure drop is required, which is about 2.5 times lower cost than the DOE target on a comparable throughput basis. The cost vs. performance analysis of our products meets this stringent target set by our customer.

5. CO Conversion and H₂ Separation via Our Full-Scale Palladium Membrane Reactor

Although numerous bench top membrane reactor studies have been performed, no experimental work has been performed using a full-scale Pd membrane. During this year, we successfully demonstrated the membrane reactor using a 30"L Pd membrane as summarized in Figure 2 as a transition step for us to move this technology to the field. Using the synthetic reformate as feed, the low-temperature WGS reaction was performed at 300°C using a commercial catalyst at 30 and 50 psi under the conditions of with and without permeate purge. High CO conversion and high purity hydrogen product at a high hydrogen recovery ratio was obtained. Specifically, ~83% H₂ recovery ratio and 99% CO conversion at >99.9% H₂ purity were obtained from this experimental study.

Conclusions and Future Direction

• The low-cost Pd membranes supported on our ceramic substrate were developed, which can meet the very stringent cost target set by our commercialization partner.
• We have improved the 1st generation module and successfully verified its stability (i.e., acceptable leak through thermal cycling, Figure 3) and performance, which was successfully field tested at our end user side for hydrogen separation from reformate.
• The 2nd generation module, i.e., Pd membrane bundle, which is more economical and less prone to leaks, has been developed and successfully tested (Figure 4). This module will be used for field test in Phase II.
• Greater than 99% CO conversion and >99.9% purity hydrogen at >83% hydrogen recovery ratio was demonstrated experimentally using a reactor packed in our full-scale Pd membrane with a commercial catalyst. We are now ready to move to the field test of the membrane reactor to be undertaken in Phase II.

Our Phase II activities will focus on:

• Prepare 2nd generation membrane/modules for use as a full-scale WGS-membrane reactor.
• Design and construct the full-scale membrane reactor for field test at the selected end-user site.
• Conduct field test at the participated end-user site.

Start Date: July 1, 2005  
End Date: October 30, 2011

Objectives

• To synthesize chemically and thermally stable silicalite membranes with hydrogen permeance \( >5 \times 10^{-7} \text{ mol/m}^2\text{s.Pa} \) and \( \text{H}_2/\text{CO}_2 \) selectivity \( >50 \).
• To fabricate tubular silicalite membranes and membrane reactor module suitable for membrane reactor applications.
• To identify experimental conditions for the water-gas shift (WGS) reaction in the zeolite membrane reactor that will produce a hydrogen stream with at least 94% purity and a \( \text{CO}_2 \) stream with 97% purity.

Technical Targets

This project is focused on fundamental studies of zeolite membrane reactor for the WGS reaction for hydrogen production. Insights gained from these studies will be applied towards the development of low-cost, high-efficiency technology for distributed and central hydrogen production that meets the following DOE 2010 hydrogen storage targets:

• Cost: $0.4/kg
• Flux rate: 200 scfh/ft\(^2\)
• Hydrogen recovery: >80%
• Hydrogen quality: 99.5%
• Operating capability: 400 psi
• Durability: 26,280 hr

Accomplishments

• Optimized the template-free secondary growth for MFI (a zeolite structure code) zeolite membrane synthesis.
• Improved MFI zeolite membrane stability by applying a yttrium-stabilized zirconia (YSZ) barrier layer between the \( \alpha \)-alumina porous support and MFI zeolite membrane.
• Conducted the WGS reaction in chemical vapor deposition (CVD)-modified tubular MFI membrane reactors at different conditions and the optimal operating conditions were obtained.
• Modeled WGS reactions in CVD-modified MFI tubular membrane reactors with different catalyst packing configurations.
• Optimized the process for centrifugal casting of tubular supports with reduced resistance for gas flow.
• Developed and characterized the most effective catalysts for high-temperature water-gas shift (HTWGS).

Introduction

Gasification of biomass or heavy feedstock to produce hydrogen fuel gas using current technology includes partial oxidation to produce syngas, the WGS reaction to convert carbon monoxide with water to hydrogen, separation of hydrogen from the product stream, and removal of water vapor and other impurities (such as \( \text{H}_2\text{S} \)) from the \( \text{CO}_2 \) containing stream.
Commercially, WGS is normally conducted in two or more reactor stages with inter-cooling to maximize conversion for a given catalyst volume. Complete conversion of WGS is possible in a single membrane reactor at high temperatures (~400°C). The membrane removes product hydrogen from the reactor, facilitating higher conversion at a given temperature.

This project is focused on experimental and theoretical studies of the synthesis of a new hydrogen permeable and thermally/chemically stable zeolite membrane and its use in the membrane reactor for the WGS reaction to produce hydrogen- and CO2-rich streams. The membrane reactor system is designed for operation with feeds containing sulfur or other biomass residual contaminants. The zeolite membrane consists of a continuous thin (1-3 μm), aluminum-free silicalite film without intercrystalline micro pores on a support with macroporous zirconia and mesoporous silicalite intermediate layers. These composite silicalite membranes in disk and tubular geometries were prepared by a unique technique that combines several synthesis methods including a template-free secondary growth step. Research efforts were also directed towards development of the cost-effective microwave method to synthesize the MFI zeolite (silicalite and high Si/Al ratio ZSM-5) membranes in disk and tubular geometries.

A new catalyst was developed for the WGS reaction under membrane reactor conditions. The final research task is to perform experimental and modeling studies on the performance of the WGS reaction in the membrane reactors with the silicalite membranes and the catalyst developed in this project. The results obtained in this project will enable development of a large-scale one-step membrane reactor process for the WGS reaction for cost-effective production of hydrogen to below $0.40/kg.

**Approach**

The approach used in this project is to study fundamental issues related to synthesis of high quality, stable zeolite membranes and a membrane reactor for WGS reaction and hydrogen separation. The details of project are to (1) synthesize disk-shaped and tubular supports with desired intermediate layers and silicalite membranes with a template-free hydrothermal synthesis method, (2) optimize the hydrothermal synthesis condition and perform thorough permeation and separation characterization of silicalite and ZSM-5 membranes, (3) perform CVD for improvement of H2 permeability, (4) develop a microwave synthesis approach to more efficiently and cost-effectively synthesize high quality silicalite membranes, (5) obtain a new WGS catalyst with activity and selectivity comparable to the best available commercial catalyst with improved chemical stability for SO2 and H2S containing WGS reaction stream, and (6) develop methods to fabricate a tubular membrane support with desired intermediate layers and a membrane module and sealing system for a tubular membrane reactor that can be operated in WGS conditions.

**Results**

The work conducted on MFI zeolite membranes during the reporting period was focused on the experiments and simulations of HTWGS reactions in CVD-modified zeolite membrane reactors. Several different kinds of ferrite-based WGS catalysts were developed and tested in this research. The best catalyst was packed in central composite design-modified tubular membrane reactors for WGS reactions. The feasibility of applying a YSZ barrier layer between the α-alumina porous support and zeolite membrane to improve the stability of MFI membranes was demonstrated successfully on the disk membranes. This technique will be transferred onto the tubular membrane to improve the stability of modified tubular membrane reactor during WGS reactions.

In this research, tubular zeolite membranes for WGS reaction were synthesized and CVD-modified according to the procedure reported in the previous annual reports. The CVD-modified tubular zeolite membrane reactor was packed with the best catalyst that was synthesized in the project. Extensive tests of HTWGS reactions have been conducted in the modified tubular MFI zeolite membrane reactor and a traditional reactor as a function of H2/CO ratio (H2/CO ratio=1-3.5) at a fixed weight-hourly-space-velocity (WHSV) (60,000 h-1) and temperature. The results showed that the highest CO conversion and hydrogen recovery were obtained at H2/CO=3.5 in both the modified MFI tubular membrane reactor and traditional reactor (Figure 1). The results also showed that the CO-conversion in the modified membrane reactor is higher than that in the traditional reactor due to the on-stream separation of H2 from the membrane reactor.

Based on these experimental results, the WGS reaction was further tested at different temperatures and different WHSVs while keeping H2/CO at 3.5 to obtain the optimum operating conditions. Figure 2 shows the experimental χCOe (CO-conversion) and RH22 (H2-recovery) for WGS reactions in a zeolite membrane reactor and packed-bed traditional reactor, as a function of WHSV. As can be seen from this figure, The χCO in both membrane and traditional reactors increased with decreasing WHSV because of the prolonged residence time for WGS reaction and H2 transport. The enhancement of χCO by reducing WHSV was more pronounced at low temperatures where kinetic and mass transport limits are severe. The gas permeation and separation performance of the modified membrane before and after WGS reactions was also studied. The HTWGS reactions lasted about 300 h in the modified MFI zeolite membrane reactor. It was found that the
silicalite seed layer on the YSZ coated porous support (Figure 3(b)), and the MFI zeolite membrane grown on a YSZ coated porous support (Figure 3(c)). Similarly, a YSZ will be applied between the tubular porous support and zeolite membrane to improve the stability MFI tubular zeolite membrane reactor during WGS reactions. To accomplish it, a YSZ will be coated onto the inner surface of the α-alumina tubular supports through centrifugal casting of YSZ slurry.

WGS reactions in the modified membrane reactor have also been modeled at different conditions with more attention focused on studying the effect of different membrane reactor configurations on the CO-conversion and H₂ recovery of a membrane reactor. The schematic diagrams of the MFI tubular membrane reactors with different catalyst packing configurations for WGS reactions are shown in Figure 4(a): (1) the catalyst particles are packed in part of the membrane permeation zone, (2) the catalyst particles are packed in the whole membrane permeation zone, and (3) the catalyst particles are packed in both the membrane permeation zone and non-permeation zone. The non-permeation zone was glazed with dense glass. Note that the mass of the active catalyst and the particles packing density for these cases are assumed to be the same. Figure 4(b) and (c) show that the reactor configuration has some effect on the performance of the MFI membrane reactor. The final CO conversions of these cases are in the order of: case 3 > case 2 > case 1 > conventional fixed-bed reactor, and the order of H₂ recovery in these membrane reactor configurations is: case 1 > case 3 > case 2 at different temperatures. At a fixed contact time and feeding conditions, the performance of the membrane reactor is mainly determined by the permeation of a gas species through the membrane, while the permeation is determined by both the driving force and the effective permeation area. As expected, the CO conversions of these three cases are all higher than those of the conventional fixed-bed reactor due to the on-stream removal of the product H₂. In particular, the equilibrium of the WGS reaction can be overcome by the MFI membranes reactors, as shown in Figure 4(b).

During the reporting period, the work on catalysts was focused on screening the best catalysts for HTWGS reactions. Several different kinds of ferrite-based WGS catalysts were synthesized according to the procedure reported in the previous annual report. The activity of the synthesized catalysts was tested at different conditions (temperature, steam/CO ratio, and WHSV) in a fixed-bed traditional reactor. The results showed that Fe/Cr and Fe/Ce catalysts with various Fe/Cr and Fe/Ce ratios are the best catalysts for HTWGS reactions. Figure 5 shows the WGS activity results of Fe/Cr- and Fe/Ce-based catalysts with various Fe/Cr and Fe/Ce atomic ratios. In this study, WGS reactions were performed at a constant steam to CO ratio of 3.5 and at temperatures 400°C and 500°C. A relatively
high space velocity of 60,000 h\(^{-1}\) was maintained in all experiments. Figure 5 (a) shows the activity results of Fe/Ce catalysts with different atomic ratios. The order of WGS activity for the Fe/Ce catalysts is Fe\(_2\)O\(_3\) < Fe/Ce (10:0.5) < Fe/Ce (10:1) < Fe/Ce (10:2) > Fe/Ce (10:2.5).

The rapid increase in WGS activity with increase in reaction temperature from 400\(^\circ\)C to 500\(^\circ\)C is due to the improvement in the oxygen storage capacity of ceria at higher reaction temperatures.

FIGURE 2. Effect of WHSV on CO-conversion for a fixed \(R_{\text{H}_2\text{O}/\text{CO}}\) of 3.5: \((-\cdots-\) \(\chi_{\text{CO}_e}\); \((-\cdot--\cdot-\cdot-\) \(\chi_{\text{CO}}\) in a membrane reactor; \((-\Delta-)\) \(\chi_{\text{CO}}\) in traditional reactor; \((\times)\) \(\text{H}_2\)-recovery.

FIGURE 3. SEM micrographs: (a) YSZ barrier layer on an \(\alpha\)-alumina porous support, (b) silicalite seed layer on the YSZ barrier layer, and (c) MFI zeolite membrane.
Among the various Fe/Cr catalysts, Fe/Cr (10:0.5) shows better WGS activity compared to the other catalysts as shown in Figure 5(b). X-ray diffraction and crystallite size measurements suggest that the addition of Cr decreases the crystallite size of hematite up to the Fe/Cr (10:0.5) atomic ratio and further increase in the amount of chromium increases the crystallite size slightly. Mossbauer spectroscopic results inferred that in the pure magnetite, structural rearrangements of Fe$^{2+}$ and Fe$^{3+}$ ions take place during the WGS reaction which leads to the lower WGS activity. These rearrangements continue to happen in Fe/Cr (10:0.2) catalyst as well. On the other hand, in the other Fe/Cr catalysts with the atomic ratios 10:0.5, 10:1, 10:2, chromium stabilizes the magnetite phase during the WGS reaction and thus leads to a higher WGS activity. A slight decrease in the WGS activity for Fe/Cr (10:1) and Fe/Cr (10:2) catalysts compared to Fe/Cr (10:0.5) might be due to the smaller Brunauer-Emmett-Teller surface area as well as larger crystallite size.

Previously, centrifugal casting of membrane supports has been performed with AKP30 $\alpha$-$\text{Al}_2\text{O}_3$ powder (300 nm particle size, Sumitomo Chemical Corp.) which resulted in an optically smooth inner tube surface. To reduce gas flow resistance, centrifugal casting is currently being performed with AA3 $\alpha$-$\text{Al}_2\text{O}_3$ powder (Sumitomo Chemical Corp.) with a particle size of ~3 μm. Due to the increased particle size of the AA3 particles, colloidal stabilization with pH 2 HNO$_3$ is not sufficient to prevent particle sedimentation. To produce AA3 $\alpha$-$\text{Al}_2\text{O}_3$ (Sumitomo Chemical Corp.) tubular supports with sufficient green strength for removal after centrifugal casting, cross-linking of polyvinyl alcohol (PVA) is being investigated. The cross-linker that was selected is 2,5-dimethoxy-2,5-dihydrofuran (DMDF) which is reported to increase the green strength of gel-cast parts. It was found that gelation of ~3 mL dispersion/solution of 79.82 wt% AA3, 0.76 wt% PVA, 0.55 wt% HNO$_3$, and 0.26 wt% DMDF, resulted in a rigid body in about 10 min. at 65°C. First, the mold was filled with the above AA3 dispersion and placed in a preheated oven at 80°C for approximately 15 min. Then, the mold was removed from the oven and allowed to cool at room temperature. After drying.

---

**FIGURE 4.** Modeling of WGS Reactions in a Membrane Reactor  (a) schematic diagrams of the tubular MFI membrane reactor with different catalyst packing configurations (1-3); (b) effect of temperature on the CO conversion in different catalyst packing configurations; and (c) effect of the temperature on the hydrogen recovery in different catalyst packing configurations.
particles did not form a cast and remained in dispersion. This is believed to be caused by excessive stability or viscosity of the dispersion. The dispersion chemistry will be adjusted in the future by reducing the binder and cross-linking agent content. Preheating of the Delrin mold to accelerate the rigidification of the cast tube will also be investigated.

Conclusions and Future Directions

Conclusions

- The stability of the MFI zeolite membranes was improved by applying a YSZ barrier layer between the \( \alpha \)-alumina porous support and MFI zeolite membrane layer to avoid the diffusion of \( \text{Al}^{3+} \) from the porous support into the zeolite membrane.
- WGS reactions were conducted in CVD-modified MFI tubular membrane reactors at different WHSV, \( \text{H}_2\text{O/CO} \) ratio, and temperatures. Optimum WGS conditions were obtained.
- WGS reactions were modeled at different operating conditions and catalyst packing geometries to guide the WGS reaction experiments.
- \( \alpha\text{-Al}_2\text{O}_3 \) tubular porous supports with reduced resistance for gas flow are prepared by centrifugal casting of \( \alpha\text{-Al}_2\text{O}_3 \) powder with particle size of \( \sim 3 \mu\text{m} \). The dispersion chemistry of the slurry was optimized to obtain integral and robust porous supports.
- Several different kinds of ferrite-based catalysts were synthesized and tested in a fixed-bed traditional reactor, the best catalyst was selected for sulfur-tolerant HTWGS reactions.

Future Work

- Further optimization of MFI zeolite membrane synthesis and CVD modification for enhancement of the \( \text{H}_2/\text{CO}_2 \) separation factor of the modified membranes.
- Improve the stability of MFI tubular zeolite membrane reactor for WGS reactions by applying a YSZ barrier layer between the tubular porous support and zeolite membrane. The YSZ layer will be coated onto the inner surface of tubular supports by a centrifugal casting technique.
- Optimize the dispersion chemistry and improve the centrifugal casting process for fabrication of tubular porous supports with reduced resistance for gas flow.
- Perform high-pressure kinetics of two most effective WGS catalysts.
- Develop highly active and time stable (extensive up to time on stream: up to 2 months on stream)
catalysts for WGS reaction in the modified MFI zeolite tubular membrane reactor.

- Economic evaluation of the project results to validate the scale up and operation in an industrial scale.

E-mail: Jason.Hissam@netl.doe.gov

Contract Number: DE-FC26-07NT43058

Subcontractor:
Adsorption Research, Inc., Dublin, OH

Project Start Date: May 7, 2007
Project End Date: May 6, 2011

Objectives

The primary project objectives are:

- Synthesis of composite palladium (Pd) and Pd/alloy porous Inconel membranes for water-gas shift (WGS) reactors with long-term thermal, chemical, and mechanical durability with special emphasis on the stability of hydrogen flux and selectivity.
- Demonstration of the effectiveness and long-term stability of the WGS membrane shift reactor for the production of fuel cell quality hydrogen.
- Research and development of advanced gas cleanup technologies for sulfur removal to reduce the sulfur compounds to <2 ppm.
- Development of a systematic framework towards process intensification to achieve higher efficiencies and enhanced performance at a lower cost.
- Rigorous analysis and characterization of the behavior of the resulting overall process system, as well as the design of reliable control and supervision/monitoring systems.
- Assessment of the economic viability of the proposed intensification strategy through a comprehensive calculation of the cost of energy output and its determinants (capital cost, operation cost, fuel cost, etc.), followed by comparative studies against other existing pertinent energy technologies.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(N) Hydrogen Selectivity
(P) Flux
(N) Hydrogen Selectivity
(K) Durability

Technical Targets

A number of composite Pd and Pd/alloy porous Inconel membranes for WGS reactors have been and will be synthesized and their long-term thermal, chemical, and mechanical stability and hydrogen flux and selectivity have been determined. Technical targets and current membranes operational data are listed in Table 1.

Accomplishments

- Successfully synthesized Pd, Pd/Cu and Pd/Au membranes on 316L porous stainless steel and porous Inconel supports and demonstrated high permeances and selectivities which exceeded the DOE 2010 targets.
- Completed characterizations and stability testing of the Pd, Pd/Au and Pd/Cu membranes in the temperature range of 350-525°C.
- Successfully implemented a one-dimensional simulation to predict the optimal operating conditions for isothermal and adiabatic WGS-composite membrane reactors (CMRs) for process intensification. The model was accurate in predicting the experimental CO conversion values.
- Demonstrated the cost effectiveness of the isothermal CMRs over the non-isothermal CMRs with an unsteady-state WGS-CMR process control model.
- Achieved experimentally a 98% CO conversion and 87 and 85% H₂ recovery at 400 and 450°C, respectively in a Pd-based WGS–CMR operated at: \( \Delta P = 212 \text{ psi (} P_{\text{Low}}=14.7 \text{ psia)} \), \( H₂O/CO = 2.6 \) and gas hourly space velocity (GHSV) = 1,000 h⁻¹. The
long-term stability of the CO conversion and H$_2$ recovery were demonstrated for 80 h.

- Demonstrated the tolerance of Pd/Au and Pd/Cu membranes to H$_2$S over the temperature range of 350-500°C and atmospheres of 0.2–50 ppm H$_2$S/H$_2$ mixtures.

- Demonstrated for pressure swing absorption (PSA) that for five component gas mixtures with 1,000 ppm H$_2$S, the H$_2$S absorbent 5A achieved He recoveries of 99% and the product stream contained less than 0.05 ppm H$_2$S if a recycle of the blowdown gas was used.

\[
\text{Combining} \quad \text{the} \quad \text{WGS} \quad \text{reaction} \quad \text{and} \quad \text{hydrogen} \quad \text{separation} \\
\text{reduces} \quad \text{capital} \quad \text{costs} \quad \text{and} \quad \text{improves} \quad \text{efficiency.}
\]

Since the separation of hydrogen in the WGS reaction requires high fluxes, as well as high separation selectivity and ability to operate at elevated temperatures, dense metal membranes, particularly Pd-based membranes are well suited for this type of application.

The objective of this project is to reduce the number of unit operations required for hydrogen production through process intensification. In collaboration with Adsorption Research, Inc. (ARI), Worcester Polytechnic Institute (WPI) will produce an advanced synthesis gas (syngas) cleanup system and an asymmetric composite Pd-Pd/alloy membrane integrated downstream of the coal gasifier. The high-pressure CO$_2$ from the membrane shifter would be appropriate for recycling, sequestration, and/or conversion to industrially useful products. Compared with unsupported metal membranes, the development of an asymmetric composite membrane with a porous support and thin Pd or Pd-alloy dense layers would provide both higher trans-membrane flux and lower Pd loading.

**Approaches**

This project will develop an integrated, cost-effective, hydrogen production and separation process.
using a unique hydrogen separation membrane for WGS reactors under process intensification conditions. A patented (WPI) membrane synthesis process has been used to synthesize thin layer Pd membranes. The process consists of pre-treatment of the porous metal support, in situ formation of an oxide layer to minimize the inter-metallic diffusion for long-term membrane stability, and surface activation and plating of Pd by electroless plating. Specific targets are for production of a Pd layer around 3-5 μm, as well as successful production of Pd/alloy layers of ~2 μm or less.

The synthesized membranes are characterized for their hydrogen permeation characteristics and potential membrane reactor performance. The characterization will include a determination of the hydrogen mass transfer characteristics associated with the membrane configuration and valuation of the thermal and mechanical stability properties of the membrane through multiple thermal cycling. Characterizations will be conducted on Pd, Pd/gold (Au), and Pd/copper (Cu) membranes. The hydrogen permeation tests will examine effects of Pd alloy compositions and exposure of the membranes to gas mixtures containing sulfur.

Figure 1 shows the test set-up for measurements of membrane properties and permeation rates.

**Results**

Several high permeance Pd, Pd/Au and Pd/Cu membranes were tested in pure H\textsubscript{2} and He atmospheres for permeation and selectivity characterization. Figure 2 shows the Sieverts’ Law regressions performed at 450°C for the Pd membranes #038 and #039. Figure 2 shows that both #038 and #039 followed Sieverts’ Law and exceeded the DOE 2010 target with fluxes of 250 and 225 scf/h ft\textsuperscript{2} respectively, at a ΔP of 100 psi (P\textsubscript{low} = 14.7 psia). The selectivities were 250 and 240 respectively, yielding a H\textsubscript{2} purity of 99.6 and 99.58%, also meeting the 2010 DOE target. Furthermore, the Pd and Pd/alloy membranes also exceeded DOE 2010 flux and hydrogen purity targets.
• WGS-CMR experiments using syngas feed (41.6% CO, 40.3% H₂ and 18.1% CO₂ [dry basis]) achieved CO conversions of 97.9% (15% above equilibrium) at 400°C with a ΔP of 212 psi (P_{rev} = 14.7 psia) and GHSV values of 1,100 h⁻¹. Conversions of 98.2% (5.2% above equilibrium) were achieved at 450°C with a GHSV of 2,900 h⁻¹. A simple mathematical model predicted the experimental conversion data reasonably well.

• H₂ recoveries of 87% were achieved at 400°C and a GHSV of 1,000 h⁻¹. However, the simulation exceeded the experimental H₂ recovery data by as much as 20% at high GHSV values due to not accounting for radial mass transfer resistance in the simple model. The model further predicted that the flux ratio of H₂ to the other components (CO, CO₂, H₂O) had little effect on the CO conversion for both isothermal and adiabatic CMRs. However, to prevent the conversion from decreasing by 3% or more, the separation factors of the isothermal and adiabatic CMRs would need to be at or above 15,000 and 7,500, respectively. Reducing the catalyst weight from 15 to 0.3 g resulted in no decrease in the conversion for both adiabatic and isothermal CMRs, allowing for a more efficient use of catalyst.

• The model predicted that isothermal operation at 450°C resulted in a maximum CO conversion and H₂ recovery of 97 and 91% respectively, while operating at and above 60% permeability of the Pd foil. Adiabatic operation yielded slightly higher conversions than the isothermal operation at 98–99% for GHSV values below 4,000 h⁻¹ at a permeability of 60% of the Pd foil. However, adiabatic operation caused hot spots to form exceeding 565°C, which would be detrimental to the stability of both the membrane permeance and selectivity.

• The model further predicted that the flux ratio of H₂ to the other components (CO, CO₂, H₂O) had little effect on the CO conversion for both isothermal and adiabatic CMRs. However, to prevent the conversion from decreasing by 3% or more, the separation factors of the isothermal and adiabatic CMRs would need to be at or above 15,000 and 7,500, respectively. Reducing the catalyst weight from 15 to 0.3 g resulted in no decrease in the conversion for both adiabatic and isothermal CMRs, allowing for a more efficient use of catalyst.

• Exposing Pd and Pd alloy membranes to H₂S resulted in an increasing permeance decline with increasing H₂S feed concentration. However, at 15 ppm the Pd membrane formed a bulk Pd₃S which destroyed the membrane. The Pd/Cu and Pd/Au membranes both reached a steady-state values of permeance, retained their selective properties and did not form bulk sulfides within the H₂ selective layer even up to 50 ppm H₂S/H₂ mixtures. At concentrations <5 ppm H₂S, the Pd/Cu membrane performed better than the Pd/Au membrane which performed better than the Pd membrane.

• Higher temperatures were required to recover the permeance loss during poisoning due to the exothermic nature of H₂S adsorption on metals. Roughly 80% of the permeance of the Pd/Cu membrane could be recovered at 500°C after poisoning. At 500°C, the recovery in H₂ was nearly 100% for Pd/Au membranes.

• Based on the isotherms and diffusivity tests for the gas phase components, the two best adsorbent candidates for H₂S were 5A and Hisiv 3000. 5A was deemed the better choice due to the higher adsorption capacity and H₂ recovery and lower cost.

• For five component mixtures with 200 ppm H₂S, He recoveries up to 98.76% could be achieved with no H₂S detected in the product stream if a recycle of the blowdown gas was used. Increasing the H₂S concentration to 1,000 ppm resulted in several hundred ppb H₂S detected in the product stream with He recoveries up to 99.10%. Further increasing the H₂S concentration to 4,800 and 9,500 ppm reduced the He recoveries to roughly 91 and 88% respectively, and increased the H₂S in the product stream to a few ppm.

Conclusions and Future Directions

The membranes developed and tested during this period exceeded both the DOE 2010 flux and selectivity targets. The membrane stability during long-term WGS reactions and atmospheres containing small quantities of H₂S has been demonstrated. High CO conversions (98%) and H₂ recoveries (87%) have been achieved in the Pd-based WGS-CMRs and simulations incorporating process control, capable of predicting the experimental CO conversion values, have predicted the optimal conditions for isothermal and non-isothermal WGS-CMR operation for process intensification. The adsorbent 5A was deemed to be the best choice for PSA and yielded He recoveries as high as 99% for five component gas mixtures which included 1,000 ppm H₂S.

Future work will:

• Continue long-term WGS reaction studies with and without H₂S for Pd, Pd/Au and Pd/Cu membranes.
• Complete 2010 technical target screening and qualification tests.
• Improve flux and selectivity of Pd, Pd/Au and Pd/Cu membranes.
• Initiate economical analysis for the proposed process intensification framework.
• Add carbon oxysulfide to the feed mixture for PSA testing.

**FY 2010 Publications/Presentations**

II.D.2 Development of Robust Hydrogen Separation Membranes

Objectives

The main objective of this research is the development of robust hydrogen separation membrane(s) for integration into coal conversion processes, including integrated water-gas shift (WGS) membrane reactor. Studies suggest that incorporating separation membranes into coal conversion processes can reduce costs by 8%.

Included in the primary project objectives are the definition of a \( \text{H}_2 \)-membrane test protocol that:

- Will advance the technology towards application to coal conversion processes.
- Is consistent with overall Fossil Energy Program metrics.
- Yields a basis for an “apples-to-apples” comparison.

Research will be divided into two tasks: Task 1: Performance testing of external membranes and the “NETL \( \text{H}_2 \) Membrane Test Protocol” and Task 2: Robust Metal Membrane Development.

Technical Barriers

This project addresses the following technical barriers from the 2008 Hydrogen from Coal Program: Research, Development and Demonstration Plan:

(G) \( \text{H}_2 \) Embrittlement
(H) Thermal Cycling
(I) Poisoning of Catalytic Surface
(J) Loss of Structural Integrity and Performance

Technical Targets

The technical targets are DOE’s 2015 targets as shown in Table 1.

* For 100 psi \( \Delta \text{P} \) (hydrogen partial pressure basis)

\( \Delta \text{P} = \text{total pressure differential across the membrane reactor} \)

Accomplishments

- Completed a survey to determine the effluent composition of a WGS unit (Figure 1).
- Developed COMSOL model to predict the influence of WGS reaction and/or \( \text{H}_2 \) removal on overall gas composition:
  - Identified the test conditions and gas compositions that are relevant to syngas conversion flowsheet options:
    - Test 1: Shifted syngas, with no sulfur
    - Test 2a: Shifted syngas with 20 ppm \( \text{H}_2\text{S} \)
    - Test 2b: Shifted syngas with ~50% \( \text{H}_2 \) removal
    - Test 2c: Shifted syngas with ~90% \( \text{H}_2 \) removal
- Moved the membrane test units to a new location:
  - Modified membrane units to accommodate the “test protocol”.
- Flow ranges and membranes to test:
  - Conducted detailed analysis of the flow requirements to test a variety of membranes being developed:
    - Disks, tubes
    - Performing at 2015 targets
Determined that for surface stability:
- Pd-terminated surfaces are least stable.
- S-Pd-terminated surfaces are most stable.

Determined that for catalytic activity:
- Incorporation of S into the Pd system decreases catalytic activity.
- Pd-participation in the surface reaction allows rates high enough to meet DOE targets (either Pd-terminated or Sub-surface Pd).

Hydrogen-Deuterium exchange study:
- Modified quartz reactor system.
- Developed kinetic model.
- Initiated experimentation on Pd, Cu and 80Pd-Cu. The 80Pd-Cu system is “more catalytic” than pure Pd in H2.

Synthesis of multi-layered membranes:
- 25 μm PdCu substrate (corrosion resistance).
- Synthesized continuous and dispersed overlayers.
- Mono-layer Mo film:
  - Expected performance in H2.
  - H2S catalyzed the corrosion of PdCu substrate.

Directly measured the H2 permeability of Pd4S:
- In the presence of H2, appears to follow Sievert’s law.
- Permeability of Pd4S is ~10x less than Pd and consistent with face-centered cubic-phase 60Pd-Cu.

Collaborations:
- The research team conducting the work on the task consisted of participants from Carnegie Mellon University.
- NETL Reaction Chemistry & Engineering Group.
- NETL Computational Research Group (Dominic Alfonso).
- Provide unbiased performance verification testing:
  - REB Research
  - Oak Ridge National Laboratory
  - Eltron Research
  - Western Research Institute

Introduction
Hydrogen is viewed as the fuel source for the 21st century. The objective of this project is to support the development of test protocols to include more “commercially relevant” conditions.

Approaches
- This project will apply an understanding of engineering principles, membrane technology and coal conversion processes to define a sequential protocol to test various membranes for an “apples-to-apples” comparison.
- The development of a multi-layered membrane system (Figure 2) that utilizes the catalytic activity shown with Pd4S and the corrosion resistance of select PdCu alloys:
  - Use computational and experimental techniques to understand the catalytic activity at the gas-scale interface (Pd, Cu, Mo, Fe, Ni, Co, etc.).
  - Hydrogen transport properties of the layers and interfaces stability and growth scale.
Conclusions and Future Directions

Conclusions

- A test protocol has been developed and NETL’s test systems have been modified to allow testing of various membrane geometries and performance levels.
- Evaluation of the catalytic activity of potential membrane catalyst layers has been initiated utilizing density functional theory, kinetic Monte Carlo and H2-D2 exchange in the presence of H2. 80Pd-Cu appears more catalytic than Pd.
- Pd,S shows catalytic properties for H2 dissociation.
- Several multi-layered membrane systems have been fabricated using both continuous and dispersed catalysts. Thin catalyst layers appear to catalyze the corrosion of a corrosion resistance PdCuAlloy.
- The characterization of sulfide permeability has been initiated. Pd4S is approximately 10x lower than pure Pd.

Future work

- Continue to support the development of test protocols to include more “commercially relevant” conditions.
- Higher transmembrane pressure differentials.
- Contaminants other than H2S.
- For example, Cl-and N-compounds for biomass co-feed.
- Integration of WGS reactor and membrane separator.

Objectives

Develop low-cost hydrogen separation technology which:

- Produces high purity hydrogen from coal-derived synthesis gas (syngas).
- Retains carbon dioxide (CO₂) at coal gasifier pressures.
- Operates near water-gas shift (WGS) conditions.
- Tolerates reasonably achievable levels of coal-derived syngas contaminants.
- Delivers pure H₂ for use in fuel cells, gas turbines, and hydrocarbon processing.
- Meets DOE technical and economic targets in terms of cost-effectiveness compared to alternative technologies for hydrogen separation and carbon capture.

Accomplishments

- Partnered with Eastman Chemical Company to perform scale up testing of Eltron’s membranes.
- Continued development of Eltron’s membrane system that meets or exceeds the 2010 DOE targets for hydrogen flux and selectivity at the desired operating temperature and pressure ranges and performs well at expected carbon monoxide (CO) concentrations.
- Down-selected tubular membranes for scale up and procured 250’ of ½” outside diameter, 500 micron wall tubing.
- Developed electrodeposition techniques for depositing catalyst on the inside and outside surface of tubular membrane up to 5’ long.
- Tested tubular membranes between 6” and 2’ long under a variety of conditions including pressures up to 600 psig. Hydrogen recoveries as high as 90% were observed.
- Continued development of modeling tools to characterize and design membranes systems.
Introduction

The objective of this multi-year project is to develop and scale up a membrane-based system enabling >95% carbon capture from an integrated gasification combined cycle (IGCC)-based power plant, while simultaneously producing essentially pure hydrogen at high flux. The system and hydrogen transport membranes are designed to operate under a variety of conditions and gas compositions, allowing flexible process design and engineering. Additionally, the hydrogen transport membranes can operate at the temperatures and pressures of WGS reactors, which enable effective integration with upstream and downstream process units. Particular focus is intended to address low-cost hydrogen separation that demonstrates improved tolerance to CO and syngas impurities, such as sulfur and mercury, as well as considerations for materials selection and mechanical configuration, which will lead to improved design and overall cost reduction when compared to conventional technologies. Process engineering and economic studies show that improved thermal efficiency and cost of electricity for plants incorporating this technology are likely.

Approach

This project will develop, test, and screen membrane compositions, preparation techniques, and structures (membrane, catalyst, disks, and tubes) in bench- to small pilot-scale units. This work includes evaluating commercially applicable manufacturing techniques for these systems. In addition to performance testing, detailed analytical characterization and evaluation of the mechanical characteristics of the membranes will be completed. Performance screening will be conducted at commercially applicable conditions (up to 1,000 psig and 250°C to 440°C) and feed compositions, including CO, water (H₂O), CO₂, and hydrogen (H₂).

Another major area of interest is the modeling of the process – from surface kinetics to mass transport models, to system performance, to fully integrated IGCC process and economic models. These models are used to guide the research and development effort and to ensure that the technology being developed is competitive with conventional and other emerging technologies. The engineering is also being done to design the next phase of the project – evaluation of a sub-scale engineering prototype that will be tested on “live” coal-derived syngas in an operating facility.

Results

During the past year Eltron Research & Development, Inc. has partnered with Eastman Chemical Co. to scale up Eltron’s hydrogen membrane technology for pilot plant testing in a gasified coal feed stream. This partnership will result in a pilot plant demonstration of a hydrogen membrane reactor integrated with warm gas cleaning run on a gasified coal slip-stream. During the proposed work plan Eltron and Eastman will design, construct, and operate two different scale-up reactors. First, a 12 lbs/day hydrogen membrane reactor will be designed, constructed, and operated to demonstrate membrane performance on real syngas. Second, a 250 lbs/day reactor will be integrated with appropriate sorbent beds or with Eastman’s warm gas cleaning pilot unit and operated.

Eltron down-selected tubular membranes and procured 250’ of membrane substrate tubing from 2 different suppliers. This tubing was down-selected by Eltron based on performance and engineering considerations. The tubing is ½” outside diameter with a 500 micron wall thickness. Tubing received from one supplier is shown in Figure 1.

Eltron scaled up the equipment and techniques for depositing catalyst on tubular membranes. Catalyst was successfully deposited onto both the inside and outside feed stream. This partnership will result in a pilot plant demonstration of a hydrogen membrane reactor integrated with warm gas cleaning run on a gasified coal slip-stream. During the proposed work plan Eltron and Eastman will design, construct, and operate two different scale-up reactors. First, a 12 lbs/day hydrogen membrane reactor will be designed, constructed, and operated to demonstrate membrane performance on real syngas. Second, a 250 lbs/day reactor will be integrated with appropriate sorbent beds or with Eastman’s warm gas cleaning pilot unit and operated.

This tubing was down-selected by Eltron based on performance and engineering considerations. The tubing is ½” outside diameter with a 500 micron wall thickness. Tubing received from one supplier is shown in Figure 1.
Tubular membranes up to two feet long have been tested under a variety of conditions. Tubes were tested under simulated WGS gas compositions at temperatures between 300 and 400°C and at feed stream pressures up to 700 psig. Figure 3 shows data collected for a membrane tested up 600 psig feed pressure in a 100% H₂ feed stream. Flux rates up to 175 SCFH/ft² were observed at these high hydrogen partial pressures.

Once it was demonstrated that tubes could survive high hydrogen partial pressures, Eltron tested longer tubular membranes. The longest tube that Eltron can test in our facilities in Boulder, CO is a two foot tubular membrane. Eltron successfully tested a two foot long membrane in two separate tests. Each test was performed at pressures up to 600 psig. The first test utilized a feed stream mixture containing H₂ and N₂ and the second test was conducted under a simulated WGS feed stream. Results showed that in both cases the two foot long tubular membranes were limited by the low flow rates of gases relative to the high surface area of the membranes. High hydrogen recoveries were observed up to 85% H₂ recovery; however, low flux rates were observed. This was attributed to bulk diffusion limitations on the feed side of the membrane.

To determine the effect of impurities on membrane performance, planar and tubular membranes were exposed to a live gasified coal feed streams. Eltron membranes were sent to Eastman and exposed to gasified coal syngas that had passed through a ZnO sorbent bed. This exposure was performed at 340°C and 700 psig. Following exposure the membranes were sent back to Eltron for characterization and permeation testing. The exposed membranes were tested in a 50% H₂/50% He stream at 300 psig and 340°C. Permeation results for exposed membranes were compared to membranes that had not been exposed, as shown in Figure 4.

Figure 4 shows that the membrane that had been exposed to gasified coal syngas had a hydrogen flux rate ~50% lower than a membrane that had not been exposed. Scanning electron microscopy and X-ray diffraction analysis showed that this drop in flux was due to the presence of sulfur, arsenic, and mercury on the surface of the membrane.

Eltron and Eastman have completed design and construction of a 12 lbs/day membrane reactor. Design specifications for the reactor included:

- 300 SCFH coal-derived syngas
- 450–900 psig feed pressure
- 500°C maximum operating temperature
- 85% H₂ recovery
The reactor will contain ten feet of Eltron’s tubular membrane. Engineering design activities included preparation of piping and instrumentation diagrams, associated interlock narratives, and a process hazards analysis. Equipment was specified and procured and the reactor skid was constructed by Continental Technologies.

Conclusions and Future Directions

Eltron’s hydrogen membranes met or exceeded most DOE 2010 targets in bench-scale operations. Process economic evaluations have shown that they provide significant improvements over conventional technologies for capturing CO₂ and providing high purity hydrogen for an IGCC power plant. Future work required to bring these to commercial reality includes:

- Construct and operate 12 lbs/day H₂ membrane reactor on gasified coal slip-stream.
- Design, construct, and operate 250 lbs/day H₂ membrane reactor integrated with warm-gas cleaning on a gasified coal slip-stream.
- Continue life and impurity testing on new materials as required.
- Maintain and improve techno-economic models.

Contract Number: DE-FE0001057

Subcontractors:
• David Sholl, Georgia Institute of Technology (Georgia Tech), Atlanta, GA
• Thomas Barton, Western Research Institute (WRI), Laramie, WY

Project Start Date: September 30, 2009
Project End Date: September 29, 2012

Objectives

The objective of this project is to model, fabricate, and test thin film amorphous alloy membranes which separate hydrogen from a coal-based system with performance meeting the DOE 2015 targets of flux, selectivity, cost and chemical and mechanical robustness, without the use of platinum group metals.

Technical Targets

Year 1: The first year consisted of demonstrating an amorphous alloy with the following targets identified for this initial phase:
- Fabricated at least six membrane samples with compositions consistent with those used by Georgia Tech for H₂ flux modeling.
- Tested and established thermal stability of amorphous alloys.

Year 2: The focus of the effort will be to evaluate the performance and fabrication options to produce membranes that are an improvement over those published in the literature. The following targets have been identified for this second phase:
- SwRI® will fabricate a minimum of 20 doped amorphous alloy membrane specimens based on Georgia Tech hydrogen transport predictions for the most promising ternary element additions.
- Testing at WRI of a second set (≤12) of alloys from the optimization trials by pure gas (H₂ and N₂) permeation experiments.

Year 3: The final year will focus on optimization of identified compositions and fabrication techniques through an iterative progress approach of modeling, making and testing the amorphous alloys. The following targets have been identified in this final phase:
- SwRI® will produce a minimum of four optimized membranes for testing at WRI.
- Complete two gasifier tests (or a smaller number of longer duration tests) at WRI on optimized membrane materials with multiple additions of H₂S, carbon oxysulfide, HCl, and metallic impurities.

Table 1 lists current test information for a number of membranes and compares it with DOE target values.

Accomplishments

- Have demonstrated our modeling approach is sufficient to generate realistic samples of these amorphous materials.
- Have concluded that the quantitative discrepancy between theoretical predictions and the amorphous film experiments is relatively small and that our methods are capable of making useful predictions about these properties.

- Have demonstrated the permeabilities by 32 atom cells are in good agreement with those by 108 atom cells as published in J.Mem.Sci. 350, 402 (2010).
- Have identified several new novel binary and ternary amorphous alloys with predicted permeabilities similar to Pd.
- The precise deposition of metal coatings by two magnetron sources and by co-deposition using two magnetron sources have been demonstrated for deposition of NiZr coatings.
- WRI has conducted all X-ray powder crystallography and elemental composition tests of the as deposited samples and has begun thermal annealing tests.
- Completed multiple project conference calls and joint calls with the other DOE-funded team at the University of Nevada, Reno working on amorphous alloy membranes.

**Approach**

The approach of the project is to incorporate modeling, fabricating, and testing all operating concurrently to develop thin film amorphous alloy membranes which separate hydrogen from a coal-based system with performance meeting the DOE 2015 targets of flux, selectivity, cost and chemical and mechanical robustness, without the use of precious group metals. This collaborative effort will involve work at SwRI®, Georgia Tech and WRI. The proposed project can be summarized in the three primary tasks that will run concurrently:

1. **Materials modeling and composition selection:** Building upon recent work at Georgia Tech using density functional theory (DFT) to identify promising ZrNi alloy compositions with improved hydrogen permeability, an expanding range of additive concentrations will be investigated. New calculations based on refined assumptions and boundary conditions will be used to direct the materials development effort in an iterative manner.

2. **Fabrication of high-performance amorphous alloy membranes:** SwRI® will lead the development of thin amorphous alloy membranes using advanced physical vapor deposition methods including magnetron sputtering. The unique feature of these techniques is the ability to rapidly produce membranes of almost any alloy composition with good uniformity and large areas (up to 100 in²) onto stainless steel supports.

3. **Membrane testing and evaluation:** WRI will perform initial screening testing of experimental membranes under controlled atmospheres and confirm that the targeted structures and compositions have been produced. Initial performance data will be used to further refine DFT-based modeling and guide the vacuum deposition effort. Once one or more promising classes of alloys have been identified, WRI will evaluate these membranes under DOE specified test conditions for extended periods up to several hours. Compositional and structural analysis of exposed membranes by scanning electron microscopy (SEM), energy dispersive X-ray, and X-ray diffraction (XRD) will be employed in an effort to identify likely degradation pathways.

**Introduction**

Thin film amorphous alloy membranes are a nascent but promising new technology for industrial-scale hydrogen gas separations from coal-derived syngas. This project uses a combination of theoretical modeling, advanced physical vapor deposition fabricating, and laboratory and gasifier testing to develop amorphous alloy membranes that have the potential to meet all DOE targets in the testing strategies outlined in the National Energy Technology Laboratory Membrane Test Protocol.

**Results**

**Modeling**

Georgia Tech has developed a general method based on first-principles calculations and statistical modeling to predict the permeability of pure H₂ through amorphous metal films [1,2]. This approach requires no
experimental input or parameterization, so it is suitable for use in materials screening efforts. However, this method was based on DFT calculations with 108 atom supercells, which requires large amount of calculations and thus is time-consuming to perform screening from multiple candidates.

To accelerate the calculation, we use different size supercells to check the convergence of the calculated permeability convergence for Zr55Co25Al20. We use 32, 64, 108-atom supercells to calculate solubilities, diffusivities and permeabilities. Figure 1 shows the calculated permeability. Although there is some variation between the calculations with the smaller supercells and the results when using a 108-atom supercell, these differences are small enough that we can use the smaller calculations as a screening tool.

We have therefore performed extensive calculations for amorphous alloys that have not been studied in previous experiments with the aim of novel materials discovery using 32-atom supercells. To this end, we examine amorphous Ta40Ni60, Ta25Ni50Ti25, Ti32Co67, Hf44Cu56, Hf25Cu60Ti15, Zr45Cu45Al10, Zr30Cu60Ti10, Zr54Cu46, and Nd60Fe30Al10. Selection of these materials are based on the relative high crystallization temperatures reported experimentally for these materials (at least >720 K). To make permeability predictions, first principles methods were used to predict the solubility and net diffusivity of interstitial H in each amorphous material.

Membrane Deposition, Composition and Microstructure Optimization

The coating system setup used in this work is shown in Figure 2. Two direct current magnetrons using 4” diameter targets were installed at the bottom of the vacuum processing chamber for a co-sputtering deposition process of the amorphous alloy with argon as the processing gas.

XRD analysis of the crystallinity of NiZr coatings and ribbons has demonstrated a strong correlation between their structure and thermal stability vs. their composition. Coatings with higher concentrations of Zr survived annealing for 1 hour at 250°C without re-crystallization. The re-crystallization started during 1 hr of annealing at 300°C in coatings with lower Zr content (Figure 3 plot #1), while coatings with Zr content >12 at% (#4 & 5) do not re-crystallize, showing XRD patterns after annealing similar to the melt-spin ribbon (#13) with optimal Zr content associated with amorphous NiZr alloy as shown in Figure 3 (Ni0.64Zr0.36 ribbon sample #12). On the other hand, the ribbon sample #13 having Ni0.3Zr0.7 composition was fully transformed into the polycrystalline state after 1 hr of annealing at 300°C. The optimal composition of

![FIGURE 2. Magnetron Co-Sputtering Scheme](image)

![FIGURE 3. XRD Patterns of NixZr1-x Coatings and Bulk Metallic Glass Ribbons Subjected to 1 Hour Annealing at 300°C.](image)
the NiZr amorphous alloys with Zr concentration near 30 at% is in agreement with published work presented in Refs. [3,4].

Conclusions and Future Directions

The project is on schedule and on budget with SwRI®, Georgia Tech, and WRI all operating independently and concurrently. Georgia Tech has demonstrated the modeling approach is sufficient to generate realistic samples of these amorphous materials. The precise deposition of metal coatings by one magnetron source and by co-deposition using two magnetron sources have been demonstrated for deposition of NiZr coatings. NiXZr1-x coatings with x ranging from 0.71 to 0.93 were deposited by magnetron co-sputtering process. It was found that as-deposited films are more amorphous with an increase of Zr content starting from x = 0.9 and reaching a XRD-amorphous state at x >0.88. Mechanical properties of these coatings are strongly correlated with their composition. Amorphous films with higher Zr content have retained their XRD measured amorphous state after 1 hr annealing in an argon/2% hydrogen atmosphere at 300°C. Further amorphization of some of the coatings, with lower Zr content, occur during thermal annealing below their re-crystallization temperature which may indicate the influence of a solid reaction amorphization mechanism on the coating structure evolution. The partial re-crystallization in films with the highest Zr content occurs after 24 hours of annealing. The Ni0.71Zr0.29 coating has demonstrated the best thermal chemical stability developing a mixture of a polycrystalline phase embedded within an amorphous matrix during annealing. The XRD spectrum of this film is nearly identical to the XRD spectrum of a melt-spun bulk metallic glass ribbon subjected to the same annealing treatment, indicating that thin film coatings deposited by co-sputtering and bulk metallic glass ribbons prepared by the melt-spinning technique have about the same thermal stability which is determined by their elemental composition and not by the method of fabrication.

Future work will consist of:

- Georgia Tech performing both solubility and diffusion calculations on ZrCu, ZrCuTi, HfCu, and HfCuTi systems.
- Future work will be conducted to better understand the mechanisms of formation of amorphous metal coatings and their thermal stability, which is critical for their applications in hydrogen separation membranes.
- SwRI® will fabricate a minimum of 20 doped amorphous alloy membrane specimens based on Georgia Tech hydrogen transport predictions for the most promising ternary element additions.
- Testing at WRI of (≤12) of alloys from the optimization trials by pure gas (H2 and N2) permeation experiments.
- Complete two gasifier tests (or a smaller number of longer duration tests) at WRI on optimized membrane materials with multiple additions of H2S, carbon oxysulfide, HCl, and metallic impurities.

II.D.5 Experimental Demonstration of Advanced Palladium Membrane Separators for Central High-Purity Hydrogen Production

Objectives

- Develop and construct hydrogen (H₂) membrane separators using sulfur-resistant palladium (Pd) alloys and membrane separators using proprietary palladium copper transition metal (PdCuTM) alloys.
- Establish the stability and resistance of proprietary PdCuTM trimetallic alloys to carbon and carbide formation and, in addition, resistance to sulfur, halides, and ammonia (NH₃).
- Develop a sulfur-, halide-, and NH₃-resistant alloy membrane with a projected H₂ permeance of 25 m³m⁻² atm⁻¹ h⁻¹ at 400°C and capable of operating at pressures of 12.1 MPa (∼120 atm, 1,750 psia).
- Construct and experimentally validate the performance of 0.1 kg/day H₂ PdCuTM trimetallic alloy membrane separators at feed pressures of 2 MPa (290 psia) in the presence of hydrogen sulfide (H₂S), NH₃, and hydrogen chloride (HCl).

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (K) Durability
- (L) Impurities
- (N) Hydrogen Selectivity
- (P) Flux

Technical Targets

This project consists of three parts: atomistic modeling, H₂ separator fabrication, and membrane separator experimental evaluation. The project has entered the final phase of work where the testing and evaluating of “best of class” H₂ selective separators will be completed. The progress toward achieving the DOE technical targets based on the atomistic modeling predictions and experimental data is shown in Table 1.

Accomplishments

- Developed an atomistic modeling screening approach to evaluate materials for susceptibility to sulfur attack.
- Evaluated the performance of face-centered cubic (FCC) PdCu separators under the DOE testing protocol.
- Confirmed the sulfur resistance and stability of the PdCu alloy.
- Produced single tube separators with the UTRC ternary PdCuTM composition with doubled performance versus early 2009 results.
- Identified a polishing process to remove the surface barrier produced during manufacture of PdCuTM tubes.

Introduction

This project is focused on increasing the technology readiness level of Pd-based metallic membranes for H₂ separation from coal-biomass gasifier exhaust or similar H₂-containing gas streams. Quantum mechanical atomistic modeling was performed in a previous contract to develop a ternary PdCu alloy for a water-gas shift membrane reactor (WGSMR) in a coal gasifier system. The alloy was based on the concept of making the body-centered cubic (BCC) phase of a PdCu binary alloy stable at WGSMR temperatures in the presence of high concentrations of poisons such as sulfur. The
BCC phase of PdCu has a much higher H₂ permeability than the FCC materials and the FCC materials have been shown to have good sulfur resistance. Thus, a stabilized BCC alloy should be able to obtain the high permeability of alloys like PdAg with the sulfur tolerance of FCC PdCu. One of the major objectives of this work is to experimentally validate the UTRC PdCu ternary alloy performance. An additional objective is to experimentally evaluate the best commercially available FCC PdCu alloy from Power+Energy for meeting the DOE technical targets.

**Approach**

The approach for this project is to experimentally validate two different PdCu-based alloys for H₂ separation. Additional atomistic modeling has been performed to examine performance characteristics, such as resistance to carbon formation and sulfur poisoning. In parallel with the modeling, separator units of both the Power+Energy and UTRC alloys were manufactured by Power+Energy and tested for their H₂ separation capabilities at UTRC.

The experimental efforts were divided into two distinct parts: (1) low pressure laboratory screening to quantify basic membrane performance and (2) high pressure testing to quantify durability and poison resistance of the two alloys. The objectives of the low pressure (<10 atm) laboratory testing were to characterize the membrane separator H₂ permeability as a function of temperature and to quantify the effect of different gas species (CO, CO₂, H₂O, and N₂) on the permeability. The high pressure (>10 atm) testing involved testing with gases containing different concentrations of poisons such as H₂S and NH₃, including DOE membrane testing protocol conditions. The high pressure mixed gas was used in the >500-hour durability tests to quantify the effect of gas mixtures and poisons on the H₂ permeability of the PdCu separators.

**Results**

Although irreversible corrosion product formation (i.e. Pd₄S) has been reported on a number of Pd-based alloys exposed to sulfur (S)-bearing atmospheres [1,2], S adsorption has been observed at UTRC to be reversible on PdCu alloys with recoverable H₂ permeability at higher temperatures. This finding motivated a systematic, first principles, atomic modeling study to pinpoint alloy characteristics that control the reversibility/irreversibility of S interactions on a range of Pd-based alloys. This understanding could then be used to develop a predictive tool to guide the development of S-tolerant alloys for dense metallic H₂-selective membranes.

Figure 1 provides a graphical representation of a useful approach to evaluate Pd-alloys for their susceptibility to irreversible sulfur attack. On the abscissa is plotted the reaction enthalpy for S absorption. The reaction enthalpy for Pd segregation and Pd₄S formation upon S absorption is plotted on the ordinate. A positive value on the abscissa implies that sulfur absorption on the surface is not favorable, while a negative value suggests the material can incorporate sulfur into the subsurface lattice structure. If sulfur is incorporated into the structure, a negative value on the ordinate predicts the material should undergo sulfur corrosion. For example, pure FCC Pd (111) and FCC Pd₃Ag (111) surfaces, both known to be sulfur intolerant
UTRC has previously demonstrated the reversible sulfur tolerance of PdCu alloys. After the project inception, the DOE developed a testing protocol for evaluating membrane performance [3]. Figure 2 shows the results of DOE test protocol testing on an FCC PdCu membrane produced for this project which lasted 527 hours. The testing was performed under pure H\textsubscript{2} as well as test conditions 1, 2a, and 2b. The data in Figure 2 show that under the specific test conditions, the pure H\textsubscript{2} flux of this separator was 45±2 ft\textsuperscript{3}ft\textsuperscript{-2}h\textsuperscript{-1}.

![Figure 1](image1.png)

**FIGURE 1.** The analysis of reaction enthalpy for Pd segregation and Pd\textsubscript{S} formation upon S absorption versus the change in enthalpy for S incorporation by absorption relative to S adsorption. This serves as a predictive tool to delineate irreversible from reversible S interactions.

![Figure 2](image2.png)

**FIGURE 2.** DOE protocol test data for an FCC PdCu separator which had been tested for 527 hours at DOE protocol test conditions 1, 2a, & 2b at 450°C.
with a $H_2$ recovery of $>80\%$ at 450°C and 200 psia. Upon exposure to the DOE test 1 conditions, this flux decreased to $14\pm 2 \text{ ft}^3\text{ft}^{-2}\text{h}^{-1}$ with a similar recovery. When 20 ppmv $H_2S$ was introduced during test 2a conditions, the flux was further reduced to $11\pm 1 \text{ ft}^3\text{ft}^{-2}\text{h}^{-1}$ with a corresponding decrease in recovery to $(61\pm 7)\%$, however, membrane performance remained stable during the 100+ hours at each condition. Finally, when the $H_2$ concentration was decreased and the sulfur level increased to 40 ppmv, the flux was reduced to $6\pm 1 \text{ ft}^3\text{ft}^{-2}\text{h}^{-1}$ with a $H_2$ recovery of $(50\pm 6)\%$. The decrease in $H_2$ flux due to composition effects was completely reversible based on measurements taken with pure $H_2$ between each of the gas compositions and also the fact that the membrane did not leak. This further supports the conclusion that FCC PdCu is sulfur resistant and not susceptible to sulfur corrosion.

Development of the UTRC ternary PdCuTM alloy resulted in a permeability performance in July 2009 that was similar to that of the FCC PdCu alloy (see Figure 3). Further characterization was performed to determine the root cause of the lower than expected performance. An unwanted TM-oxide surface scale forms during manufacturing of the separator tubes and requires removal. The separator performance in July 2009 was measured after chemical etching which resulted in selective dissolution of the Cu, leaving the surface Pd-rich. It is known from the literature [4,5] that a PdCu alloy with greater than $\approx 50 \text{ at}\% \text{ Pd}$ has a rather poor permeability compared to pure Pd. As a result, a mechanical polishing technique was developed to remove the surface oxide scale without affecting the surface PdCu composition. The data for the polished separator tubes, measured in April 2010, is also given in Figure 3 and shows that the performance was improved by a factor of two.

A technical and economic modeling analysis was performed for the FCC PdCu dense metallic membranes. Similar assumptions to those used in the DOE test protocol [3] were used in the calculations. A mean flow rate of $6.425\times10^5 \text{ kg.h}^{-1}$ was used for membrane sizing calculations based on different gasifier systems operating in the range of 520 MW to 640 MW [6]. For the purposes of the analysis, the gas was assumed to be at the DOE protocol test 1 composition (50% $H_2$, 1% CO, 30.0% $CO_2$, and 19.0% $H_2O$). Figure 4 shows the $H_2$ recovery as a function of membrane surface area at 450°C. The recovery curves are presented as a function of the membrane feed pressure. Higher feed pressures result in higher fluxes and thus a reduced area for the same $H_2$ recovery.
For a high $H_2$ recovery, a dense metallic PdCu membrane for this size system would require an area approaching 60,000 m$^2$ and the metal would cost on the order of $200,000,000. However, one advantage of the dense metallic membranes is that the raw materials can be recycled and the Pd cost can be significantly reduced by a lease and recycling strategy. In addition, the very high $H_2$ purity achievable by dense metallic membranes, along with their higher technology readiness level, makes the dense metallic approach a viable path forward for $H_2$ separation while other, longer-term, low-cost technology paths are further developed.

Conclusions and Future Directions

- An atomistic modeling screening approach for evaluating susceptibility to irreversible sulfur attack was developed that could assist other development projects on $H_2$ separation membranes.
- Dense metallic FCC PdCu separators can operate under the DOE testing protocol conditions and maintain their stability. In addition, the impact of poisons, such as sulfur, has been found to be reversible.
- Single tube separators with the UTRC ternary PdCuTM composition showed doubled performance versus early 2009 results after an improved polishing process was identified to remove the surface barrier produced during manufacturing of the PdCuTM tubes.
- No additional work is planned on the current project.
- Future work in this area should move in the direction of larger scale demonstrations with real gasifier exhaust.

Contract Number: DE-FE0001050
Project Start Date: September 30, 2009
Project End Date: September 29, 2012

Objectives

The overall goal of this project is to develop and test novel supported molten metal membranes (SMMMs) suitable for hydrogen separation in conjunction with a coal gasification plant, based on low-melting, non-precious group metals (non-PGM) or alloys, supported as thin films on an inert porous ceramic, or on a porous metal support with or without an intermetallic diffusion barrier. The specific objectives of the project are:

- Identify non-PGM molten metals and alloy candidates for membranes that provide good hydrogen dissociation ability, solubility, and diffusivity, and are tolerant to other syngas species such as carbon monoxide, and to poisons such as sulfur.
- Identify porous ceramic and porous metal supports with an intermetallic diffusion barrier that are readily wetted by the molten metals, and allow stable molten metal membranes to be fabricated.
- Develop fabrication procedures for supported molten metal membranes on porous supports that allow inexpensive, rapid, and reproducible membrane synthesis.
- Establish the basic feasibility of the SMMM technique.
- Narrow down the list of promising SMMM candidates based on preliminary permeability experiments.
- Investigate in detail the permeability, selectivity, and durability of the most promising SMMM candidates vis-à-vis DOE technical targets.
- Relate membrane development/optimization to a fundamental experimental and theoretical characterization of the SMMM structure, composition, and mechanism.
- Fully investigate the best SMMM candidate(s) under increasingly realistic conditions based on the DOE Test Protocol and to compare their performance against exceeding the DOE 2010 Technical Targets.

Technical Barriers

This project addresses the following technical barriers within the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan for the Pd-based dense metallic membranes:

- Hydrogen embrittlement at temperatures below 500°C
- Thermal mismatch between metal membrane and support
- Pinhole formation
- Membrane sintering at higher temperatures
- Poisoning by S, CO, and other trace contaminants in coal derived H₂
- High cost of PGM-based membranes

Technical Targets

The project is currently in its initial stages of identifying molten metal and alloy candidates, porous supports, and in developing the fabrication procedures for these novel membranes. Once these steps are completed, and following initial feasibility investigations, the membranes will be developed further in an effort to meet or exceed the 2010 DOE technical targets listed in Table 1.

Accomplishments

During the first three quarters of Year 1 (Phase I) of this project, the following technical accomplishments have been made:

- The initial candidates for low-melting metals (M₁) have been identified (Sn, In, Ga, and Bi).
The initial non-PGM candidates for catalytic metals (M2) have been identified (Ni, Co, Cu, Fe, Ag, W, Mo, Nb, Ti, and Ta).

- The metallic (Inconel, porous stainless steel) and ceramic (Al2O3, ZrO2, TiO2, SiC, and Porous Vycor® glass) porous supports have been identified.
- SMMM fabrication procedures have been developed based on electroless- and electro-plating, soldering, and melt imbibition.
- SMMM membrane candidates of Sn and In have been fabricated on porous Inconel and on α-Al2O3 supports.
- Initial feasibility studies of these fabricated membranes have been completed.
- The reasons for failure of these first two candidates have been identified. For the case of metal supports, thus, the molten metal diffuses, reacts, and forms a dense non-permeable solid film with the substrate metal. For the ceramic membrane tested so far (α-Al2O3), the molten metal is found not to wet it, so that a microporous, rather than a dense, membrane results.
- From these early results, promising support candidates to be tested next have been identified, and include ZrO2, TiO2, SiC, Porous Vycor® glass as ceramic support candidates, and porous stainless steel (PSS) with a ZrO2 layer as a metal support candidate.
- A new permeability apparatus suitable for both tubular and disk (coupon) membranes capable of going up to 650°C and of recording permeation data automatically over an extended period based on LabVIEW® has been designed and built.

- The DOE Hydrogen Program FY 2010 Annual Progress Report

## Introduction

Coal gasification is promising for the centralized co-production of electric power and hydrogen via integrated gasification combined-cycle (IGCC) technology, when combined with carbon dioxide sequestration. For this, the main commercial technologies available for separating H2 from other syngas components, i.e., pressure-swing adsorption (PSA) and cryogenic distillation, however, are expensive and energy intensive. Thus, membrane separation of H2 is being investigated. The current dense metallic membranes based on Pd, however, are expensive, and still fall short of the desired permeability, selectivity, low cost, chemical and mechanical robustness, and durability. Hence, novel dense membranes based on non-PGM metals are sought that might overcome these barriers.

Thus, we have proposed a novel dense membrane technology for the separation of H2 from syngas based on non-PGM SMMMs, comprising of a thin film (<25 μm) of a liquid metal or alloy, with a melting point in the range of 200-500°C, and supported on a porous ceramic or porous metal support. The proposed membranes would be less expensive, more robust to species such as CO, and resistant to poisons such as sulfur. In addition, they would obviate issues related to solid dense membranes, i.e., sintering, H2 embrittlement, thermal mismatch between the membrane and the support, and formation of pin-holes.

## Approach

Figure 1 shows a schematic of the proposed SMMM. It comprises of a porous ceramic/metal support on which a thin but dense layer of a molten metal or molten metal alloy is deposited. Further, an oxide/ceramic layer is interposed in the case of a porous metallic support to...
avoid any diffusion and alloying reaction between the molten metal and the porous metal support.

The dense molten metal membrane comprises of two components: 1) a low-melting metal (M₁) to provide an open and fluid lattice desirable for ready dissolution and diffusion of hydrogen atoms, H₂; and 2) a non-precious group transition, or other catalytic, metal (M₂), to facilitate dissociation of hydrogen molecules at the membrane surface, in keeping with the accepted mechanism of hydrogen diffusion through a dense metallic membrane, wherein the H₂ molecule first dissociates and adsorbs on the surface, followed by ingress into the lattice, and subsequent diffusion through it, both of which steps are presumably facilitated by lattice defects and vacancies present in a liquid metal film.

Results

Due to the novelty of the proposed membranes, the work had to start from scratch, namely, identification of initial metal and support candidates, and development of the fabrication procedures for the membranes. Thus, as a start, it was decided to pick Sn as our initial choice for the molten metal M₁, since it has a large liquidus range (melting point [M.P.] = 232°C, boiling point [B.P.] = 2,602°C), and is relatively resistant to sulfur and carbonaceous deposits. This choice was subsequently supplemented with In (M.P. = 157°C, B.P. = 2,072°C), also abundant and nontoxic like Sn. As our initial choices for the porous supports, we picked: 1) a porous Inconel support as a porous ceramic support; 2) a porous alumina support as the porous ceramic support; and 3) a PSS with a ZrO₂ layer obtained from Pall Corporation. With the initial choice of the molten metal and the porous supports in hand, the next focus of the work was on developing a protocol for the fabrication of the SMMM. The various techniques investigated were: 1) electroless plating, 2) electroplating, 3) molten metal imbibition, and 4) soldering.

During the deposition of Sn on porous Inconel support, it was found that Sn is not conducive to thick deposits via electroless plating, because of the self-passivating nature of the metal, i.e., unlike, Pd, or Cu, for instance, it has low catalytic activity for the reductant oxidation reaction at room temperature. Thus, the plating stops once an impenetrable self-passivating layer of the metal has been deposited on the substrate. As a result, only a thin layer of Sn on porous Inconel could be obtained via electroless plating. Consequently, in order to deposit thicker tin layers, electro-plating was utilized. The electrodiposition experiment was carried out using four electrodes configuration in a cylindrical cell. The porous Inconel tube support was the cathode. The three cleaned tin rods were used as the anodes and symmetrically placed around the cathode to obtain uniform deposition. In this manner, any deposit thickness could be readily obtained. However, it was found that Sn electrodiposition is prone to whisker formation. However, these could be readily scraped off. The resulting Sn/Inconel membrane is shown in Figure 2.

However, when this membrane was tested for hydrogen/helium permeability above the M.P. of Sn, it was found that it was rendered virtually impermeable. The membrane post permeability testing is shown in Figure 3.

It appears thus that an alloying reaction has taken place between the Sn and Inconel, possibly forming a solid, dense, impermeable layer. Post-mortem microscopic characterization via scanning electron microscopy (SEM)/energy dispersive X-ray (EDX) is planned to confirm the alloying and formation of a dense solid film. It, thus, appears that porous metal supports without an intermetallic diffusion barrier are unsuitable for SMMM due to the ingress and reaction of the molten metal with the porous metal substrate.

Since porous metal supports are not, thus, suitable for SMMM, the fabrication of a Sn/α-Al₂O₃ ceramic support membrane was undertaken. A thin 2-µm layer of Sn/Cu was first predeposited on the α-Al₂O₃ support via electroless plating, over which, subsequently, a thick layer of Sn was deposited via electroplating at a low current density. The predeposition of the Sn/Cu layer is, of course, essential to allow the support to be used as an electrode. The resulting membrane is shown in Figure 4.

When this membrane was subjected to permeability testing at elevated temperatures, a very high flux and low selectivity between H₂ and He were found, characteristic of a microporous membrane (Figure 5) rather than a dense membrane. In other words, upon melting, only a thin microporous layer of Sn remained on the Cu/α-Al₂O₃ porous substrate. It was, thus, determined that α-Al₂O₃ is not wetted by the molten Sn.

Conclusions and Future Directions

In summary, we are still working on fabricating a dense supported molten metal membrane, and hope to accomplish this shortly. The following work is planned for the upcoming year (Year 2):

- We will test the suitability of other ceramic supports (ZrO₂, SiC, TiO₂, Vycor glass), along with metal supports with intermetallic diffusion barrier ceramic layers, for forming stable molten metal membranes.
- Once molten metal membranes with our initial choice for M₁ are thus fabricated and tested for basic permeability, the next step would be to alloy them with the catalytic metal M₂, and narrow down the selection to a handful of final SMMM candidates.
- The most promising SMMM candidates hence fabricated will be subjected to H₂ permeability, selectivity, and durability testing under increasingly realistic conditions of temperature, pressure, gas composition, poisons.
- The best SMMM membranes will be subjected to detailed physical, microstructural, and chemical characterization before and after the permeation test.
- We will develop a detailed kinetic/diffusion theoretical model for SMMM, including dynamics of all the sequential steps including dissociative adsorption/desorption and diffusion, so that no arbitrary assumptions are necessary regarding the rate-limiting step.

In the third and final year of the project, we will fully investigate the best SMMM candidate(s) under increasingly realistic conditions based on the DOE test protocol and compare their performance against exceeding the DOE 2010 targets (Table 1).

Subcontractor:
HyPerComp Engineering, Inc., Brigham City, UT
Project Start Date:  May, 2008
Project End Date:  September, 2011

Objectives

- Achieve a 15x increase in the gas production rate of a single high-pressure hydrogen production cell over the current standard Avalance cell.
- Demonstrate the high-pressure cell composite wrap which results in significant weight reduction.
- Build and test a 1/10th scale pilot plant.
- Create fabrication-ready drawings for a full-scale plant (300 kg/day, 750 kW).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Generation by Water Electrolysis section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(G) Capital Costs
(H) System Efficiency
(J) Renewable Electricity Generation Integration

Technical Targets

Distributed Water Electrolysis Hydrogen Production

In this project Avalance is developing an enlarged version of its present electrolyzer design that will have 15x the capacity of the current single tubular cell. To achieve this, the diameter of the current Avalance design individual tubular cell is being enlarged to enable an innovative cell core design: multiple coaxially arranged cylindrical electrodes, nested in a uni-polar configuration. This design is the core of a distributed water electrolysis hydrogen production system that will meet the following DOE 2017 targets:

- Hydrogen Cost: $3.00/gge
- Electrolyzer energy efficiency: 74 kWh/kg

Accomplishments

- Identified and tested formable sheet membrane material. (Figure 1)
- Successfully demonstrated membrane tube forming and seam joining. (Figure 2)
- Identified vendor and ordered 6,500 psi capable electrical isolation hoses.
- Completed design of single-cell test article and test apparatus.
- Demonstrated 6,500 psi production on small capacity cells.
- Began construction of the test cells to test the recirculation approach to enable 6,500 psi operation. (See Figure 3).
- Initial testing of 6,500 psi operation on the existing small-scale units has been completed demonstrating long-term operating potential of the core technology at very high pressure. Avalance completed the initial round of testing to evaluate the present cell design operation at 6,250 psi with the entire array of
IIE. Hydrogen Production / Electrolysis

Avâlence, LLC

II.E Hydrogen Production / Electrolysis

Introduction

Avâlence has existing technology that is globally unique in its ability to deliver hydrogen directly at storage-ready pressures of 2,500 and 6,500 psi without a separate compressor. Using an alkaline electrolyte process, the Avâlence Hydrofiller systems integrate the production and compression processes by operating the electrolytic cells at the desired delivery pressure. The systems can interface directly with renewable electricity supplies and have been shown in previous work (DOE Small Business Innovation Research project completed in April 2005) that the electrolyzer operates through the full range of voltages output from the connected photovoltaic array without using any power conditioning equipment. These characteristics result in a renewable hydrogen production and delivery system that is significantly more efficient and reliable, and substantially less expensive than existing commercially available electrolyzer and compressor system sets. The smaller scale Hydrofillers are based on a single cathode/anode tubular cell design with production capability of about 0.1 kg/day per cell. A revolutionary design approach to this high-pressure cell core is needed for an order-of-magnitude capacity scale up of the individual electrolyzer modules.

Approach

In this project, an enlarged version of the current Avâlence design is being developed that will have at least 15x the capacity of the present single tubular cell. To achieve this, the diameter of the individual tubular cell will be substantially increased in order to enable an innovative cell core design – multiple coaxially arranged cylindrical electrodes, nested in a uni-polar configuration – enabling up to 1½ kg/day of production per individual cell. To accomplish this diameter increase with a practical pressure boundary while operating at either 2,500 or 6,500 psi, Avâlence has partnered with a composite cylinder manufacturer, HyPerComp Engineering Inc. They will develop a custom designed containment vessel/cathode using their composite technology expertise that will allow an increase in the diameter of the individual electrolysis cell, enable operation at 2,500 psi and above, and reduce the cell weight and cost relative to conventional metal containment (similar to what is seen today with composite storage tanks used on vehicles). Ninety-six of these high-capacity cells will now produce a single unit (module) with a production capacity of 150 kg/day.

To complete this development process, Avâlence is proposing to build a quarter-scale pilot plant to be composed of 20 cells that will replicate the full plant design and operation, but minimize the cost to DOE for this technology demonstration. The pilot plant will be sent to the National Renewable Energy Laboratory.
for verification testing over the last three months of this nominal 30 month project. The final result of the project will be a commercially operating 30 kg/day pilot plant integrated with a wind turbine and/or photovoltaic array, and delivering hydrogen gas at pressure directly to storage cylinders. Operation of this plant and extensive testing of this and earlier development versions throughout the course of the project will thoroughly document the performance and operation of the technology. This combination of an operating pilot plant and substantial performance and operating data will position the technology for commercialization.

**Results**

In order to minimize project risk, a decision was made to demonstrate 6,500 psi operation in existing Avâlence technology prior to and as a step towards designing and building the large cell prototype. A number of findings resulted from this action. While it was shown that as expected, that the basic electrochemistry work, some issues arose need to be addressed going forward.

- It was found that that the 80 mm membrane created a larger voltage drop between the anode and cathode and therefore resulted in decreased efficiency. Table 2 lists the energy requirement per kg of hydrogen produced for both the 40 and 80 mm membrane tests.

<table>
<thead>
<tr>

<td>67 kWh/kg</td>
</tr>
</tbody>
</table>

- At high pressure, all leak paths also become more of an issue. As a result:
  - Pipe threads had to be removed from the cell design.
  - Multiple attempts were made before finalizing the design of the Parker dielectric hoses.
  - Internal cell seals have been redesigned on the head of legacy cells; and the new design concept is being used on the large cell.

- In achieving the goal of 6,500 psi operation, it was found that the present standard cell design requires periodic depressurization and electrolyte mixing to maintain cell performance and gas purity over the long term. Gas bubbles being formed are very small (almost invisible) and the velocity of bubbles is low, causing masking of the electrodes. As a result, high-pressure operation, which results in reduced buoyancy and smaller bubbles makes gravity based sweeping problematic at higher (design point) rates. A further issue is that since velocity is lower, dwell time in cells increases. This by itself can impact impurity, because there is more time to react with any electrolyte contaminants and greater time for any side electrolysis reactions (hoses) to accumulate.
impurity. Also, since diffusion is either steady or increasing with pressure, the additional dwell time amplifies any impurity as a result of diffusion. To address all of these issues, it is proposed that a different, constant recirculation approach may eliminate the depressurization cycle need and therefore increase production availability, oxygen side purity, and production efficiency. The electrolyte will be circulated to cool the system and to sweep the electrodes of gas bubbles to maintain gas production rates (current density). Additional components required for recirculation such as pumps and blowers actually simplify other parts of the system such as passive level control, water addition, and cell-to-cell electrolyte balancing, which become essentially automatic (see Figure 3).

Other findings include:

- Electrical isolation hoses need to be eliminated in order to move the Y-axis intercept on purity to above 99% (see Figure 1).
- Structural issues can be addressed using a conventional design of an overwrap to the metallic inner pressure vessel (see Table 3).
- Gas production rates are achievable as long as masking does not block electrode surface.
- High surface area cathode treatment can be employed to increase production rate.

### Conclusions

- Avâlence has shown that the biggest challenge of 6,500 psi with no compressor can be met.
- A robust large cell design is complete, ready to build/test.
- The technology is valid:
  - structurally (composites exit criteria)
  - electrochemically (2.1 v, 1,800 A exit criteria)
  - thermally (derived)
  - economically (DOE goal met @ 1,000 units/yr exit criteria)

- We feel that demonstration of the large cell nested operation is very low risk.
- We feel that demonstration of composite overwrap to achieve containment is also very low risk.

### Future Directions

- Demonstrate large diameter cell operation at 1,000 psi.
- Test long-term 6,500 psi operation approaches:
  - Using existing small cell apparatus.
  - Purified gas “recirculation/dilution” approach as required to achieve the lower explosive limit (see Figure 3).
  - Neutral electrolyte chamber approach – membrane related effort.

Accomplishments

- Membrane
  - Demonstrated enhanced dimensionally stable membrane (DSM™) performance (>Nafion® [1] 1135 membrane)
  - Completed 1,000-hour life-test with DSM™ (@ 80°C)
  - DSM™ operating lifetime estimated at 55,000 hours
  - Reduced membrane support cost by one-order of magnitude

- Cell-Separator
  - Demonstrated reduced hydrogen embrittlement in titanium/carbon cell-separator
  - Projected longevity of the carbon/titanium cell-separators (> 60,000 hours)

- Preliminary Electrolyzer Stack and System Design
  - Completed electrolyzer stack and system design utilizing low-cost components
  - Completed process and instrumentation diagram, process flow diagram (PFD), system control diagrams and layout drawings
  - Completed extensive safety review of electrolyzer system
  - Completed modeling of electrolyzer capital and operating costs; performed economic analysis using the DOE H2A model illustrating cost-reductions.

✿ ✿ ✿ ✿ ✿ ✿ ✿
Introduction

The Department of Energy (DOE) has identified hydrogen production by electrolysis of water at forecourt stations as a critical technology for transition to the hydrogen economy, and as the hydrogen economy matures, for hydrogen production at centralized locations using renewable energy sources. However, state-of-the-art electrolyzers are not economically competitive for forecourt hydrogen production due to their high capital and operating costs. The cost of hydrogen produced by present commercially-available electrolysis systems is estimated to be $4.80/kg-H\textsubscript{2}, considerably higher than the DOE target of $3.70/kg-H\textsubscript{2} by 2012 [2]. Analysis of electrolyzer systems performed by GES and others using the DOE H2A model indicate that the major cost elements are the cost of electricity, the capital costs of electrolyzer stacks and systems, and the high cost of hydrogen compression, storage, and delivery.

GES has developed PEM-based electrolyzer technology that operates at differential pressure for producing hydrogen at moderate to high pressure directly in the electrolyzer stack, while oxygen is evolved at near-atmospheric pressure. In this system, liquid water, which is a reactant as well as coolant, is introduced into the oxygen side at near atmospheric pressure. The goals of the project are to reduce the cost of the stack and system, improve electrolyzer efficiency, and to demonstrate electrolyzer operation at moderate pressure.

Approach

To reduce the cost of PEM-based electrolyzers, GES is improving electrolyzer stack efficiency and reducing stack cost through development of an advanced low-cost, high strength, membrane using a perforated polyimide support imbibed with perfluorosulfonic acid (PFSA) ionomer. GES is also reducing stack capital cost and increasing stack life through development of a long-life bipolar stack cell-separator, decreasing stack costs by initiating scale-up to a larger active area, and reducing the system capital cost by applying commercial production methods to PEM-based electrolyzer systems. In each of the key development areas, GES and its team members are conducting focused development of advanced components in laboratory-scale hardware, followed by life-testing of the most promising candidate materials. The project will culminate in fabrication and testing of an electrolyzer system for production of 0.5 kg-H\textsubscript{2}/hr and validation of the electrolyzer stack and system in testing at NREL.

Successful development of the advanced electrolyzer stack and system will result in a high efficiency; low capital cost electrolyzer that will meet the DOE cost targets for hydrogen production, assuming high-volume production. This will provide competitively priced hydrogen for delivery at forecourt stations to enable transition to the hydrogen economy.

Results

**DSM™ Membrane Performance:** To improve electrolyzer efficiency, GES has developed an advanced supported membrane having an ionic resistance comparable to that of a 0.0020- to 0.0035-inch-thick Nafion® membrane, but having significantly improved mechanical properties. This advanced membrane is referred to as a dimensionally stable membrane (DSM™) due to the membrane support that minimizes changes in dimensions (swelling/contraction) under high-pressure operation and with changes in water content. The support structure utilized in the development of the DSM™ consists of a polyimide (Kapton®) base film with a definable open pattern. Two separate techniques were employed in the fabrication of the DSM™ support. This includes membranes fabricated with a laser-drilled support (L-DSM™) and those with a recently developed low-cost chemically etched support (C-DSM™), Figure 1. The support structures are then imbibed with 850 and 1100 equivalent weight (EW) PFSA ionomer to a thickness of 3 mil (0.003”).

Polarization scans of the DSM™ were conducted through a current density range of up to 3000 mA/cm², a differential pressure of 300 psid, a temperature of 80°C, and with similar cathode and anode electrode structures. Results were compared to Nafion® 1135, Figure 2. During testing, both L-DSM™ and C-DSM™ exceeded the criterion for performance: each membrane exhibited lower cell voltages and thus higher cell efficiencies than that of a Nafion® 1135 membrane. In a direct comparison of DSM™ support structures imbibed with 1100 EW PFSA ionomer, L-DSM™ slightly outperforms C-DSM™. At an operating current density of 1,500 mA/cm², the performance of the L-DSM™ is 1.72 V, C-DSM™: 1.75 V. The slight loss in performance
of the C-DSM™ is attributed to the larger landing width within the chemically etched support structure resulting in an increase of the proton-transport path and thus restricting the proton-transport kinetics. The loss in performance of the C-DSM™ is overcome using a lower EW PFSA ionomer, namely 850 EW. It has been shown that the performance of the “low-cost” C-DSM™ (850 EW) is equivalent to that of the L-DSM™ (1100 EW) as noted:

L-DSM (1100 EW) = C-DSM (850 EW) > C-DSM (1100 EW)

Durability of the DSM™ was also demonstrated in full-size 160-cm² active area hardware via fluoride-release-rate (FRR) measurements at constant current operation. Since PFSA ionomer is used as the membrane material and in the binder for the catalyst layer, the loss of fluoride is used as a measurement of membrane degradation. An FRR rate of 3.7 μg F⁻ ion/hr or less than 10 micrograms F⁻ ion/L (<10 ppb) was present in the cathode effluent (electro-osmotically transported water) at the end of the 1,000-hour life test. Based on electrolysis FRR results, the lifetime of the DSM™ is projected to be between 45,000 and 55,000 hours, which exceed the durability requirements of the electrolyzer system. In addition to its durability, the DSM™ exhibits high cell efficiencies in the range of 75% LHV (88.8% higher heating value) at an operating current density of 1,500 mA/cm².

Cell-Separator Development: The cell-separator is a gas-impermeable conductive sheet that separates the hydrogen and oxygen compartments in the bipolar stack. The separator must be highly conductive, as well as resistant to hydrogen embrittlement and to corrosion in an oxidizing environment. The proven GES high-pressure naval electrolyzer uses a complex multi-layer separator incorporating a conductive compliant member and sheets of niobium and zirconium metal. Zirconium is used due to its high resistance to hydrogen embrittlement. GES has previously evaluated a low-cost, dual-layer titanium cell-separator. Although performance was comparable to that of niobium/zirconium cell-separators, lifetimes were limited to 5,000 hours due to hydrogen embrittlement.

The most promising approach for long-term implementation has been achieved by coating titanium with a low-cost electrically conductive, embrittlement-resistant carbon coating. The challenge was the development of a pinhole-free, highly adherent coating with the required characteristics. Under the cell-separator development task, GES demonstrated performance of a low-cost carbon/titanium separator in 160-cm² hardware comparable in performance to a dual-layer titanium separator at 1/40th the cost of niobium-zirconium cell-separators. In addition, life expectancy of the carbon/titanium separator, determined via hydrogen-uptake analysis over a 500-hour period, indicates lifetimes exceeding the 50,000-hour system requirement.

Preliminary Electrolyzer Stack and System Design: As a result of the component and membrane development conducted in this project, the overall projected capital cost of the electrolyzer stack has decreased from greater than $2,500/kW in 2001 to $463/kW in 2010, with a further projected decrease to <$400/kW by 2012. In addition to the use of low-cost cell-separators, the completed preliminary stack design shown in Figure 3 includes several modifications to the previous hardware; (1) an increase in cell active area
from 160 to 290 cm², effectively reducing the number of cells required to produce a given amount of hydrogen, thus reducing the stack manufacturing labor and the materials scrap rate, (2) an overall decrease in parts count per cell (from 41 to 11), (3) a 75% reduction in catalyst loadings, (4) molded thermoplastic cell frames resulting in a cost reduction of 95% for this component alone, and (5) the use of a pressurized dome that encloses the electrolyzer stack to conform to the regulatory code requirements pertinent to hydrogen generators.

Our subcontractor, Parker Hannifin Ltd. (Parker) has completed the preliminary system design which includes the PFD, the P&ID, and the control logic diagrams. The dimension of the electrolyzer system shown in Figure 4 is roughly 6’ x 6’ x 6.5’. The layout is effectively broken into three zones, namely the oxygen (O₂) compartment, the hydrogen (H₂) compartment, and the controller section. The O₂ compartment contains the oxygen gas-phase separator, a circulating liquid pump, and the deionized water feed tank; the H₂ compartment, encloses the high- and low-pressure hydrogen gas-phase separators, heat exchanger, cooling fans, and various flow valves. The refrigeration unit, a component of the H₂-dryer that is used to cool H₂ gas prior to entering the dryer, is located below the controller and adjacent the electronic power supply. Nitrogen (N₂) tanks provide nitrogen gas for filling the dome and for purging the electrolyzer stack during start-up and shut-down.

**Conclusions and Future Directions**

Significant progress has been made in DSM™ membrane development. GES has demonstrated membrane reproducibility and durability as well as a significant improvement in electrolyzer cell efficiency that exceeds the DOE’s 2017 target. In addition, development efforts conducted under this project have resulted in the reduction in the cost of the moderate-pressure PEM-based electrolyzer systems, an increase in the life of the low-cost cell-separators, and improved balance-of-plant components efficiency. The future objectives (by company) are to:

- **Parker Hannifin**
  - Continue fabrication and evaluation of key system components
  - Complete critical design review
  - Fabricate and operate deliverable system

- **GES**
  - Fabricate scaled-up ‘short stack’ prototype (0.1 kg-H₂/hr)
    - Scale-up DSM™ (to 290-cm²)
    - Scale-up Cell-Separators (to 290-cm²)
  - Operate short stacks at GES for 1,000 hours
  - Assist in system start-up at Parker facilities
  - Receive and install operating system at GES
  - Add cells to stack to increase capacity to 0.5 kg-H₂/hr
  - Verify stack/system performance
  - Demonstrate prototype system at NREL

- **Virginia Polytechnic Institute**
  - Complete fabrication of alternative hydrocarbon membrane
  - Evaluate 100-hour durability

**FY 2010 Publications/Presentations**

• Spectrum Automation, Denver, CO  
Project Start Date: September, 2003  
Project End Date: September 30, 2012

Objectives

• Model and evaluate the potential of using hydrogen as an energy storage mechanism when coupled to renewable electricity sources at utility scales.  
• Quantify efficiency and capital cost improvements achieved by designing and building integrated power electronics to more closely couple wind turbines and photovoltaic arrays to the electrolyzer stacks.  
• Test and characterize the impacts on commercial electrolyzer systems to accommodate the varying energy from wind turbines and photovoltaic arrays coupled directly to the hydrogen-producing electrolyzer stack.  
• Work closely with industry to provide independent testing and validation of system performance of next generation electrolyzer systems awarded under DOE contracts, and provide feedback on potential areas for improvement.  
• Characterize and evaluate performance improvements of system-level integration and optimization opportunities for renewable-energy-based electrolysis production facilities.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration (RD&D) Plan:

(G) Capital Cost  
(H) System Efficiency  
(I) Grid Electricity Emissions (distributed)  
(J) Renewable Electricity Generation Integration (central)

Technical Targets

By addressing the technical barriers of integration with renewable energy sources, this project works to achieve the DOE cost targets for distributed and central electrolytic hydrogen production. One of the objectives of this work includes the development of integrated power electronics and control theory to couple renewable electricity sources with the electrolyzer stack. This work can help reduce the capital cost and improve the efficiency to reduce the cost of renewable hydrogen production by 2012.

Distributed Electrolysis

• By 2012, reduce the cost of distributed production of hydrogen from distributed electrolysis to $3.70/gasoline gallon equivalent (gge) of H₂ (delivered) at the pump.

Central Electrolysis

• By 2012, reduce the capital cost of wind-coupled electrolyzer system to $350/kW.  
• By 2012, reduce the cost of central production of hydrogen from wind electrolysis to $3.10/gge of H₂ at the plant gate.

The 2012 electrolyzer capital costs assume a 12.5% savings on a standard H2A assumption for an advanced electrolyzer cost of $400/kW [1].

Accomplishments

• Completed the hydrogen-based energy storage analysis and companion energy storage benchmarking study.  
• Installed, commissioned and operated 13 kg/day polymer exchange membrane (PEM) electrolyzer at the wind-to-hydrogen demonstration project (loan from the U.S. Army):  
  – Relocated both small (2.2 kg/day) PEM electrolyzers to adjacent Hydrogen Test Facility to upgrade with additional 10-cell stack for further testing.
• Completed the extensive process to obtain approval to run in unattended mode of operation:
  – Operated both the PEM and alkaline systems for longer duration run-times in unattended mode.
  – In March alone achieved about 120 hours of operation of the integrated energy system test bed producing over 40 kg of hydrogen.
  – Product fuel from testing used in hydrogen-powered vehicles.
• Installed and began testing upgraded PEM electrolyzer with additional 10-cell stack electrically in series with original 20-cell stack:
  – Conducted comparison testing of 10 kW photovoltaic (PV) array directly coupled with electrolyzer stack with power converter between array and stack.
• Authors from NREL and Natural Resources Canada published book chapter as part of the 18th World Hydrogen Energy Conference.
• Installed, commissioned and began operating 5 kW PEM fuel cell in the integrated renewable energy system.

Introduction

One issue that limits greater penetration of renewable energy sources (e.g., wind and solar) is their variable and seasonal energy production. One solution may be to produce hydrogen through water electrolysis and use that hydrogen in a fuel cell, either to fuel vehicles or to produce electricity during times of peak demand. Xcel Energy and NREL have collaborated to design, install, and operate the Wind-to-Hydrogen (Wind2H2) project, which demonstrates how to make and use hydrogen with renewable energy without producing greenhouse gases or other harmful byproducts.

The Wind2H2 project is helping industry understand the hurdles and potential areas for improvement in emerging renewable electrolysis technologies. By allowing engineers to operate and configure an integrated electrolysis facility, this project has enabled the investigation and analysis of hydrogen production, compression, storage, and electricity generation that will provide valuable data, which can be used to improve the designs of future renewable electrolysis systems. A significant focus of the Wind2H2 project is to explore integration issues and opportunities for performance and cost improvements resulting from system-level optimization. NREL engineers are investigating how to maximize renewable energy use and optimize energy transfer within the Wind2H2 system.

Most electrolysers commercially available today are designed for grid-connected operation; therefore, they incorporate power electronics to convert alternating current (AC) from the grid to direct current (DC) power required by the cell stack. These power converters can represent 14% to 22% of the total cost of the electrolyzer. Power converters are also required for the renewable energy source. By designing and incorporating dedicated power converters that allow wind turbines and photovoltaic arrays to be more closely coupled to electrolyzer stacks, energy transfer within the system can be improved and costs lowered.

Approach

This RD&D project examines the design and optimization of electrolysers, power electronics, fuel cells, and energy storage system components to integrate renewables and electrolysers to improve the efficiency, cost, and robustness of these systems. The cost of the resulting hydrogen via electrolysis is heavily dependent on the cost of electricity. System integration research aims to reduce the cost of hydrogen production by:

• Exploring system-level integration and optimization opportunities for renewable-energy-based electrolysis production and storage facilities.
• Quantifying system-level efficiency improvements, system impacts, and cost reductions achieved by designing and building integrated power electronics to more closely couple varying energy from wind turbines and PV arrays to the electrolyzer stacks.
• Gaining operational experience of a hydrogen production facility, evaluating appropriate safety systems and system controls for safe unattended operation, and identifying areas for cost and efficiency improvements.
• Evaluating the potential of using hydrogen as an energy storage mechanism to help integrate variable output renewable energy on large MW-scale systems for utilities.
• Developing and optimizing advanced controls, subsystems, and power electronics to reduce electrolyzer capital cost and improve system efficiency.

Results

Experimental Findings

Direct Coupling versus Power Converter: NREL designed, installed and tested an additional 10-cell stack in a system with an existing 20-cell PEM stack. The original 7 kW rated electrolyzer could produce 2.2 kilograms of hydrogen per day. After the 10-cell upgrade, the modified PEM system requires 10 kW of electricity and produces 50% more product. More
importantly, the added ½-stack shifted the electrical operating point of the combined stacks to better align with the maximum power point of NREL's 10 kW PV array. The improved alignment allowed for a more optimal direct coupling of the array to the stack pitted against the NREL-designed power converter utilizing an algorithm for maximum power point tracking (MPPT).

NREL produced hydrogen with power provided from the 10 kW PV array, comparing power transfer from a directly-coupled array to power transfer to the stack using NREL's MPPT power converter. This testing showed that direct-coupling outperformed power electronics utilizing MPPT when irradiances were below 500 W/m² (see Figure 1).

These findings provide useful insight into future integrated system designs. Electrolyzer stack voltage is a function of temperature, stack current and age. While the PV array maximum power point varies with temperature, irradiance and age. Passively keeping these two operating points aligned and optimal would be challenging as both systems vary over their normal operating ranges. Finally, time-of-day influences irradiance from the sun and configurations can be selected based on their performance for the irradiance level. As all of these parameters drive the operating points of the source and stack it seems reasonable to employ a situational approach to energy transfer. In this case, during the morning and evenings when the irradiance is below 500 W/m² switch to the direct coupling configuration. Also, during cloudy or stormy periods when the irradiance drops below the transition point power the stack in a direct-coupled mode. All other times when the irradiance is greater than 500 W/m² the power converter utilizing MPPT will transfer more energy from the array to the electrolyzer stack.

**Long Duration Testing:** NREL completed the installation, commissioning and started operation of an H-series (13 kg/day) PEM electrolyzer on loan from the U.S. Army. This will enable the side-by-side comparison testing of similarly sized alkaline and PEM electrolyzer technologies. Both smaller S-series system were relocated from the wind-to-hydrogen demonstration project to NREL’s Hydrogen Test Facility. One of the two smaller PEM systems is the source of the previously described direct coupling versus MPPT power converter testing.

The NREL and Xcel Energy wind-to-hydrogen demonstration project has been conducting daily operations since 2006. Originally developed as a platform for research, demonstration, evaluation, and testing, the Wind2H2 system has recently undergone significant modifications to enable operations in an unattended mode, thereby allowing longer duration system testing. To run the Wind2H2 system in an unattended mode, new monitoring and control systems were developed and an extensive safety review and verification of these new systems was completed.

Since March 2010 (Figure 2) the wind-to-hydrogen system has been approved for long-duration unattended operation. However, also in March 2010 the alkaline electrolyzer, from Teledyne Energy Systems, displayed symptoms of severe gas cross-over within the stack. A replacement stack has been ordered and the existing stack will be returned for failure analysis. The PEM system has now been operated overnight and all the way through weekends to keep up with the demand of NREL’s leased 12-passenger hydrogen-fueled internal combustion engine shuttle.

Long-duration testing showed the system could operate safely without operator attendance. Long-duration operation will continue for demonstration purposes while the wind-to-hydrogen system will also continue to be used for research and evaluation.

**Analysis**

NREL conducted a study of the life-cycle costs associated with hydrogen-based energy storage systems, and benchmarked these costs against competing energy storage systems including pumped hydro energy storage, compressed air energy storage, and battery storage. The study included full sets of analyses of hydrogen-based energy storage systems, including PEM fuel cell-based systems and hydrogen expansion-combustion turbine based systems. The study found that hydrogen-based systems were competitive with battery-based systems, with hydrogen expansion-combustion turbine systems providing stored electricity for as little as 17 cents/kWh (Figure 3).

The goal of this analysis was to develop a cost survey of the most-promising and/or mature energy storage technologies and compare them with several configurations employing hydrogen as the energy carrier. A simple energy arbitrage scenario was developed for a mid-sized energy storage system consisting of a 300-
MWh nominal storage capacity that is charged during off-peak hours (18 hours per day on weekdays and all day on weekends) and discharged at a rate of 50 MW for 6 peak hours on weekdays. The full report can be found at http://www.nrel.gov/docs/fy10osti/46719.pdf.

**Conclusions and Future Directions**

The project is relevant to the DOE targets by addressing capital cost, efficiency, and renewable energy source integration to reduce the cost of hydrogen production. The approach includes demonstrating advanced controls, system-level improvements, and integration of renewable energy sources to commercially available electrolyzer stacks via NREL-designed-and-built power electronic controllers. Testing and characterization of power electronics packages and control algorithms developed at NREL showed significant improvements in energy transfer within the system.

The experimental results from the direct-coupling versus power converter testing between the PV array and
combined PEM electrolyzer stacks provide a valuable starting point for higher voltage testing. These results establish gains in the energy transfer between renewable resources and the hydrogen-producing electrolyzer stacks as a function of the sun's irradiance.

Long-duration testing of the Wind2H2 system will continue. The new H-series PEM electrolyzer was instrumented with stack voltage and current sensors. This enables long duration testing of two (of three) PEM stacks under a wind-based stack current profile while the third stack operates at constant current. Stack voltage monitoring over long duration provides decay rates to confirm industry reports of constant current operation and enables comparison of multiple stacks receiving current based on varying wind profile. The alkaline stack will be replaced and operated under the same wind profile. Stack decay rates will be compared between the varying and constant current stacks.

NREL will test and evaluate the 5 kW fuel cell system that has been integrated into the Wind2H2 system. Hydrogen produced during long-duration system testing will be used to provide fuel for the 5 kW fuel cell. Such testing will demonstrate the use of a fuel cell in an integrated, hydrogen-based energy storage system. As part of this evaluation, NREL will characterize the performance of the fuel cell in terms of turn-down rate, turn-on time, and system efficiency at power levels below the maximum power output to better understand the real-world aspects of using fuel cells in hydrogen-based energy storage systems.

NREL will also continue to model and analyze the potential of hydrogen-based energy storage systems, including analysis of dual-use energy storage systems. These systems use hydrogen for energy storage and fuel for vehicles. The analysis will include the impact of carbon taxes and carbon policies on hydrogen-based energy storage and compressed air energy storage.

NREL will continue to work to transfer technology and foster collaborative relationships with industry. This work will enhance the existing active and informal partnerships with industry, academia, and domestic/international researchers.

Accomplishments

- A new flow field design resulted in a 20% cost savings, reductions in part count and assembly time, improved cell robustness and is ready for production validation and commercial release.
- Additional alternative flow field materials are being evaluated to provide an additional 15 to 20% cost reduction in the near future.
- Demonstrated a new catalyst formulation and application technique through the successful operation of prototype electrolyzer cells containing 55% less precious metal in the catalyst layers.
- A comprehensive electrolyzer cell model has been created at Penn State and is currently being validated against physical test data.

Introduction

This project addresses the DOE Hydrogen Program objective for distributed production of hydrogen from proton exchange membrane (PEM) water electrolysis. The DOE technical targets for hydrogen cost as well as electrolyzer efficiency and capital cost will be directly addressed through the advancement of key components and design parameters. Currently, a significant portion of the electrolyzer system capital cost comes from the cell stack(s). When added together, the flow fields and membrane electrode assemblies (MEAs) constitute over half of the total cell stack cost (Figure 1). Significant cost reductions of these components as demonstrated with this research are required in order to reach the targets. Further optimization of cell stack components

Subcontractors:
• Entegris, Inc., Chaska, MN
• The Electrochemical Engine Center at Penn State, University Park, PA

Project Start Date: September 1, 2009
Project End Date: February 28, 2011

Project Objectives

- Improve electrolyzer cell stack manufacturability through:
  - Consolidation of components
  - Incorporation of alternative materials
  - Improved electrical efficiency
- Reduce cost in electrode fabrication through:
  - Reduction in precious metal content
  - Alternative catalyst application methods
- Quantify the impact of these design changes through utilization of the H2A model.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(G) Capital Cost
(H) System Efficiency
(J) Renewable Electricity Generation Integration
results in efficiency gains at the system level and ultimately a reduction in the cost to produce hydrogen.

**Approach**

The scope of work for this project allowed for research and development in several key areas relating to cell stack cost reduction. Topics included: 1) flow field design, 2) catalyst formulation, and 3) computational performance modeling. Advancements in flow field design are intended to be advantageous for low-cost, high-volume manufacturing. Alternatives to the current flow field design include composite bipolar plates or unitized flow fields which consolidate parts and reduce the amount of required precious metal plating. Material testing samples and prototype flow fields will be fabricated and tested for compatibility with the corrosive environment known to exist within operating electrolyzer cells. Higher efficiency oxygen evolution catalysts are of interest because the oxygen evolution reaction is inefficient and therefore requires high catalyst loadings to achieve reasonable operational voltages at the desired current densities. Improving catalyst utilization can substantially reduce the cost of the MEA by reducing the noble metal content in the catalyst layers. Novel electrode structures will be constructed using alternate synthesis techniques and characterized for performance and durability. Computational modeling of an electrolyzer cell will allow for optimization studies to be performed around flow field material and architecture. Cell performance can be quantified in ways not typically possible with standard physical test experiments. Validation of all of the previously mentioned design changes will be achieved through cost analysis based on the H2A model.

**Results**

During this project, significant near-term electrolyzer cell cost reductions were identified through the testing of non-metal flow field components (Figure 2). The use of alternative conductive materials has been shown to provide comparable electrochemical performance when compared to legacy designs while allowing for the consolidation of components and the use of manufacturing methods more suitable for high volume production. Additional materials are still being evaluated that could present a further cost reduction thanks to their ability to be injection-molded in a full-scale production scenario. It should be noted that the operating potential of electrolyzer cells is typically above 2.0 V while water, oxygen and hydrogen gasses are also present at various pressures and temperatures. The challenge with alternative materials is to ensure that they can withstand these highly corrosive conditions contained within an operational electrolyzer cell while also maintaining low electrical resistance.

Specially developed emersion tests have allowed for the evaluation of several materials and coating options within the described environment. These tests indicate that while coatings can effectively protect materials from corrosion, small cracks or discontinuities in the coating may be allowing a gradual corrosion of the substrate material. Completed test runs have been limited to 500 hours, therefore, it will be necessary to perform additional longer term tests in order to better quantify the rate of corrosion. If the rate of corrosion is significant, process improvements will be required in order to ensure continuous coverage of the substrate material. Remaining testing of alternative materials will be focused on evaluating the impact of the electrical resistivity of prototype flow fields on cell potential during operation.

Significant advancements have been made in the development of an optimized catalyst formulation and application technique. This work has demonstrated a 55% reduction in the amount of precious metal used in the catalyst layers of the MEA. As a result, the cost of the MEA can be reduced and will in turn create cost savings at the cell stack and total system level. These improvements save cost and improve quality.
while maintaining cell potential performance when compared to existing commercial cell stacks operating at standard conditions (Figure 3). In order to achieve this, a mathematical model was developed and refined to accurately predict the final catalyst loading from the beginning of the formulation and application process. Using the model, it was possible to perform a concise matrix of experiments and quickly determine the lower limits of catalyst loading with respect to desired cell performance. The selected application technique represents an improvement over existing production techniques in that it allows for improved accuracy and uniformity while also enabling higher speed throughput.

A comprehensive computational model of an electrolyzer cell has been developed at Penn State and is capable of predicting performance parameters based on the geometry of the flow fields and specified operating conditions. Calculated parameters include overall cell potential, distribution of potential and current density distribution, as well as, volume fractions of water, oxygen and hydrogen in various regions of the cell. Results can be plotted in as colored gradients superimposed over three-dimensional models or as more traditional plots such as polarization curves (Figure 4). This custom-developed code merges traditional two phase flow modeling with a specialized electrochemical model. Variables common to both sets of governing equations create linkages between the sections of the model and improve the accuracy of the results.

Design parameters and operational data from a baseline design have been provided to Penn State for the purpose of validating the model. Once the predicted results are confirmed to be consistent with actual data over a larger range of conditions, the model can reliably be used for parametric analysis of electrolyzer cell designs. Cell component architecture can be refined in light of model performance predictions and the relative impact of design parameters on overall efficiency can be understood. It is anticipated that improved water distribution within the cell will allow for better thermal management. The minimization of coolant flow could reduce demands on the system such as the pump flow and pressure head requirements which can lead to reductions in capital cost and gains in system efficiency.

**Conclusions and Future Directions**

- Tests have shown that alternative conductive materials can remain stable in the corrosive environment of operational electrolyzer cells for tests up to 500 hours, however, much longer term testing is required to ensure stability beyond the 30,000 hour minimum operational life of Proton Energy Systems cell stacks.
- Cost reductions can be made by controlling the catalyst formulation process and through advanced application techniques. The next step is to implement the formulation and application processes developed during this project into Proton’s commercial production design.
- Electrolyzer cell performance can be predicted with the use of a comprehensive computational model. No future work is planned at this time but the next step would be for Penn State to develop an executable program which could interface directly with computer aided drafting and design models and provide upfront electrolyzer simulation capability.
II.F.1 R&D Status for the Cu-Cl Thermochemical Cycle-2010

Start Date:  June 2006
Projected End Date:  September 2015

Objectives

The strategic objective is to develop a robust process for producing hydrogen using the Cu-Cl thermochemical cycle. This year’s objective is to facilitate the development of the electrolyzer capable of long-term operation. The long-term goal remains an integrated laboratory-scale demonstration for the Cu-Cl cycle.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(U) High-Temperature Thermochemical Technology
(V) High-Temperature Robust Materials
(W) Concentrated Solar Energy Capital Cost

Technical Targets

The proposed target for the cost of hydrogen production is $6.00 per gasoline gallon equivalent (gge) H₂.

Accomplishments

- Initiated a development and testing program for new membrane materials for the CuCl electrolyzer.
- Collaborated with the Atomic Energy of Canada Ltd. (AECL) and five Canadian universities funded by the Ontario Research Foundation.
- Demonstrated high yields from the hydrolysis reactor with lower steam usage. Lowering the steam requirement improves the process efficiency.
- Developed a method for quantifying the amount of Cu₂OCl₂ produced from the hydrolysis reactor.

Introduction

The U.S. Department of Energy’s Office of Energy Efficiency and Renewable Energy (DOE-EERE) is supporting the development of thermochemical cycles that use solar heat. Their focus is to identify thermochemical cycles that operate with solar heat and meet efficiency and cost targets. The lower temperature option for this cycle is attractive to DOE-EERE because the solar power tower provides heat near 550°C and is near commercialization. The three reactions in the Cu-Cl cycle are shown in the following. The experimentally verified temperatures for the two thermal reactions (hydrolysis and decomposition) are within the range of the solar power tower’s process heat.

\[
\begin{align*}
\text{CuCl}_2 + H_2O & \rightleftharpoons \text{Cu}_2OCl_2 + 2HCl(g) \quad \text{Hydrolysis,} \; \sim375°C \\
\text{Cu}_2OCl_2 \rightleftharpoons 2\text{CuCl} \; \text{Decomposition,} \; 450-550°C \\
2\text{CuCl} + 2HCl & \rightleftharpoons \text{CuCl}_2 + H_2 \; \text{Electrolysis,} \; \sim100°C
\end{align*}
\]

Based on preliminary experimental and modeling work, the Cu-Cl thermochemical cycle was chosen for further development for the following reasons:

- A maximum cycle temperature of \(\sim550°C\) has been verified.
- All reactions have been demonstrated at laboratory scale.
- No catalysts are needed for thermal reactions and no catalyst is needed for the anode in the electrolyzer.
- Conceptual process design is based on commercially practiced technologies.
- Preliminary mass and energy balanced flowsheet showed promising efficiency and the corresponding H2A showed estimated hydrogen production costs were within the proposed DOE target.

While the cycle has the attributes listed above, there are significant challenges in the electrolysis reaction and in the hydrolysis reaction. Copper crossover/cell degradation is observed in the former and a large excess of steam is required for complete conversion in the latter.
**Approach**

In the early electrolysis experiments, copper crossover was observed with both anion and cation exchange membranes. Copper crossover represents a potential showstopper as it degrades the electrolyzer’s performance and prevents long-term operation of the electrolyzer at a stable cell voltage. A membrane development project has been initiated to identify and test promising membrane materials for the CuCl electrolyzer. Three types of cation exchange membranes are being tested in the first phase of this work: (1) commercial membranes such as Nafion® and CMX, (2) Nafion® coated with a low permeability layer for larger ions, and (3) new materials such as the polysulfone membranes, which can also be modified to obtain the desired cation selectivity and which were able to reduce sulfur crossover in the hybrid sulfur electrolyzer [1]. Screening tests include diffusivity, water uptake, conductivity, and ion exchange capacity measurements in high acid environments and water over a range of temperatures. The most promising samples will be tested for chemical stability and durability in electrolyzers at AECL and Pennsylvania State University (PSU). In the second phase of the work, tests will be conducted at elevated temperature and solutions with varying concentrations of CuCl, CuCl₂, and HCl. Since the electrolyzer tests are by definition long-term tests, the use of screening tests, which take a shorter time, should expedite the search for the ‘best’ membrane.

The challenge for the hydrolysis reaction was that the reactor used a large excess of steam to convert all of the CuCl₂ to Cu₂OCl₂. This high steam demand adversely impacts the efficiency of the cycle and the cost of hydrogen production. The goal of the current research was to verify the model’s prediction that subatmospheric pressure operation would reduce steam demand. At one bar, a steam to CuCl₂ molar ratio of 20-23 was required for >97% conversion experimentally, somewhat higher than the model’s value of 17. However, at 0.25 bar, the model predicts a steam to CuCl₂ molar ratio of only 7 is needed for complete conversion. A low-cost, commercially used method to obtain a partial vacuum, i.e., an aspirator or ejector, was tested. Since CuCl has been found in all of the hydrolysis products, experiments to determine the mechanism of CuCl formation were also planned. Possible mechanisms for the formation of CuCl are the decomposition of CuCl₂ or Cu₂OCl₂, or a combination of both. CuCl₂ decomposition results in the formation of Cl₂ and CuCl, while the decomposition of Cu₂OCl₂ results in CuCl and oxygen. The corrosive nature of the gaseous products prevents measurement of the mechanism and kinetics by standard techniques. However, experiments following changes in the environment around the Cu ion will provide this information. Synchrotron radiation allows this type of measurement and is available at the Advanced Photon Source at Argonne National Laboratory. Extended X-ray absorption fine structure analysis has been a key technique for determining the substitution of O with Cl or vice versa in the first coordination sphere of the copper species [1]. X-ray absorption near-edge spectroscopy (XANES) at Cu K-edge would allow us to determine the coordination geometry of Cu in the samples. The XANES spectra of the Cu species of interest have been reported in literature to be very distinctive [2] and therefore a method to obtain quantitative information on the composition of the samples during reaction. A matrix of experiments has been designed to measure CuCl₂ and Cu₂OCl₂ decomposition as a function of temperature and time and to measure the formation of Cu₂OCl₂ as a function of time, temperature, and steam to CuCl₂ molar ratio.

**Results**

**Membrane Development**

The membrane development project is new and is a collaborative effort involving several institutions. Argonne National Laboratory is preparing low permeability membranes for the anode by applying low-permeability coatings on commercial Nafion® 115 membrane. The coatings consist of either (a) substituted aromatic hydrocarbons or (b) a non-aromatic that forms a flexible network through the pores to inhibit the transport of copper ions without sacrificing the ion exchange capacity of the precursor Nafion® membrane. These membranes are then processed according to published literature. Polymer chemists at PSU and Sandia National Laboratories are developing polysulfone membranes, whose selectivity can be tuned by the choice and number of side groups [3,4]. Electrolysis experiments are conducted at PSU and AECL.

Membrane samples are now being examined. Diffusivity measurements of Cu species through the membranes are being used as the primary screening technique. The diffusion cell consists of two compartments separated by a membrane and is shown in Figure 1. The solute-rich side contains the solution of CuCl₂ dissolved in a hydrochloric acid solution and the solvent-rich side, either a solution of HCl or water. The diffusion of copper species into the solvent-rich side versus time is measured by following the change in concentration of the Cu species on the solvent-rich side.

The concentrations of Cu species are being determined by measuring the absorbance using ultraviolet-visual spectroscopy and correlating it with the absorbance of standards prepared by dissolving a known amount of CuCl₂ into the desired solution, in this case 10.2 MHCl. Standards spanned CuCl₂ concentrations from 25 to 1,000 ppm. The maximum absorbance was
measured at 380 nm. The HCl concentration for both the solute-rich and solvent-rich sides is 10.2 M because these conditions were used by AECL in their longest duration test.

Figure 2 shows the results of the diffusivity measurements of Nafion®, Nafion® with three polymeric coatings, and two samples of s-Radel, a polysulfone-type membrane. As can be seen, the new membranes have lower diffusivity with respect to copper than does Nafion®. Based on these results, new membranes are being modified to further reduce transport of Cu species.

Conductivity measurements are in progress as are measurements of the ion exchange capacity and water uptake. Samples have been sent to PSU and AECL for testing copper crossover in their electrolysers. Higher temperature tests are either in progress or will be started shortly.

Hydrolysis Reaction

The model as well as Le Chatelier’s Principle shows that reduced pressure operation should result in lower steam demand for complete conversion to the desired products in the hydrolysis reaction. An aspirator, a relatively low-cost method to obtain a partial vacuum, was added to the exit of the hydrolysis reactor. A schematic of the set-up and details of the experimental method are described elsewhere [5,6]. Experiments were conducted at 0.4, 0.7 and 1 bar. The amount of CuOCl₂ in the products was quantified using oxygen evolution from the decomposition of the solid products. The amount of O₂ produced was calibrated using a known amount of Cu to form CuO in presence of 3% O₂/He. The yield of CuOCl₂ was calculated based on the ratio of the measured O₂ to the theoretical value. The amount of CuCl was measured using a wet chemistry method.

Figure 3 shows the amount of CuCl and Cu₂OCl₂ formed at the three pressures. At 0.4 and 0.7 bar, the amount of CuCl formed is significantly lower than that formed at 1 bar at all steam to CuCl₂ molar ratios. The maximum amount of CuOCl₂, about 98%, is formed at a steam to CuCl₂ ratio of 15, a noteworthy reduction from the 20-25 used in the tests at 1 bar. From a practical standpoint, the observed increase in Cu₂OCl₂ formation at reduced pressure is consistent with the modeling results, where a favorable effect of low pressure was predicted. However, the decrease in CuCl formation was not predicted. Assuming that CuCl forms due to thermal decomposition of CuCl₂ or Cu₂OCl₂ or both, it is unclear why decreasing the pressure inhibits this decomposition. This effect maybe associated with the relative rates of the hydrolysis and decomposition reactions and the hydrodynamics of the experimental reactor. If the decomposition reaction rates are much slower at 375°C than the hydrolysis rate, the formation of CuCl should critically depend on the residence time, which is determined by particle size and flow conditions in the reactor. Additional details of this analysis are published elsewhere [5]. This analysis demonstrates the critical need for the kinetic and mechanistic studies of these reactions.

Figure 3 also shows the results of reduced pressure operation for other steam to CuCl₂ molar ratios. The amount of CuOCl₂ formed with a steam-to-Cu ratio of 11 is relatively low at <80% while the amount of CuCl was 4%. Thus a significant amount of CuCl remained, indicating insufficient mixing and/or residence time. Further optimization of the operating parameters is required.
Electrolysis Reaction

The ultimate test of the membrane development work is a demonstration of its performance in the electrolyzer. Early tests showed large increases in cell voltage within one hour of operation. Scanning electron microscopy showed copper deposits in the membrane or on the cathode. A recently completed electrolyzer test at AECL is shown in Figure 4. The two tests were run under identical conditions, 10.2 M HCl, 0.5 M CuCl and a Nafion® membrane. The reason for the differences in the results is under study. Nevertheless, these results are a significant improvement over the earlier tests as the cell voltage was stable for 72-96 hours and was near our target voltage of 0.7 V. The new membranes should provide longer duration cell performance since they have lower copper diffusivity.

Large-Laboratory Demonstration of Cycle

Collaborators at the University of Ontario Institute of Technology are planning an integrated demonstration of the Cu-Cl cycle. Large laboratory-scale reactors and ancillary equipment have been purchased and set up in a newly refurbished building. Cold testing is ongoing. As part of the collaboration, Argonne National Laboratory will study the decomposition of CuCl₂ and Cu₂OCl₂ and the hydrolysis of CuCl₂ as a function of time and temperature using synchrotron radiation. Kinetic data are needed to set operating conditions in these larger scale reactors and for further scale-up.

Conclusions

Several types of membranes have been prepared. These include Nafion® with low selectivity coatings, modified polysulfones, known as s-Radel, and a higher temperature version, known as EXSDAPP. Thus far, the diffusivities of the first two types have been measured. The results show that the new membranes are less permeable to Cu species than Nafion® and that the modifications have been successful. Based on these results further modifications are being made to further decrease the diffusivity of Cu species and to improve stability at elevated temperatures. Other characterization tests are ongoing. Electrolyzer tests will start as soon as the larger membranes required for the electrolyzers are prepared.

Operation of the hydrolysis reactor at reduced pressure provides an engineering method for reducing the steam demand. Further work is required to optimize conditions. The results of the present experiments indicated the need for measurement of the kinetics and mechanisms of the hydrolysis and the decomposition reactions of CuCl₂ and Cu₂OCl₂. Experiments to obtain these data are planned.

Future Directions

- Continue membrane development and testing that includes diffusivity measurements and characterization tests, i.e., ion exchange capacity, conductivity and water uptake.
- Change composition on the solute-rich side by adding CuCl to the CuCl₂ and HCl solutions.
- Modify the equipment for elevated temperature use and test the most promising membranes at 60-80°C.
- Investigate the use of other types of proton exchange membranes as needed.
• Continue testing of the most promising membranes in the electrolyzers at AECL and PSU and assess long-term chemical stability and durability.
• Continue the investigation of engineering methods to reduce copper crossover, including flow rates, anolyte and catholyte concentrations, temperature, etc.
• Continue synchrotron radiation experiments that monitor the nearest neighbors of Cu(II) species as a function of temperature and time to obtain mechanistic and kinetic information for CuCl₂ and Cu₂OCl₂ decomposition and CuCl₂ hydrolysis.
• Identify and test potential materials of construction.

Contract Number: DE-FG36-07GO17002

Subcontractors:
• University of Central Florida, Florida Solar Energy Center (FSEC), Cocoa, FL
• Electrosynthesis Co. (ESC), Inc., Lancaster, NY

Project Start Date: September 1, 2007
Project End Date: August 31, 2014

Objectives

• Demonstrate a cost-effective high-temperature water splitting cycle for hydrogen production using concentrated solar energy.

• Evaluate photocatalytic and electrolytic options for generating hydrogen that meet DOE’s solar high temperature H₂ production efficiency and cost goals.

• Confirm the feasibility of the selected cycle via bench-scale experiments.

• Determine the economic prospects of the selected cycle using the Aspen Plus™ chemical process model and H2A economic analysis program.

• Demonstrate a fully-integrated pilot-scale solar H₂ production unit.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1.4) of the

Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(U) High-Temperature Thermochemical Technology
(V) High-Temperature Robust Materials
(W) Concentrated Solar Energy Capital Cost
(X) Coupling Concentrated Solar Energy and Thermochemical Cycles

Technical Targets

Table 1 presents the progress made, to date, in achieving the DOE technical targets as outlined in the §3.1.4 Multi-Year Research, Development and Demonstration Plan – Planned Program Activities for 2005-2017 (updated Oct. 2007 version), Table 3.1.9: Solar-Driven, Thermo-chemical High-Temperature Thermochemical Hydrogen Production.

* Electrolytic/photocatalytic system projected costs based on revised H2A analysis.

² Based on SAIC glass-reinforced concrete structure with 10 sq.m. area and low production quantity.

³ Plant energy efficiency is defined as the energy of the hydrogen produced (lower heating value) divided by the sum of the energy delivered by the solar concentrator system plus any other net energy imports (electricity or heat) required for the process.

4 Electrolytic sulfur-ammonia (SA) thermochemical water-splitting cycle efficiency based on the most recent Aspen + flow sheet analysis.

Accomplishments

• Quantitative hydrogen production using an electrolytic cell with efficient sulfite oxidation was verified.

• The voltage of the electrolytic cell was reduced from 1.2 V to less than 1.0 V by increasing temperature/pressure, controlling pH and improving cell design.

• A short-term electrolytic cell test achieved 0.63 V at 186 mA/sq.cm using a proprietary new design/catalyst.
The basic feasibility of the all-(liquid/gas) K$_2$SO$_4$/K$_2$S$_2$O$_7$ chemistry for the high-temperature oxygen evolution sub-cycle using potassium sulfate has been demonstrated, but more lab testing is needed.

A mass balance on the oxygen evolution half cycle was performed using three sources of data; theoretical, thermogravimetric analysis (TGA) measurements and reactor experiments.

A preliminary economic analysis based on the previously fabricated half-scale prototype glass-reinforced concrete (GRC) heliostat indicates that the cost can be reduced from $126/m^2$ to $90/m^2$.

Using the Aspen Plus™ Process Design and Analysis model, trade-off studies were performed to optimize the overall plant configuration, e.g.:

- Electrical heating of the sulfur trioxide reactor was shown to be not cost-effective compared to direct solar heating.
- Electrical production from steam and ammonia in the process was shown to be sufficient to power the electrolytic process.
- Drying the aqueous ammonium sulfate material to solid form was shown to have little or no advantage over using it in aquaeous form.

Using the H2A economic model, the hydrogen production costs were determined to be $5.98/kg for the electrolytic SA cycle with K$_2$SO$_4$/K$_2$S$_2$O$_7$ sub-cycle.

Introduction

The source of hydrogen must be sustainable and the process to produce hydrogen must be efficient and thus cost-effective compared to conventional energy. The thermo-chemical production of hydrogen by splitting water with solar energy is a sustainable and renewable method of producing hydrogen. The process must be proven to be efficient and cost-effective. A limitation of most solar thermochemical cycles proposed for water splitting is that they do not take advantage of the unique characteristics of the solar resource. The spectrum of sun light contains ultraviolet and visible photons that are very energetic and able to trigger photocatalytic reactions. In the photocatalytic SA cycle, the photonic portion of the solar spectrum is used directly to accomplish the hydrogen evolution step of the cycle. This means that less energy is needed in the high-temperature oxygen production part of the cycle.

Many thermochemical water splitting cycles studied to date have difficult and/or costly product separation steps and materials handling and safety challenges. An example of the former is the Zn/ZnO mixture to prevent unwanted back-reaction to ZnO. An example of the latter is the Cd/CdO cycle that involves handling and processing of toxic cadmium metal at high temperatures. On the other hand, the sulfur-ammonia cycle has potential to circumvent these and other shortcomings of the legacy thermochemical water splitting cycles while meeting the DOE hydrogen production cost targets.

Approach

To achieve the project objectives, the Bowman-Westinghouse “sulfur-family”, hybrid thermochemical water splitting cycle (“Hybrid Sulfur, HyS” cycle) was selected and modified by introducing ammonia as the working reagent (thus sulfur-ammonia, or “SA,” cycle) to attain a more efficient solar interface and less problematic chemical separation steps. Several versions of the SA cycle were developed and evaluated experimentally, as well as analytically using the Aspen Plus™ chemical process simulator.

Two approaches were considered for the hydrogen production step of the SA cycle, namely: photocatalytic and electrolytic oxidation of ammonium sulfite to ammonium sulfate in an aqueous solution. Also, two sub-cycles have been considered for the oxygen evolution side of the SA cycle, namely: zinc sulfate/zinc oxide and potassium sulfate/potassium pyrosulfate sub-cycles. The laboratory testing and optimization of all the process steps for each version of the SA cycle were then carried out. Once the optimum configuration of the SA cycle has been identified and the cycle has been validated in closed-loop operation in the lab, it will be scaled up and tested on-sun.

Results

Cycle Evaluation and Analysis

In previous years, significant work was performed on the photo-catalytic SA cycle. During the past year, efforts have been redirected to the electrolytic SA cycle. The electrolytic SA cycle is summarized in the following equations:

1. $\text{SO}_2(g) + 2\text{NH}_4(g) + \text{H}_2\text{O} \rightarrow (\text{NH}_4)_2\text{SO}_3$ (1 – chem. absorption) 25°C
2. $(\text{NH}_4)_2\text{SO}_3 + \text{H}_2\text{O} \rightarrow (\text{NH}_4)_2\text{SO}_4 + \text{H}_2$ (2 – electrolytic) 80°C
3. $(\text{NH}_4)_2\text{SO}_4 + \text{K}_2\text{SO}_4 \rightarrow \text{K}_2\text{S}_2\text{O}_7 + 2\text{NH}_3 + \text{H}_2\text{O}$ (5 – solar thermal) 400°C
4. $\text{K}_2\text{S}_2\text{O}_7 \rightarrow \text{K}_2\text{SO}_4 + \text{SO}_2$ (6 – solar thermal) 550°C
5. $\text{SO}_2 + \frac{1}{2} \text{O}_2$ (7 – solar thermal) 850°C

An example of the latter is the Cd/CdO cycle that involves handling and processing of toxic cadmium metal at high temperatures. On the other hand, the sulfur-ammonia cycle has potential to circumvent these and other shortcomings of the legacy thermochemical water splitting cycles while meeting the DOE hydrogen production cost targets.
The electrolytic oxidation of the ammonium sulfite solution occurs above ambient temperature at reasonably low pressures. Reactions (3) and (4) form a sub-cycle by which potassium sulfate is reacted with ammonium sulfate in the low-temperature reactor, to form potassium thiocyanate. That is then fed to the medium-temperature reactor where it is decomposed to SO₂ and K₂SO₄ again, closing the sub-cycle. The potassium sulfate and thiocyanate form a miscible liquid melt that facilitates the separations and the movement of the chemicals in reactions (3) and (4). The oxygen production step (5) occurs at high temperature over a catalyst. Separation of the oxygen from SO₂ occurs when they are mixed with water in reaction (1). The net cycle reaction represented by reactions 1-5 is decomposition of water to form hydrogen and oxygen. All of the reaction steps described above have been demonstrated in the laboratory and shown to occur without undesirable side reactions. Figure 1 depicts the high-temperature reactions in a pictorial fashion.

Electro-Oxidation of Aqueous Ammonium Sulfite Solutions

Optimization of the electrolytic process continued at both ESC and FSEC. FSEC developed a proprietary catalyst and briefly demonstrated a divided cell at 0.63 V and 186 mA/cm². In a further development, an electrolytic cell with no Naftion® separator was also run. ESC tested operation of cells at elevated temperature and showed that the voltage could be reduced below 1.0 V in a conventional electrolytic cell by operating at elevated pressure and temperature. Figure 2 shows results of electrolysis runs at elevated temperatures.

High-Temperature Cycle Step Evaluation

Evaluation of the all-liquid/gas high-temperature cycle steps continued. As shown in Figure 3, TGA experiments were conducted to show the evolution of ammonia and water vapor, followed by evolution of sulfur trioxide at a higher temperature. A potential difficulty is the small temperature differences between these evolutions, which may make separation of the products more difficult. A mass balance was also successfully conducted to check that the experimental results matched the analytical predictions, as shown in Figure 4.

Solar Field Optimization

The solar field configuration continued to be updated as the thermochemical system evolved. The primary present activity is to incorporate the all-liquid K₂SO₄/K₂S₂O₇ system. A two-receiver heliostat field design has been created to separate the low-temperature and high-temperature receivers. For the highest temperature oxygen evolution process, consideration is being given to using dish concentrators in addition to the heliostat field for the other thermal processes. Control optimization to best use the variable solar resource was also performed.

Heliostat Cost Reduction

The half-scale prototype glass-reinforced concrete heliostat was successfully tested and evaluated, and design features to be carried over to a full-scale unit were identified. The cost of heliostats in low production was updated, with the results shown in Table 2. The estimated production cost is less than $100/m², a reduction of over 25% from present-day heliostat costs.

Economic Analysis

The H2A economic model for the photocatalytic SA process with separate heliostat and photoreactor fields was updated. The resulting cost for hydrogen was found to be $5.05/kg, but the system solar efficiency was only 5.2% due to the large land area needed. The cost analysis of the electrolytic SA cycle was completed, with a resulting cost of $5.98/kg and an overall system efficiency of 19.3%. The H2A results are summarized in Table 3.
The H2A cost analysis program was also used along with Aspen Plus™ calculations to perform trade-off analyses on different configurations and process designs. In particular, the following trade-off analyses were performed:

- Using solar thermal vs. electricity to heat the reactor for the 900°C reaction to reduce SO₃ to SO₂ and O₂. It was determined that the solar thermal heat would provide higher efficiency.
- Reducing the aqueous ammonium sulfate to solid form before feeding to the low-temperature reactors. Drying the ammonium sulfate led to a lower system capital cost, but required more purchase of electricity from the grid. The cost of hydrogen was practically the same for both approaches ($6.21 vs. $5.98).

### Conclusions and Future Directions

In summary:

- Significant progress was made in reducing the cell voltage and increasing the current density of the electrolytic cell.
- Initial evaluation of the all-liquid/gas high-temperature oxygen generation cycle steps appears to prove the subcycle feasibility.

- GRC continues to show promise to reduce heliostat cost substantially.
- Based on the work performed to date, it appears that the electrolytic SA cycle has the potential to meet DOE’s near- and long-term H₂ production cost and efficiency goals.

Activities planned for the upcoming year include:

- Perform a thermodynamic analysis of the overall SA cycle to recheck earlier results, provide data to verify the cycle performance and ascertain if previous work by others may preclude the need to perform certain tasks. The complete SA cycle will be modeled using Aspen Plus™ to verify that the cycle can be closed and provide data to document the chemical plant analysis.
- Completion of optimization of the electrolytic process and cell. This will include identification of catalysts that will reduce the over-potential at the anode and allow operation at high current densities, and determining approaches to recombine anolyte and catholyte streams to control and maintain fixed pH.
- Complete evaluation of the K₂SO₄ oxygen subcycle reactions, including reaction kinetics.
- Finalization of the thermal reactor/receiver designs including materials specification and testing.
- Finalization of the solar field configuration and design to match the final chemical plant requirements.
- Continue to update H2A economic analyses to document the potential cost of hydrogen from the SA cycle.

After completion of phase 1, the next phase of the project will involve laboratory validation of the closed-loop SA cycle leading to on-sun hydrogen production demonstration.

II.F.3 Solar-Thermal Atomic Layer Deposition Ferrite-Based Water Splitting Cycles

Objectives

- Use H2A analysis to provide guidance for conceptual process design that is cost-effective.
- Conceptualize a scalable central solar reactor/receiver per H2A guidance on economics.
- Develop/demonstrate suitable materials for robust redox/thermochemical cycling.
- Develop an overall plan to take the technology to the point of demonstration in five years.

Technical Targets

The technical targets for solar-driven thermochemical conversion are summarized in Table 1. The projected thermal efficiency for the developed process is 54.6% based on lower heating value (LHV), thus exceeding the >35% requirement for the 2025 case. For a solar-to-receiver annual average efficiency of 40.2%, the overall solar-to-H₂ efficiency is estimated at 21.9% (LHV). Furthermore, the $6/kg H₂ plant gate cost for the Central 100,000 kg H₂/day facility 2015 case should be easily achieved for the $126.50/m² installed heliostat cost. The $3/kg H₂ plant gate cost for 2025 for a $90/m² installed heliostat field may be achievable (details below).

TABLE 1. Progress towards Meeting Technical Targets for Solar-Driven High-Temperature Thermochemical Hydrogen Production

gge – gasoline gallon equivalent

Accomplishments

- Discovered that a ferrite/alumina-based materials system provides for a hercynite intermediate that can be thermally reduced between 1,200 and 1,450°C without high temperature sintering/deactivation issues.
- Demonstrated that <5 nm thin ferrite films can be synthesized by atomic layer deposition (ALD) and provide for significant opportunities to reduce diffusional resistances and promote radiation-driven heat transfer; both potentially providing for rapid redox cycling.
- Designed a multi-tube absorbing fixed-bed cavity reactor/receiver that provides for efficient internal heat recuperation and the potential for rapid cycling; mitigates erosion and complications associated with transporting solids.
- Carried out process design/economic evaluation indicating that ALD of ferrite materials on 100 m²/g supports cycling every 5 minutes will meet the DOE cost targets in 2015 and most likely in 2025 as well.
Developed a 5-year plan to develop materials, build a prototype device for testing and design a demonstration facility.

Introduction

The direct thermolysis to split water (H₂O → H₂ + 1/2O₂) requires materials operating at T > 3,500°C and methods to separate the H₂ and O₂ gases at high temperature [1]. This seemingly impossible task can be overcome by implementing a two-step thermochemical water splitting cycle in which a ferrite spinel material (MFe₂O₄; M=Co, Ni) can be thermally reduced using concentrated sunlight to release O₂ and the reduced ferrite then subsequently oxidized (redox cycle) with steam producing H₂ [2-4], recovering the original spinel structure in the process. It has recently been demonstrated at the University of Colorado that thin film cobalt ferrites can be deposited by ALD onto high surface area alumina (Al₂O₃) supports and that a redox cycle through a hercynite (FeAl₂O₄) pathway (Reduction: MFe₂O₄ + 3Al₂O₃ + solar energy → MAl₂O₄ + 2FeAl₂O₄ + 0.5 O₂; Oxidation: MAl₂O₄ + 2FeAl₂O₄ + H₂O → MFe₂O₄ + 3Al₂O₃ + H₂) can be cycled repeatedly and at lower temperatures than the conventional ferrite materials [5].

Approach

The primary scientific barrier to successful implementation of a solar-thermal water splitting process is access to a robust active material for efficiently and rapidly carrying out redox cycles producing H₂. Further, the key engineering barrier to successful implementation is demonstration of a large-scale solar reactor concept that allows for rapid redox cycling taking advantage of highly active thin film materials while providing for highly efficient usage of delivered solar energy. The key scientific challenges to successfully overcoming the primary scientific barrier are:

1. Identify/synthesize high surface area active materials with favorable transport properties.
2. Identify/demonstrate suitable interfacial substrate materials to facilitate rapid redox cycling.
3. Combine the active/substrate materials into a characteristic volume sample and demonstrate robust cycling to split water, particularly if able to operate the reduction in air.

High surface area active ferrite materials (MFe₃₋ₓO₄; M=Co, Ni) were synthesized using ALD to deposit nanometer thick films onto nanosized particles [6-9]. Nanoparticle substrates were placed in fluidized bed reactors and coated (Figure 1) with Fe₂O₃, CoO, and NiO thin films using self-limiting surface chemistry.

![Ultra-thin Films (2 to 10 nm)](image)

**FIGURE 1.** Thin Film Deposition of Ferrite Materials
vi metalloocene \([\text{C}_5\text{H}_5\text{M}; \text{M} = \text{Fe}, \text{Co}, \text{Ni}]\) and \(\text{O}_2\) precursors. The approach recommended is to design the nm thick ferrite films and to deposit them on high surface area (100 \(\text{m}^2/\text{g}\)) support materials.

**Results**

Unlike the conventional cobalt ferrite process that requires \(T > 1,200^\circ\text{C}\) to release \(\text{O}_2\) and is then plagued by a deactivating liquid solution “slag” phase at \(-1,525^\circ\text{C}\), the “spinel/hercynite” cycle requires reduction temperatures of only \(T > 900^\circ\text{C}\) and does not have a “slag” phase present for \(T < 1,600^\circ\text{C}\). Furthermore, nano-thick \(\text{MFe}_2\text{O}_4\) films deposited by ALD mitigate both the typical M/steam diffusional resistances and the slow conduction heat transfer that plague bulk ferrite materials. Instead, the ALD thin films provide for an opportunity to drive the redox cycle quickly using fast solar radiation heat transfer and fast mass transfer. As shown in Figure 2, the thin film “spinel/hercynite” cycle can produce significant quantities of \(\text{H}_2\) for reduction temperatures as low as \(1,200^\circ\text{C}\), while the conventional ferrite cycle requires a reduction temperature of at least \(1,450^\circ\text{C}\) (within \(75^\circ\text{C}\) of the “slag” liquid solution phase) in order to produce sufficient \(\text{H}_2\). Likewise, oxidation can be carried out for \(T > 1,200^\circ\text{C}\), providing an opportunity to drive a thermochemical cycle in which redox \(\Delta T < 300^\circ\text{C}\), thus, simplifying the recuperation of heat during redox steps. These phenomena are predicted by free energy minimization thermodynamics calculations as well [5].

A conceptualized prototype thermochemical redox receiver/reactor is shown in Figure 3. The reactor consists of a cavity-receiver, i.e. a well-insulated enclosure with a small opening – the aperture – for the access of concentrated solar radiation. Because of multiple inner reflections, the cavity-receiver is able to capture efficiently incoming concentrated solar energy. To some extent, the aperture size may be reduced with the help of non-imaging secondary concentrators, e.g. compound parabolic concentrators, placed at the receiver’s aperture in tandem with the primary concentrating system.

The cavity-receiver will contain an even number of closed-end SiC tubes. Each tube will contain a second open end SiC tube with a porous SiC plug at the base. Active high surface area and porous ferrite material, \(\text{M}_x\text{Fe}_{3-x}\text{O}_4\) in the form of catalyst honeycomb support, foams, reticulate material, etc. for the redox reactions will be packed in the annular region between the two tubes to allow for efficient heat and mass transfer and, consequently, fast overall kinetics. The active material will be deposited on a high surface area supporting alumina (\(\text{Al}_2\text{O}_3\)) substrate material in which the substrate takes part in the redox reaction (e.g. \(\text{FeAl}_2\text{O}_4\), hercynite).

![Graph](image-url)

**FIGURE 2.** “Hercynite” Cycle Compared to Standard Ferrite Cycle Performance – Theory and Experiment
The inner tube will be packed with media providing surface area for improved heat transfer to drive the vaporization of water to steam.

The redox cycle will be effected at temperatures T_R for the reduction step and T_O for the oxidation step (T_R > T_O). At a given instant, half of the tubes will be operated in the reduction mode at T_R while the remaining half will be operated in the oxidation mode at T_O. When the reactions reach completion, the operational modes will be switched. The temperatures T_R and T_O will be controlled by the endothermicity of the reaction during the reduction step and by the flow of H_2O during the oxidation step, respectively. Arrangement of the tubes inside of the cavityreceiver is a key aspect and will be such that they are arranged symmetrically in such a manner as to achieve the desired temperatures (T_R or T_O) under thermal equilibrium. Concentrated solar radiation entering the cavityreceiver and radiation emitted by the hot tubes undergoes absorption and multiple reflections. The net thermal energy absorbed by the tubes is transferred to the reaction site by combined conduction, convection, and radiation heat transfer. With such an arrangement, the sensible heat of the solids components during the switching of modes is transferred among tubes and kept inside the cavity, achieving high internal recuperation of heat. The sensible heat of the hot gaseous streams exiting the cavityreceiver will be recovered via heat exchangers and used to generate steam and preheat the cold gaseous streams to the operating temperatures.

Process/heliostat field design considerations coupled with H2A analysis indicated that 100,000 kg H_2/yr can be produced using five towers (250 m tall each) on a total of 237 acres of land. Each receiver provides for 250 MWthermal power. A net solar concentration of 4,000 suns is delivered to the receiver with a 40.2% annual average efficiency. This combined with the 54.6% LHV thermal efficiency provides for an overall solar-to-H_2 efficiency of 21.9%. A total of 2,376 GWhr annually drives the process. In order to achieve the 2015 H2A cost target of $6/kg H_2, ferrite must be produced for <$2,600/kg (Figure 4).
To achieve the 2025 cost target of $3/kg H\textsubscript{2}, ferrite must be produced for <$571/kg. Since the current cost of ALD precursors is $240/kg ferrite, cost targets appear reasonable, although 2025 is somewhat of a stretch. This design calls for redox cycling averaging 144 cycles/day.

**Conclusions and Future Directions**

- ALD films are advantageous in terms of fast redox cycling.
- The “hercynite” cycle operates in the solar thermal sweet spot of 1,200 to 1,450°C where fast radiation heat transfer dominates, but where containment issues are mitigated; forgiving chemistry with no sintering/deactivating liquid solution phase.
- Future work should demonstrate redox cycling over thousands of cycles in order to validate materials robustness.

II.G.1 Photoelectrochemical Hydrogen Production: DOE PEC Working Group Overview

Objectives

The DOE photoelectrochemical (PEC) Hydrogen Production Working Group’s primary objective is to collaboratively develop practical solar hydrogen-production technology, using innovative semiconductor materials and devices research and development (R&D) to foster the needed scientific breakthroughs for meeting DOE Hydrogen Program goals.

Technical Barriers

The DOE PEC Working Group is working to address all of the technical barriers identified in the “Photoelectrochemical Hydrogen Production” section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration (RD&D) Plan:

(Y) Materials Efficiency
(Z) Materials Durability
(AA) PEC Device and System Auxiliary Material
(AB) Bulk Materials Synthesis
(AC) Device Configuration Designs
(AD) Systems Design and Evaluation
(AE) Diurnal Operation Limitations

Technical Targets

As recognized within the PEC hydrogen research community and the DOE PEC Hydrogen sub-program, the technology is still far from maturity, and the most critical technical issues relate to the development of suitable photoactive semiconductors for water-splitting. This is reflected in Table 1, a reprint of the DOE Targets for PEC Hydrogen Production from the DOE’s Multi-Year RD&D Plan [1].

The DOE PEC Working Group utilizes its collective expertise in theoretical materials modeling, synthesis, characterization and analysis to study a diverse portfolio of promising PEC thin-film materials classes with the potential for meeting the technical targets.

Accomplishments

Important milestones have been achieved this past year through the collaborative efforts of the DOE PEC Working Group, and the associated DOE-funded projects. Significant progress has continued in the development of the Working Group’s “Tool Chest” of materials theory, synthesis, characterization and analysis techniques; and this enhanced “Tool Chest” has been

instrumental in the development and optimization of important PEC materials classes. In nano-structured molybdenum disulfide photocatalyst materials systems, for example, band-gaps up to 1.8 eV have been demonstrated for the first time, with important implications for efficient PEC production. Progress has also continued in other PEC materials classes falling within the DOE-defined “useable” band-gap range. Important new results have been achieved in tungsten-trioxide, iron-oxide, silicon-carbide, copper-chalcoprites, and the III-V materials classes, among others. DOE PEC Working Group efforts are ongoing to render these potentially “useable” materials for high-efficiency PEC hydrogen production. General accomplishments of the PEC Working Group, detailed further in following sections, can be summarized broadly as follows:

- Successful development and application of new PEC “Tool Chest” capabilities.
- Advances in PEC Focus Materials Classes toward meeting DOE-PEC performance targets.
- Further expansion of collaborative research efforts.

Introduction

PEC hydrogen production, the splitting of water into hydrogen and oxygen using sunlight, is an important enabling technology for future energy economies which will rely, in part, on hydrogen as an energy currency [2]. The traditional semiconductor-based PEC material systems studied to date, however, have been unable to meet all the performance, durability and cost requirements for practical hydrogen production. PEC semiconductors such as titanium-dioxide and other metal-oxides, for example, have proven to be stable in aqueous solutions, but suffer from low solar conversion performance due to their high band-gaps [3]. Based on these inherent limitations, it has become increasingly clear that new, more advanced materials need to be developed. Technology enabling breakthroughs in materials R&D are needed for the success of PEC hydrogen production.

Toward this end, the U.S. DOE currently funds a number of research institutions from the academic, industrial and national laboratory sectors with the objective of discovering, engineering and optimizing such advanced PEC materials systems for solar water-splitting. To facilitate progress, the project participants, have formed a national Working Group on PEC hydrogen production, bringing together experts in analysis, theory, synthesis and characterization from the academic, industry and national laboratory research sectors. The 2010 DOE Hydrogen Program Annual Merit Review held in Washington D.C. featured numerous presentations from participating PEC Working Group institutions, as illustrated in Figure 1. An overview of the collective approach and past-year’s progress is presented in the following sections.

Approach

The general approach of the collaborative effort among the DOE PEC Working Group researchers is to integrate state-of-the-art theoretical, synthesis and analytical techniques to identify and develop the most promising materials classes to meet the PEC

FIGURE 1. PEC Working Group Members with current DOE financial support, including the 2010 DOE Hydrogen Program Annual Merit Review oral/poster presentation designations.
challenges in efficiency, stability and cost. From the application of density-functional theory (to calculate band-structures and effects of co-incorporants on valence and conduction band positions) through the use of diverse synthesis techniques (including combinatorial methods, to create tailored materials); and by employing microstructural, electron spectroscopic, and electrochemical characterization techniques, a comprehensive picture of the materials properties and resulting performance is being developed. Within the DOE PEC Working Group, the approach has been applied to a number of “focus materials” deemed of particular interest for PEC applications.

PEC Hydrogen Production has already been successfully demonstrated on the laboratory scale. High solar-to-hydrogen (STH) efficiencies, between 12-16%, have been demonstrated for limited durations in devices based on expensive high-quality crystalline semiconductors, such as the III-V tandem GaAs/GaInP₂ cell [4]. In addition, lower STH efficiencies, in the 3-5% range have been demonstrated in devices based on lower priced thin-film semiconductor materials. Multi-junction devices, for example using WO₃ films as a PEC top-junction, have been reported in this performance category [5]. To achieve practical PEC hydrogen production, new semiconductor materials systems with both high performance and low cost are needed. One specific approach is the further development of the traditional PEC semiconductor thin-films and nano-structures for higher efficiencies. Examples include improvements to iron-oxide and tungsten trioxide. Another approach is the adaptation of efficient photovoltaic semiconductor thin-films and nano-structures for effective use in PEC. This includes, for example, copper chalcopyrites and amorphous silicon compounds.

Other innovative approaches include the development of entirely new materials classes, such as quantum-confined WS₂ and MoS₂ nanoparticle systems, and the development of breakthrough synthesis technologies to reduce the cost of high-performance crystalline semiconductors, such as GaAs/GaInP₂. Future progress in all these approaches is integrally tied to the DOE PEC Working Group’s continued development and deployment of its tool-chest capabilities, and continual feedback among the theory, synthesis and characterization efforts.

Results

To expedite technical progress, the DOE PEC Working Group has initiated Task Forces to coordinate important PEC research activities. While some of the collaborative task forces center on the R&D of specific PEC materials classes, others focus on critical activities to advance the supporting science and technologies in the PEC tool chest. Important activities in the latter category have resulted in significant progress, including:

- Significant Progress in Establishing PEC Testing Standards [6,7]
  - First revision drafts of 16 protocol documents completed.
  - Web site set up to facilitate international review/revision process.

- Important Advances in PEC Characterizations [8,9]: Project PD051
  - Ultraviolet/soft X-ray/electron spectroscopic tools for evaluating optoelectronic and chemical properties of PEC materials' surfaces, near-surfaces and bulk fully operational.
  - “Solid And Liquid Spectroscopic Analysis” characterization facility installed at the Lawrence Berkeley National Laboratory Beamline 8.0 Advanced Light Source for the in situ evaluation of PEC semiconductor/electrolyte interfaces (as illustrated in Figure 2).

- New Advances in PEC Materials Theory [10,11,12]: Projects PD052, PD058
  - First principle models of the PEC interface constructed based on III-V semiconductors, exploring effects of O, H and OH termination (as illustrated in Figure 3a).
Important correlations between surface morphology and interaction with interfacial water molecules established.

Theoretical band structures of new PEC materials classes investigated (as illustrated in Figure 3b).

- First Phase of PEC Hydrogen Production Techno-economic Analyses Completed [13]
- Incorporating performance and processing cost feedback from the broader materials R&D efforts, coordinated through Directed Technologies, Incorporated.
- Sensitivity analyses indicating hydrogen production costs as low as $1.86/kg hydrogen for some PEC systems configurations based on available plant technologies, and using projected high-performance PEC semiconductor materials.

Continued feedback between the theory, synthesis, characterization and analysis among PEC Working Group participants is providing fundamental insights needed to promote technical breakthroughs in a broad spectrum of promising PEC materials classes. The Working Group serves to organize, focus, and track scientific research progress in PEC R&D. This approach over the past year has resulted in important progress toward DOE PEC Materials & Device Targets. Examples include:

- Successful first-time demonstration of bandgap tailoring in photoactive MoS2 nanoparticles at Stanford University [14,15]: Project PD033
  - Nanoparticle sizes ranging from 25 down to 5 nm have exhibited band-gaps ranging from 1.0–1.8 eV (as shown in Figure 4a).
  - Initial exploration of photocatalyst nanorods, in collaboration with University of Louisville (as shown in Figure 4b).

- Identification of thin-film device configurations based on current chalcopyrite and silicon compound materials at MVSSystems Incorporated and the University of Hawaii with potential for meeting DOE Performance Targets [16,17]: Projects PD053, PD055
  - Identified complex multi-junction device having >5% STH using current copper gallium diselenide materials.
  - PEC interfacial barrier identified as limit to >10% STH tandem.
  - New theory and characterization tools to be used to address the interface barrier problem for meeting DOE performance targets.

- Identification of crystalline semiconductor device configurations based on current III-V materials with >15% STH conversion efficiency at the National Renewable Energy Laboratory [18]: Project PD035

In addition, notable progress also has continued over the range of PEC materials classes under investigation by the PEC Working Group, including progress in:

- Tungsten-oxide and related modified compounds [19-21]: Project PD054
- Iron-oxide and related modified compounds [22,23]: Project PD034
- Amorphous silicon-carbide based photoelectrodes [24,25]: Project PD053
- Copper indium gallium diselenide based photoelectrode systems [26,27]: Project PD055
Conclusions and Future Directions

The DOE’s Working Group on PEC Hydrogen Production has taken a collaborative approach in the R&D of novel PEC material systems. This approach, incorporating a broad spectrum of state-of-the-art techniques in theory, synthesis, characterization and analysis, is proving invaluable in the identification and development of the most promising materials for practical PEC hydrogen production. Continued Working Group efforts in conjunction with expanded international collaborations are expected to greatly facilitate the discovery and optimization of material systems and devices capable of meeting the DOE PEC hydrogen production targets. Specific future directions include:

• Continued Advancement of DOE PEC Working Group Efforts
  – Further PEC “Tool Chest” development efforts.
  – Standardization of materials and device testing protocols.
  – Further discovery and optimization of viable PEC semiconductor materials.
  – Integration of best available PEC materials into optimal device and system configurations.

• Continued Expansion of Collaboration Efforts: Nationally and Internationally
  – DOE PEC Working Group expansion.

The ultimate aim is to make the materials and device advances necessary for high-efficiency, low-cost PEC hydrogen production.

Special Recognitions & Awards/Patents Issued

Publications/Presentations

II.G.2 Nanostructured MoS₂ and WS₂ for the Solar Production of Hydrogen

Objectives

Develop novel nanostructured dichalcogenide materials for photoelectrochemical (PEC) production of hydrogen from water

- Synthesize nanometer scaled MoS₂ and WS₂ as (1) nanoparticles, (2) nanowires, and (3) a three-dimensional double-gyroid network.
- Explore and optimize bandgap and bandedge position as a function of size and architecture for water splitting.
- Study photo-generated charge separation and transport in nanostructured materials.
- Investigate catalytic ability for water splitting as a function of surface structure.
- Incorporate optimized nanostructures into a PEC device and determine efficiency and durability.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration (RD&D) Plan:

(Y) Materials Efficiency
(Z) Materials Durability
(AB) Bulk Materials Synthesis
(AC) Device Configuration Designs

Technical Targets

The focus of this project is the development of semiconductor materials with strong solar absorption characteristics that efficiently store energy from the sun by splitting water into hydrogen and oxygen. If successful, this project will address the following DOE technical targets as outlined in the FCT Multi-Year RD&D Plan:

Accomplishments

- Achieved low temperature (150°C) sulfidization of molybdenum/MoO₃ to produce MoS₂.
- Synthesized tungsten nanoparticles and air-stable nanoscaled MoS₂ nanoparticles in various sizes ranging from 5-25 nm.
- Achieved quantum confinement of MoS₂ nanoparticles with indirect bandgaps up to 1.8 eV.
- Electrochemical testing of the MoS₂ nanoparticles supported on fluorine-doped tin oxide revealed activity for the hydrogen evolution reaction with Tafel slopes of ~200 mV/decade.
- Developed a macroporous indium tin oxide support to allow vertical integration of nanoparticles for increased absorption.
- Synthesized quantum confined nanowebs of MoS₂ with bandgaps up to 1.6 eV.
- Synthesized Nb doped MoS₂ films that produced cathodic photocurrent.
- Produced highly stable nanoscaled double-gyroid RuO₂ counter electrodes for efficient oxygen evolution with over 19 times the exchange current density of a comparable thin film.
- Developed nanoscaled alumina templates for nanowire synthesis with mean pore diameter of 15 nm.
• Investigated sulfidization of MoO$_3$ nanowires up to 700°C without significant sintering in collaboration with Prof. Mahendra Sunkara at the University of Louisville, Kentucky.

Introduction

PEC water splitting for hydrogen production was first demonstrated by Fujishima and Honda in 1972 using titanium dioxide (TiO$_2$) [1], a material limited to a maximum solar-to-hydrogen efficiency of ~1% due to its large bandgap of 3.0 eV. Since the maximum solar-to-hydrogen efficiency of a material is ultimately determined by its ability to absorb light, research efforts have primarily focused on improving solar absorption characteristics, including the use of semiconductor doping/alloying [2-6], tandem absorbers [7,8], and dye sensitization [9,10]. However, the best absorbers to date are often hindered by other issues such as poor charge transport [11], slow kinetics for the hydrogen evolution reaction or oxygen evolution reaction [12], and/or poor stability [13,14]. Thus, no material system exists that can yet be considered as a wide-scale deployable solution. The world record PEC device with 12.4% solar-to-hydrogen efficiency was developed by Khaselev and Turner in 1998 [14], but it exhibited significant material instability and extremely high cost [15,16]. New approaches are necessary to accelerate the development of highly efficient, durable, and low-cost materials for PEC water splitting.

Approach

The project discussed here aims to improve upon previous material deficiencies through the nanostructuring of low-cost semiconductor materials—in particular, molybdenum disulfide (MoS$_2$) and tungsten disulfide (WS$_2$). Both materials exhibit a bandgap of ~1.2 eV [17-20], which enables absorption of a significant portion of the solar spectrum. However, this value is too small to provide the photovoltage necessary to split water, which requires a minimum thermodynamic potential of 1.23 eV in addition to the overpotentials required to drive the kinetics of the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER). The minimum bandgap value will likely lie in the range of ~1.8-2.0 eV [21]. Nanostructuring materials can result in an effect known as quantum confinement [20,22,23], which enables widening of the bandgap to a larger, more useable value for water splitting in the case of MoS$_2$ and WS$_2$. In addition, edge sites at the surface of MoS$_2$, which are more prominent when nanostructured, have been documented as centers of high catalytic activity for the HER [24]. This translates into a smaller required bandgap and higher theoretical efficiency.

Furthermore, controlling the material conductivity has important consequences on its PEC properties. By focusing on the development of MoS$_2$ and WS$_2$ as photocathodes (rather than photoanodes), the possibility of photo-oxidizing the sulfide is minimized and stability can be improved since photogenerated electrons drive the HER at the semiconductor-electrolyte interface while oxidizing holes flow to the counterelectrode to drive the OER [25-29]. One approach to develop a material that exhibits photocathodic behavior with minimum input bias is to increase its work function by the addition of dopants. In the case of MoS$_2$, doping with niobium can produce a p-type semiconductor [30] that is more likely to behave as a photocathode. Consequently, a photocathode that drives the HER requires a counterelectrode that efficiently drives the OER. Ruthenium dioxide (RuO$_2$) is a material known to exhibit high conductivity, chemical and thermal stability [31-35] and catalytic activity for the OER [34-36]. By nanostructuring RuO$_2$ in a double-gyroid geometry [37] it is possible to improve its catalytic ability even further [38].

Results

Our efforts within the project have focused on the development of MoS$_2$, since it represents a material with a rich history of catalysis and photoactivity [23,39-41]. We achieved the sulfidization of molybdenum in our laboratory using temperatures as low as 150°C, confirmed using ultraviolet-visible transmission (UV-Vis) spectroscopy and X-ray photoelectron spectroscopy (XPS).

Synthesis of supported MoS$_2$ nanoparticles in various sizes was accomplished using a reverse micelle encapsulation method [42-44]. The low temperature sulfidization process minimized nanoparticle sintering. The nanoparticles were imaged using atomic force microscopy as shown in Figure 1. Scanning electron microscopy (SEM) revealed size distributions ranging from 5-25 nm. Despite their small size, these nanoparticles are resistant to oxidation from exposure to air, as confirmed using XPS shown in Figure 2. The same reverse micelle encapsulation method was used to synthesize tungsten nanoparticles, which are currently under further development.

UV-Vis spectroscopy of the MoS$_2$ nanoparticles revealed a blue-shift in their absorption onset. Furthermore, the degree of blue-shifting increased with smaller nanoparticle size. This behavior is expected and is characteristic of the quantum confinement phenomenon. Tauc plots of the indirect bandgaps are shown in Figure 3.
During attempts to synthesize MoS$_2$ nanoparticles, we found that using a highly hydrophilic precursor (MoCl$_3$ instead of Mo(OCOCH$_3$)$_2$) could disrupt the micelle network and form an interconnected web morphology. These nanowebs still exhibited a quantum confined blueshift in the absorption onset up to 1.6 eV, slightly less than the blueshift seen with nanoparticles. One reason for this may be because of a greater degree of electron delocalization in the interconnected structures.

In order to obtain measurable photocurrent from the MoS$_2$ nanoparticles, they must first be supported in a structure that allows them to absorb a significant number of photons. This is difficult to achieve with a sub-monolayer of nanoparticles supported on a planar surface due to the short absorption path length. One approach is to develop a macroporous transparent conducting oxide which enables the vertical integration of nanoparticles to increase absorption path length without sacrificing absorption or limiting the diffusion of reactants and products to the active sites. Using this approach, we synthesized a macroporous indium tin oxide support structure, and are currently optimizing its conductivity.

While MoS$_2$ crystals in nature can be found to intrinsically have either n-type or p-type conductivity, leading them towards photoanodic or photocathodic behavior, we synthesized a p-type photocathodic MoS$_2$ by doping with Nb. Activity was assessed using photocurrent measurements under a negative applied bias in a PEC cell. The observed photocurrent was cathodic and increased with greater negative applied bias.

As part of the effort to develop photocathodes of sulfides, it is necessary to produce counter-electrodes that efficiently drive the oxygen evolution reaction. Using an electrochemical deposition technique followed by a heat treatment, we produced RuO$_2$ films that exhibit a 320 mV earlier onset for oxygen evolution compared to Pt. The films demonstrated strong stability over 100 cycles of oxygen evolution, even when subjected to a +2 V bias vs. the Ag/AgCl reference electrode in a highly acidic 0.1 M H$_2$SO$_4$ solution. To develop even more active RuO$_2$, we used a silica template made with a poly(ethylene oxide)-poly(propylene oxide)-alkane tri-...
block copolymer surfactant [37,45,46] to form a double-gyroid RuO$_2$ structure. In comparison to the thin film of RuO$_2$, which produced an exchange current density of $3.67 \times 10^{-9}$ A/cm$^2$ for the OER, the double-gyroid RuO$_2$ structure produced an exchange current density of $7.11 \times 10^{-8}$ A/cm$^2$, over 19 times greater than the thin film.

To synthesize nanowires, we have focused on the development of anodic alumina templates [47-51]. Using this technique, we have synthesized templates with 13 nm pores, as imaged by SEM, and are continuing to optimize the synthesis towards even smaller pore sizes. We are also working to synthesize double-gyroid MoS$_2$ structures using the same silica template developed for the double-gyroid RuO$_2$. We plan to fill the templates and develop the inverse Mo and W structures using an electrodeposition technique optimized in our laboratory.

We are also working in close collaboration with Mahendra Sunkara, Professor of Chemical Engineering at the University of Louisville, Kentucky. Using a hot-wire chemical vapor deposition technique, Sunkara has successfully formed vertical nanowires of MoO$_3$. We convert the nanowires to MoS$_2$ using our sulfidization furnace and study their physical and PEC properties as a function of sulfidization temperature. Once sulfidized, the nanowires change in color from transparent blue to an extremely opaque black with imperceptible amounts of reflection and transmission, indicating very high levels of photon absorption, as confirmed by UV-Vis. SEM reveals that our sulfidization process results in minimal sintering of the nanowires, even up to 700°C. Transmission electron microscopy shows the formation of polycrystalline layers of MoS$_2$, which is further confirmed by X-ray diffraction. We are continuing to work on the development of substrates that can withstand the effects of higher sulfidization temperatures, yet retain the necessary conductivity and electrochemical inertness for PEC testing.

**Conclusions and Future Directions**

We have made significant progress in developing nanostructured MoS$_2$ for PEC water splitting, with the most significant results being summarized as follows:

- Synthesized air stable MoS$_2$ nanoparticles in various sizes that exhibit a size-dependent quantum confinement up to 1.8 eV.
- Developed a highly porous nano-scale double-gyroid structure of RuO$_2$ with very high activity for the OER.
- Synthesized air stable MoS$_2$ nanowires in collaboration with the University of Louisville that show extremely high photon absorption.

Our work on this project continues with the development of substrates that will enable PEC testing of nanostructured MoS$_2$. In order to achieve this goal, we will:

- Optimize the conductivity and transmissivity of the indium tin oxide macroporous network upon which we will support quantum confined MoS$_2$ nanoparticles. This will allow vertical stacking of the nanoparticles for improved photon absorption, while retaining the required conductivity for the photogenerated electrons and holes.
- Investigate the use of molybdenum foil and other metals as substrates for MoS$_2$ nanowires. Unlike the nanoparticles, the nanowires are already excellent absorbers of light, and simply need a substrate that can withstand the sulfidization process and retain good conductivity.

Upon achieving photoresponse from our nanostructures, we will proceed with a full battery of PEC studies, including the determination of the flat-band potential using:

- Illuminated open circuit potential
- Mott-Schottky
- Photocurrent onset

The flat-band potential will enable determination of the surface electronic structure of our semiconductor materials and provide insight into their ability to actively split water using sunlight without an applied bias. We will also pursue other PEC measurements on the supported nanostructures, including:

- Monochromatic photoresponse to obtain the incident photon-to-current conversion efficiency.
- Photoresponse under an applied bias to obtain the applied bias photon-to-current conversion efficiency.
• Photoresponse under zero applied bias to obtain the solar-to-hydrogen conversion efficiency.
• Assessing the hydrogen and oxygen products in the headspace to obtain the Faradaic efficiency for water-splitting by gas chromatography.

These studies will help to elucidate fundamental charge transport and interfacial properties of our materials and enable an improved degree of scientific understanding necessary to meet the goals set forth in Table 1. These techniques are explained in further detail in one of our recently published articles that outline proper methods, definitions, and protocols for developing materials for PEC hydrogen production [52].

Lastly, work is underway to further develop the anodic alumina templates, as well as the nanoporous double-gyroid networks. The templates will enable the development of MoS2 and WS2 nanowires and double-gyroid networks using an electrodeposition process. Although initial efforts have focused on MoS2, work is already underway to develop WS2 nanostructures. WS2 is an important avenue of study due to its structural and electronic similarities to MoS2. By studying both MoS2 and WS2 in multiple nanostructured forms, we address the challenge of developing a deployable PEC water splitting device using state-of-the-art techniques, with significant potential for producing knowledge that spans a large number of scientific fields, including photovoltaics and heterogeneous catalysis.

II.G.3 Photoelectrochemical Hydrogen Production Using New Combinatorial Chemistry Derived Materials

The overall project objective is to discover and optimize an efficient, practical, and economically sustainable material for PEC production of bulk hydrogen from water – a clean, renewable route to

Objectives

- A focus on the use of abundant and non-toxic elements in the development of improved photoelectrocatalyst materials for the capture of solar radiation to catalyze chemical reactions of interest.
- Utilize high-throughput screening to identify candidate materials that, with optimization, might meet the DOE performance and stability targets.
- Explore the effects of morphology on the photoelectrochemical (PEC) material system efficiency making use of nanostructures to minimize charge carrier path lengths and maximize reactive surface area.
- Explore processing and synthesis parameters to optimize efficiency through increased conductivity and minimized charge trapping and surface recombination of selected materials.
- Continue synthesis of libraries of semiconductor heterostructures for improved charge separation efficiency and/or stability.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the

Accomplishments

- Investigation of iron oxide electrodes with different levels of Ti doping by spray pyrolysis.
- Investigation of the PEC performance of Ti-doped hematite photoanode with oriented crystallography and different Ti%.
- Synthesis of bulk Ga$_{1-x}$Mo$_x$P (x ≤ 0.1) powders and deposition of cocatalyst.
- Exploration of the PEC activity of Ga$_{1-x}$Mo$_x$P (x ≤ 0.1) powders for hydrogen iodide (HI) and hydrogen bromide (HBr) splitting.
- Investigation of surface modification/passivation of InP wafer for increased corrosion resistance during HI and HBr splitting using simulated solar radiation.

Introduction

The overall project objective is to discover and optimize an efficient, practical, and economically sustainable material for PEC production of bulk hydrogen from water – a clean, renewable route to
hydrogen energy. The properties of the semiconductors investigated for this application, which are similar to those in photovoltaic devices, must satisfy conditions in several areas if cost-effective hydrogen production is to be realized: (1) efficient solar absorption, (2) effective charge separation/transport, (3) appropriate conduction band/vacance band energies relative to H⁺ and O₂ redox potentials (“band matching”), (4) facile interfacial charge transfer, (5) long-term stability, and (6) low cost. A material which satisfies all the above conditions simultaneously could provide clean hydrogen in bulk and at low cost; unfortunately, no such material or system has been discovered or developed to date. The DOE has identified the following future targets for solar-to-hydrogen efficiency and durability: 2006, 4%; 2013, 8% and 1,000 hrs; 2018, 10% and 5,000 hrs.

Hematite (α-Fe₂O₃) has many potential advantages for hydrogen photoproduction. It has a bandgap of 2.2-2.3 eV (absorbs approximately 40% of the solar spectrum), it is stable in electrolytes over a wide range of pHs and is abundant, inexpensive and non toxic [1-3]. However, several qualities have limited the use of this material as an efficient photocatalyst, including high electrical resistance and recombination rates of photogenerated electrons [4,5] and a lower conduction band-edge relative to the redox level of H⁺/H₂. Our hypothesis is that by deliberately doping hematite with selected heteroatoms [6] (e.g. Ti) and controlling the growth dimensions, crystal orientation and facets exposed, these limitations may be overcome. Phosphides have a narrow bandgap (~1.3 eV), which can utilize most of the visible light radiation, and a higher conduction band potential relative to the redox level of H⁺/H₂, which is preferable for hydrogen production using solar energy [7,8]. By surface modification and back contact engineering, a respectable incident photon conversion efficiency (IPCE) and chemical stability can be achieved in strong acid electrolyte.

Approach

The approach of this project involves the application of spray pyrolysis and solid state reaction methods to synthesize and optimize PEC materials and systems for cost-effective hydrogen production. This presents a systematic exploration of new metal-oxide-based solid-state materials. Our approach focuses upon the investigation of semiconductor materials that are inherently inexpensive, such as iron oxide, InP, and GaP. Iron oxide thin films doped with various amount of titanium have been synthesized by rapid spray pyrolysis of Fe(CO)₅ and TiCl₄, and screened by investigation of their PEC performance using a high through-put screening system. Gallium molybdenum phosphate powders were prepared through solid state reaction involving alloying of a stoichiometric amount of Ga₂O₃ and Mo metal through high temperature calcination. The resulting alloy was treated with H₃PO₄ and calcined in air at 500°C for 24 h and further reduced in H₂ flow at 875°C for 20 h. Pt nanoparticles were deposited on the powder samples which were then dispersed in 0.5 M HI or HBr solution in sealed vials. The PEC performance of these slurry systems were then tested in a high-throughput PEC reactor.

In parallel to our research on particulate phosphide systems, the PEC performance of n- and p-type InP wafers with ohmic contacts in HI and HBr systems were also investigated. Various passivation treatments were implemented in order to minimize the dark (corrosion) current of InP in the acidic solutions. Moreover, using the planar electrodes of InP would allow for determination of IPCE and PEC properties of InP in any electrolyte of interest. The ultimate results from these experiments enable one to select the best working conditions for any particular synthesized transition metal phosphide in a PEC particle system. Sulfur passivation was achieved by treatment of InP wafer with 7% aqueous (NH₄)₂S with added elemental sulfur (saturated solution) [9].

Results

Hematite photoanodes with various Ti doping densities were prepared by spray pyrolysis of Fe(CO)₅ and TiCl₄ and their PEC performance in water splitting was investigated. The feature size of the thin films increases from 10 nm to larger than 300 nm with an increase of Ti from 0-35% (Figure 1a-e). Orientated crystallography was observed in all the thin films as prepared with different Ti%, as shown in the X-ray diffraction (XRD) patterns (Figure 1f). The IPCE of the thin films at 0.4 and 0.6 V vs. Ag/AgCl was plotted as a function of Ti% in Figure 2a, which shows the highest IPCE of 27.5% at 400 nm from sample with Ti% of ~0.78%. With the increase of Ti%, the IPCE decreases. All samples show a low IPCE at 0.2 V vs. Ag/AgCl, which was ascribed to the higher density of trap states and the presence of the magnetite crystal phase when titanium was used in higher concentrations (7.17% and 34.5). Calcination at 500°C diminished the amount of magnetite present in these two samples and improved the performance of the Ti-doped hematite thin films at 0.2 and 0.4 V vs Ag/AgCl except the sample with 34.9% of Ti. The pure hematite sample shows almost no photoelectrocatalytic activity both before and after 500°C calcinations. This indicates that the poor performance of this thin film is not related to its crystallinity.

The PEC H₂ production from HI splitting on bulk GaₓMoᵧP and Pt/GaₓMoᵧP (x≤0.1) particles is shown in Figure 3a and b. The improvement of the performance by deposition of cocatalyst (Pt nanoparticles) is significant. The GaₓMoᵧ₀.₀Po.₀P sample with and without Pt cocatalyst in HI splitting...
the best performance. The Ga$_{1-x}$Mo$_x$P samples also showed a high activity in HBr splitting, a much more valuable reaction than pure hydrogen production. Figure 3c shows the performance of the Ga$_{0.95}$Mo$_{0.05}$P sample in both HBr and HI over the course of 50 hours continuously. The efficiency of HBr splitting is approximately half of HI splitting.

Intensive hydrogen evolution from p-InP wafer surface was observed in 0.5 M HI solution under 100 mW/cm$^2$ white light illumination. The efficient hydrogen production was confirmed by the IPCE and photocurrent measurements in a two electrode configuration under no applied bias. The IPCE of this p-InP in 0.5 M HI yields an average value of ca. 35% in a wide range of visible light from 500-900 nm, Figure 4a. A short-circuit photocurrent of 10 mA/cm$^2$ was also observed under 1 sun illumination, Figure 4b. The abrupt change of photocurrent as shown in Figure 4b is attributed to the bubbling of hydrogen. In addition, our experimental data has shown that n-InP is a promising candidate for HBr splitting even in the absence of any cocatalyst. However, compared to our obtained results in HI, the photocurrent recorded in HBr electrolyte is in the range of 0.5–1.0 mA/cm$^2$.

One of the main flaws of n- and p-InP in HI and particularly HBr solutions is the relatively high dark (corrosion) current. Undoubtedly, one of the main requirements of any potential material to function as a sustainable and stable photocatalyst is to exhibit an acceptable corrosion rate. Thus, a great deal of effort in our laboratory has been devoted to the investigation of efficient chemical passivation to minimize the corrosion rate with no adverse impact on the photoactivity of the material. To date, sulfur passivation of n-InP has been the most effective passivation treatment, remarkably minimizing the corrosion rate of n-InP in
The dark current over the course of 1 week in solution and three 16 h light periods (100 mW/cm²) remained constant at about 0.1 µA/cm². Untreated samples display dark current on the order of 200 µA/cm² after a single light cycle. The main advantage of this treatment is the possibility of application of this treatment to our slurry phosphide systems such as Ga₁₋ₓM₀ₓP with no need to apply any external bias.

Conclusions and Future Directions

• The methodology of combinatorial material science has been applied to expedite the discovery of improved photocatalytic materials for hydrogen production.
A spray pyrolysis system has been used to synthesize Ti-doped iron oxide thin films with various Ti concentration and orientated cryptography. The Ti-doped iron oxide thin films show a remarkable improvement in efficiency for PEC water splitting compared to undoped samples.

Surface modification by saturated aqueous ammonium sulfide solution has been successfully applied to passivate InP wafer for PEC use in strong acid electrolyte.

Ga$_{1-x}$Mo$_x$P ($x \leq 0.1$) powders have been prepared and shown high activity in HI and HBr splitting under visible light illumination with Pt cocatalyst.

Development of novel synthetic methods for nanoscale/nanostructured Ga$_{1-x}$Mo$_x$P ($x \leq 0.1$) powders.

Synthesis of Ga$_{1-x}$M$_x$P (M = Ni, W, Fe) powders and PEC performance testing in HI and HBr splitting under visible light illumination with Pt cocatalyst.

II.G.4 Semiconductor Materials for Photoelectrolysis

Objectives

Identify, synthesize, and characterize new semiconductor materials that have the capability of meeting the criteria for a viable photoelectrochemical (PEC) hydrogen-producing device, either as a single absorber or as part of a high-efficiency multi-junction device.

Technical Barriers

This project addresses the following technical barriers from the Photoelectrochemical Hydrogen Production section of the Fuel Cell Technologies Program’s Multi-Year Research, Development, and Demonstration Plan (MYPP):

(Y) Materials efficiency
(Z) Materials durability
(AB) Bulk materials synthesis
(AC) Device configuration designs.

Technical Targets

The 2013 technical targets from the MYPP PEC hydrogen production goals are as follows:

- Bandgap of 2.3 eV
- 10% conversion efficiency
- 1,000 hr lifetime

Accomplishments

- In addressing the MYPP barrier Z, preliminary testing of CuGaSe2 (CGS) was completed. UNLV analysis of CGS samples that were subjected to PEC testing showed that biasing the material alters the chemical environment of Ga and immersion into an acidic electrolyte appears to remove a native SeO2 feature. Further analyses are necessary to determine how these changes might affect stability and performance.
- Our Stanford subcontractor synthesized tungsten nanoparticles and air-stable MoS2 nanoparticles in various sizes ranging from 5-25 nm and achieved quantum confinement of MoS2 nanoparticles with indirect bandgaps up to 1.8 eV.
- We characterized a-SiC, deposited by plasma-enhanced chemical vapor deposition (PECVD) to address barriers Y, Z, AB and AC. We determined a-Si/a-SiC hybrid photoelectrodes have poor efficiency when operated at zero bias and poor durability when moderate current (-3 mA/cm2) was applied. Removing the surface SiOx layer with an hydrofluorhydric acid (HF) etch can improve water splitting efficiency to just over 1%.
- In addressing barriers Y, Z, and AC we determined InxGa1-xN thin films have appropriate interfacial energetics for spontaneous water splitting, exhibit good durability, and can be incorporated into multi-junction absorber cells to improve photoconversion efficiency.
- We published a manuscript to the Journal of Materials Research on standardized PEC methods which was the culmination of a year-long effort with other members of the PEC working group. The document is intended to establish standard practices for reporting water splitting efficiencies within the PEC community.
- Stabilization of the GaInP2 electrolyte interface through electrochemical nitridation and thin oxide coating by atomic layer deposition show these strategies may be able to passivate the corrosion-prone surface. If these highly efficient materials (12.4% solar-to-hydrogen, STH) could be made more durable, the MYPP 2013 technical target or 10% efficiency for 1,000 hours would be satisfied.
- Density functional theory (DFT) calculations showed W would make a good n-type dopant in BiVO4 and efforts to incorporate W during synthesis are underway.
- We made a “no-go” decision on continued study of a-SiNx and Cu-W-O materials and a “go” decision on protective coatings and nitride treatments on high-efficiency III-V photoelectrodes.
Future Direction

- Continue to synthesize and characterize nitride materials (GaNP, GaInN, GaInPN) for higher efficiencies and longer lifetimes. Synthesize InGaN on conductive substrates.
- Investigate nitridation of III-V surfaces for corrosion passivation.
- Evaluate additional PEC semiconductor candidates in collaboration with others.
- Work with UNLV to correlate surface and near-surface spectroscopic results with test conditions to identify corrosion pathways and performance barriers related to surface composition.

Introduction

Photoelectrochemistry combines a light harvesting system and a water splitting system into a single monolithic device. A semiconductor immersed in aqueous solution comprises the light-harvesting system. The catalyzed surface of the semiconductor is one electrode of the water-splitting system, and the other is an electrode in a separate compartment. The key is to find a semiconductor system that can efficiently and sustainably collect solar energy and direct it towards the water splitting reaction.

The goal of this work is to discover and characterize a semiconductor material set or device configuration that (i) splits water into hydrogen and oxygen spontaneously upon illumination, (ii) has a solar-to-hydrogen efficiency of at least 5% with a clear pathway to a 10% water splitting system, (iii) exhibits the possibility of 10 years stability under solar conditions and (iv) can be adapted to volume-manufacturing techniques.

Approach

Our approach has two thrusts, (i) the study of current material sets used in commercial solar cells as well as related materials, and (ii) the discovery of new semiconducting materials using advanced theoretical calculations to identify promising candidates, closely coupled with synthesis and state-of-the art characterization. The latter is in collaboration with NREL’s theory group.

Results

III-V Nitride Materials

We characterized InGaN alloy samples from Los Alamos National Laboratory grown by molecular beam epitaxy (MBE). InGaN is a promising emerging material with a bandgap between 0.7-3.4 eV, depending on the In:Ga ratio. Nitride materials have well documented stability in contact with electrolytes, therefore InGaN alloys may be stable and efficient photoelectrodes for PEC water splitting because of their chemical inertness and ability to absorb visible photons. These materials were characterized to determine bandgap, bandedge alignment, water-splitting efficiency, and stability. Samples were grown on sapphire substrates, which are electronically insulating. Contacts were applied to the periphery of the front surface in order to fabricate electrodes, a non-ideal configuration that results in poor carrier collection. Despite these non-ideal contacts, we were able to determine some basic material properties.

The samples had obvious visible absorption as evidenced by their colored appearance (Figure 1a). The material composition varied across the surface of the wafer due to issues with the gallium source within the MBE reactor. The bandedge positions were appropriate for water splitting according to Mott-Schottky measurements. Illuminated open-circuit measurements and photocurrent onset potential measurements indicated the flatband potential was too positive, i.e. the conduction bandedge was too low to drive the hydrogen evolution (reduction) half-reaction. Two-electrode measurements (Figure 1b), however, demonstrated zero-bias photocurrent, which we correlate with spontaneous water splitting. Though the InGaN was capable of zero-bias photocurrent, the efficiency was very low, generating 10s of μA/cm² instead of mA/cm² that would be expected of a material with a bandgap in the visible region. We believe the inconsistent bandedge analyses and low conversion efficiency is due to the long carrier collection distances due to the non-ideal contacts. Initial durability analysis showed moderate stability, but it is doubtful that the uneven spatial distribution of current replicated what an appropriately contacted material might experience. Realistic appraisals of efficiency and durability cannot be made until the contact geometry is modified to a more ideal vertical collection is achieved by using conductive substrates.

Thin-Film Amorphous SiN and SiC Systems (with MVSystems)

In collaboration with our industrial partner, MVSystems, Inc., who performed the material synthesis, we studied amorphous silicon nitride (a-SiN) and silicon carbide (a-SiC) samples grown by PECVD. PECVD is a scalable process that can yield low-cost photoelectrodes and although the instability of amorphous silicon (a-Si) makes it a non-ideal PEC material, stability might be achieved when synthesized as a nitride or carbide.

We characterized PECVD grown a-SiN, that was synthesized with an appropriate bandgap (~2.0 eV) for water splitting; however, the bandedges at the electrolyte semiconductor interface were not favorable.
for spontaneous water splitting. When assembled into a p-type device, a-SiNx electrodes can produce milliamps of photocurrent per square centimeter but only under a strong negative bias of -3 V. A 30 second 5% HF surface treatment damaged the film surface and did not significantly improve photocurrent onset potential. Holding the sample at -2.6 V vs. Pt-black counter electrode for 24 hours produced numerous pinholes in the a-SiNx film and allowed the passage of dark current from the conductive tin oxide substrate. Because of the questionable efficiency and durability of this material, a-SiNx has limited promise for PEC water splitting applications, and thus we made a “no-go” decision on continued study of this material.

The PEC performance (efficiency and durability) of a-Si(photovoltaic, PV)/a-SiC(PEC) was determined. These types of cells are known as a PEC/PV hybrid because they incorporate a photovoltaic absorber in series with a PEC absorber as a monolithic device. When these cells are fabricated into solid-state devices, the short-circuit current density under air mass (AM) 1.5 G illumination is about 4.5 mA/cm². When similar cells were tested in a PEC environment, the short-circuit (water splitting) current densities were below 1 mA/cm².

HF etching can improve the photocurrent by removing the insulating SiOx interfacial layer, but the effect is only temporary. We have been unable to identify an active catalyst to facilitate the hydrogen evolution reaction on the surface of these photocathodes. Our typical applications of platinum by electrodeposition or immersion in colloidal solutions have not been effective for these amorphous materials. Platinum applied by sputtering also led to diminished photocurrents.

The STH efficiencies achieved in pH 0, 5, 8, 10, and 14 under AM 1.5 G illumination were all lower than 0.25% when a platinum counter electrode was used. The use of a RuO₂ counter electrode in pH 0 sulfuric acid achieved the highest STH efficiency of about 1%, and was stable over the 20-hour test period. However, no bubbles were observed from the working electrode so the cathodic current could not be unambiguously attributed to water splitting. Our collaborators at the University of Hawaii observed that using an HF acid treatment, the overall efficiency could be as high as 1.6% (RuO₂ counter, in pH 0 phosphoric acid).

When a current of -3 mA/cm² was applied by external biasing, (the current that a 3.6% efficient electrode would generate) severe degradation of the surface was observed in less than 24 hours. The electrodes developed several pinholes that were visible without magnification that increased with extended testing (Figure 2).

For a-SiC coated a-Si to be considered for PEC water splitting devices, the efficiency and durability both must be improved.

Protection Strategies for High-Efficiency III-V Materials

Tandem cells based on p-GaInP₂/n/p-GaAs semiconductors have demonstrated over 10% STH, which exceeds the DOE near-term technical target, but are prone to corrosion during operation. The unprotected cells only last a few days in operation. Improving the durability to 1,000 hours could yield a
photoelectrode that satisfies both the efficiency and durability technical targets. This year we examined two different pathways for III-V photoelectrode passivation. One strategy is to use an electrolyte that has constituents that modify the semiconductor surface in a way that leads to protection. The other approach focuses on applying a protective coating through a chemical deposition process.

Initial results from our lab found that operating a p-GaInP₂ for 24 hours in a pH 1 NH₄NO₃ solution resulted in less surface degradation, as determined by optical microscopy and scanning electron microscopy (SEM), than running it in our standard 3M H₂SO₄ solution. Our hypothesis is that the passivation is due to electrochemical nitridation that occurs during the durability testing. X-ray photoelectron spectroscopy on a sample that had been run in the NH₄NO₃ solution found ammonia on the surface after rinsing the electrode with deionized water post durability testing. We are following up to determine if the difference in pH (3M H₂SO₄ pH = -0.5) plays a significant role. We are also investigating the origin of the ammonia, whether from the cation or anion, so we are testing in (NH₄)₂SO₄ and KNO₃. In addition we are performing durability analysis on tandem GaInP₂/GaAs electrodes to see if the protective effect is observed when the electrode is biased internally instead of via a potentiostat.

The second strategy for electrode passivation involves applying a thin coating that should provide protection. The coating must not significantly attenuate visible light, and be robust enough to protect the surface while not impeding electron flow to the electrolyte. Our first attempt was to coat p-type GaInP₂ with 20 nm of TiO₂ by atomic layer deposition (ALD). TiO₂ is a fairly stable oxide material that has a wide bandgap and is naturally a good (n-type) electron conductor. We cleaved GaInP₂ wafers and sent half of each one to our colleagues in the Sunkara group at the University of Louisville to have the oxide coating applied. We mounted the coated and uncoated samples into electrodes to compare their ability to generate photocurrent and determine their durability characteristics.

We were unable to determine if the coating attenuated photocurrent because there was high variability between individual electrodes from the same wafer, but some of the highest photocurrents were achieved on coated electrodes. For durability analysis, the electrodes were operated for 22 hours at -5 mA/cm² in 1M KOH. We were unable to find significant differences in post-durability performance or variation in solubilized Ga in the testing solution. We believe the durability test conditions were not harsh enough to observe corrosion effects on either the coated or uncoated samples.

Visual analysis of the coated and uncoated samples did reveal differences after the durability testing. The uncoated samples displayed a degraded surface from their initially shiny and featureless appearance while the coated electrodes had areas where the coating had flaked off but otherwise appeared free from degradation. SEM imaging of a coated electrode showed that the TiO₂ film has fissures that probably contributed to its inability to adhere to the semiconductor surface (Figure 3). The fissures appear to be a native feature of the TiO₂ coating because they are evident in an area which was masked by epoxy during the testing. This result indicates a thicker coating may be required to achieve an uninterrupted film with the required stability.

Because of the promising results obtained so far, we made a “go” decision for continued study of both nitrided and ALD-coated III-V surfaces for corrosion remediation.
II.G Hydrogen Production / Photoelectrochemical

Chalcopyrites Materials based on Cu(In,Ga,Al)(S,Se,Te)₂

This year we continued potentiostatic (constant applied potential) durability analysis of CGS materials on fluorine-doped tin oxide substrates obtained from the University of Hawaii. In addition to samples sent to UNLV for synchrotron analysis (results reported by our subcontractor NREL project: subcontract NO. NFH-8-88502-01 under prime contract NO. DE-AC36-99GO10337) we performed our own surface and electrochemical analysis. Figure 4 illustrates how a pinhole can lead to cracking and delamination of the CGS thin film during durability.

Theory of Metal Oxide, Nitrides and Other Materials

BiVO₄ has attracted significant interest as a semiconducting material for the PEC decomposition of water. Our analysis of BiVO₄ by density functional theory indicated good electronic properties for this material such as high hole mobility and good band edge positions. For PEC applications, the semiconductor must be doped p-type or n-type to a reasonable carrier concentration in order to support current flow. Therefore, we studied the effect of doping of W in BiVO₄ using DFT.
We previously calculated that the valence band of BiVO_4 is derived from hybrid Bi lone pair 6s and O 2p states. Tungsten can have various ionized states in oxides. We find that if a W occupies a Bi site, W is shallow donor. From the calculated band structure and site projected density of states, it was found that the states introduced by W are in the conduction band, indicating that indeed W is a very shallow donor. In this case, W is 5+ and Bi is 3+, therefore W on Bi site results in double donors. Beside Bi sites, W may also occupy a V site where the states introduced by W are also in the conduction band, meaning W at V site is also a shallow donor. However, in this case, W is a single donor.

Our results conclude that W at either a Bi site or a V site is a shallow donor, suggesting W would be an excellent dopant for making n-type BiVO_4, and we will be pursuing the synthesis of this material for PEC testing.

**NREL Synthesis of Metal Oxide Alloy Thin Films**

We synthesized Cu-W oxide thin films by co-sputtering. In order to produce Cu-W oxide materials with tunable band gaps and avoid phase separation, amorphous Cu-W oxide films were synthesized. Considering the fundamental gap as direct, the band gaps for a series of samples with Cu to W ratios of 1:3, 1:1:1, and 2:2:1 were 2.63 eV, 2.05 eV, and 1.88 eV respectively. The trend of the bandgaps correlate well with values expected from the composition. The fundamental bandgaps correspond to the transition between Cu 5d-derived valence band and W 5d-derived conduction band.

Although these materials have optimal bandgap energies, they are unstable in both basic and acidic solutions. In light of their instability, we made a “no-go” decision on amorphous Cu-W oxide for PEC applications.

**Conclusions**

- InGaN shows promise for a single junction water splitting electrode with potential for high efficiency and durability if the contacts can be improved. Synthesis on conductive substrates should remedy this situation and these efforts are underway.
- Thin film a-Si carbides have the potential to be inexpensive water splitting electrodes if durability and efficiency can be improved.
- Protection of highly efficient, but corrosion prone photoelectrodes could result in a single material that meets the DOE technical targets for efficiency and durability. Results from GaInP cells with nitride treatments and thin oxide coatings suggest this route is viable.
- CGS appears to suffer mechanical stability, which could be overcome by synthesis modifications. CGS could potentially serve as the outer coating for a tandem cell and obtain high efficiency.
- DFT has indicated that W is a good dopant for BiVO_4 which we are currently synthesizing.

• National Renewable Energy Laboratory (NREL) project: subcontract #NFH-8-88502-01 under prime contract number DE-AC36-99GO10337

Project Start Date (UNLV project): October 1, 2004  
Project End Date (UNLV project): December 31, 2010 (no-cost extension)

Project Start Date (NREL project): May 6, 2008  
Project End Date (NREL project): May 5, 2011

Objectives

Enhance the understanding of photoelectrochemical (PEC) materials and interfaces and promote breakthrough discoveries by:

• Utilizing and developing cutting-edge soft X-ray and electron spectroscopy characterization.
• Determining electronic and chemical structures of PEC candidate materials.
• Addressing materials performance, materials lifetime, and capital costs through close collaboration with partners from the PEC working group.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(H) System Efficiency  
(K) Durability  
(G) Capital Cost

Technical Targets

• Collaborate closely with partners within the DOE PEC working group to determine the electronic and chemical structure of candidate materials for solar water splitting.
• Aid the collaboration partners in the development/modification of novel candidate materials.
• Monitor deliberately introduced modifications of PEC candidate materials in view of the electronic and chemical structure.

Accomplishments

• Further studies of the impact of Mo doping/alloying in WO$_3$:Mo/WO$_3$ bilayer structures (with University of Hawaii/Hawaii Natural Energy Institute).
• Investigation of the band gap of a-SiC and its change after surface treatments (with MVSystems).
• Studies of PEC-tested and untested CuGaSe$_2$ samples (with University of Hawaii/Hawaii Natural Energy Institute and NREL).
• Completion of Fe$_2$O$_3$ thin film analysis (with University of California, Santa Barbara).

Introduction

This project is embedded into the Department of Energy’s efforts to develop materials for PEC water splitting. If successful, PEC will provide an important route to convert the energy supplied by solar irradiation into a transportable fuel. In order to achieve this goal, suitable materials need to be developed that simultaneously fulfill several requirements, among them chemical stability and optimized electronic structure, both for absorption of the solar spectrum and for electrochemical water splitting at a solid/electrolyte interface. This project experimentally derives the chemical and electronic structure information to (a) judge the suitability of a candidate material, (b) show pathways towards a deliberate optimization of a specific material, and (c) monitor whether deliberate modifications of the material indeed lead to the desired changes in electronic and chemical structure.

Approach

A unique “tool chest” of experimental techniques is utilized that allows to address all technical barriers.
related to electronic and chemical properties of various candidate materials. With these techniques it is possible to measure surface and bulk band gaps, the energy level alignment at interfaces, the chemical stability of the materials, and the impact of alloying and doping.

The tool chest includes photoelectron spectroscopy with X-ray (XPS) and ultraviolet excitation to determine the occupied electronic states (core levels and valence electrons) and inverse photoemission to determine the unoccupied electronic states. These techniques, performed in the lab at UNLV, are surface-sensitive and allow a complete determination of the electronic and chemical surface structure. They are complemented by X-ray emission (XES) and X-ray absorption (XAS) spectroscopy, performed at Beamline 8.0 of the Advanced Light Source, Lawrence Berkeley National Laboratory. XES and XAS also probe the occupied and unoccupied electronic states, but with a larger information depth. Furthermore, they also give insight into the chemical structure, again complementary to the electron-based techniques performed in the lab at UNLV.

**Results**

In collaboration with our partners, we have investigated numerous sample series on a variety of PEC candidate materials. Results are immediately shared with the collaboration partners and discussed in detail through powerpoint presentations, at phone conferences, and working group meetings. In the brevity of this report, we will focus on one materials class only, namely copper gallium diselenide (CGS) samples grown at the University of Hawaii and PEC-tested at NREL. Results for other material classes (tungsten trioxide, amorphous silicon carbide, and iron oxide) are shown in the annual review presentation.

To demonstrate the chemical insights that can be gained with our experimental tool chest (complementary to the electronic structure information described in last year's report for, e.g., WO$_3$ thin films), we will focus on five samples as described in Table I.

Figure 1 shows Se M-edge and S L-edge XES spectra of the CGS samples and of CdSO$_4$ (top spectrum) and Cu$_2$Se (bottom spectrum, showing a significant Se oxidation and sulfate contamination) references. Sample A (untested CGS) shows a dominant Se M$_{2,3}$ emission line at 143 eV and some weaker features at higher emission energies (three peaks from 152 to 157 eV and one broad peak around 162 eV). The latter are indicative of Se oxide formation and show that the untested CGS sample is weakly oxidized. In contrast, the emission spectrum of Sample B (CGS in H$_2$SO$_4$ electrolyte for 24 hours) is dominated by the sulfate and/or selenium oxide features. The sulfate formation is likely from residual sulfuric acid on the surface of the samples, while selenium oxide formation is likely due to the CGS exposure to the aqueous sulfuric acid solution. Note that the cross section for Se L$_{2,3}$ emissions is significantly larger than that for Se M$_{2,3}$ emission, and thus the observed features are more likely due to sulfate deposition.

The spectra of samples C–E at first glance appear to be similar to that of sample A, but upon closer
inspection significant differences are visible. In particular, the sulfate/selenium oxide peak intensity increases in the order D–C–E.

Additional analysis was performed on the spectrum of sample D in Figure 2 by subtracting the spectrum of sample A (weighted by 0.9) to account for the signal originating from the CGS substrate (difference spectrum shown in red). The difference spectrum is characteristic of sulfur emission (specifically sulfide) with a dominant peak at 146 eV. This suggests that a new sulfur-containing species is present on the surface of the tested sample. Note that this is not a sulfur oxide species, because the characteristic features at emission energies above 153 eV, are notably absent in the difference spectrum. As one possibility, we note that the difference spectrum is similar to that of a copper sulfide (e.g., Cu$_2$S, shown in the same figure, in green), but other sulfides might also play a role.

We thus find that the PEC testing influences the local Se environment at the surface. Additionally, we are able to detect S atoms adsorbed onto the CGS surface after PEC testing, in some cases as a sulfide and in others as a sulfur oxide. We find that the chemical structure of the samples (with respect to the local Se and S environments) varies between samples, and thus allow correlation with the PEC test parameters that were used.

The CGS samples described in Table I were also investigated with XPS at the UNLV lab to elucidate the chemical surface composition after testing. Survey scans of the three samples are shown in Figure 3. In the control sample A, copper, gallium, and selenium are observed (as expected). Significant surface contamination is also found, as indicated by the presence of oxygen and carbon. For the tested samples B and E, the same five elements are detected, but their relative intensities differ. For sample B, the signals ascribed to copper and selenium are enhanced, while the oxygen signal has decreased when compared to the control sample A. Sample E has similarly increased signals of copper and selenium, but the oxygen has decreased much less. Thus, even just based on the survey spectra, a qualitative comparison between the different tested and non-tested samples already reveals significant changes in surface composition.

Detailed spectra (with a smaller energy range and better resolution) of Cu, Ga, and Se core levels were acquired to monitor the chemical changes of the CGS surface as a function of PEC testing. In Figure 4a, the Cu 2p$_{3/2}$ region of all three samples is shown. The peak shape and energetic position of samples B (tested in dark) and E (tested in light) are very similar to that of sample A (untested). Although the copper signal in samples B and E has increased, the copper present on the surface of all three samples appear to be in the same chemical environment. In contrast, the Ga 2p$_{3/2}$ region (Figure 4b) of the untested sample (A) and the tested samples (B and E) are all at different binding energies. The tested samples are at higher binding energies (at about 1,119 eV), while the untested sample is at about 1,117 eV. The Ga 2p$_{3/2}$ (energetic) position of the tested samples is in agreement with reported Ga$_2$O$_3$ values [1]. At first glance, the tested samples (B and E) appear to be similar to each other, but upon
closer inspection, the spectral width of sample E is wider than that of sample B, and the peak maximum of sample B is at slightly higher binding energy. This is an initial indicator that the gallium on the surface of sample E may be in two different chemical environments, one of them possibly identical to that of sample B. We thus find that the details of PEC testing (in particular, dark vs. illuminated) do affect the chemical Ga environment on the surface. In the case for Se, the main peak (at about 53.5 eV) positions are about the same for all three samples. However, the untested sample (A) has an additional peak at higher binding energies which is in agreement with literature values of Se 3d in SeO₂ chemical environments [1], and which has also been previously found by our group on Cu(In,Ga)Se₂ surfaces [2]. This additional peak is absent in the tested samples. This absence could be due to the acid exposure of the samples, which etched away the oxide Se surface atoms.

From XPS, we thus find that the PEC testing influences the local chemical environment of the Se and Ga atoms at the surface. Such results give valuable insights into the atomic-scale effects on PEC candidate material surfaces under operating conditions and will contribute to a guided search for custom-tailored stable PEC materials.

Conclusions and Future Directions

In conclusion, development of the spectroscopic "tool chest" to give a comprehensive picture of the electronic and chemical structure has become a key component of the DOE PEC research and development efforts. Evaluating a variety of PEC candidate materials in view of their electronic and chemical properties has enhanced progress in many of the DOE PEC working group projects. Continued experiments within excellent collaboration structures with a large number of partners of the DOE PEC working group has been critical to recent progress, and is vital to future success in meeting DOE targets. As a result, future directions include:

- Continue the collaborations with our existing partners and bring new partners “on board”.
- Continue to determine electronic and chemical properties of various PEC candidate materials manufactured by the collaboration partners within the DOE PEC working group.
- Continue to improve the currently available experimental approaches.

Objectives

The main focus of the project is to:

- Understand the performance of current photoelectrochemical (PEC) materials.
- Provide guidance and solution for performance improvement.
- Design and discover new materials.
- Provide theoretical basis for go/no-go decisions to DOE PEC H₂ projects.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

(Y) Materials Efficiency
(Z) Materials Durability
(AB) Bulk Materials Synthesis

Technical Targets

This project is intended to provide a theoretical understanding of the performance of current PEC materials and provide feedback and guidance for performance improvement.

Accomplishments

- Studied theoretically the properties of Cu delafossite (CuXO₂, X= group-IIIA, or IIIB) materials for PEC water splitting.
- Proposed solution for enhancing the optical absorption for Cu delafossite through symmetry breaking.
- Investigated the effects of W doping in BiVO₄, a potential material for PEC water splitting.

Introduction

Cu delafossites, CuMO₂ (M = group-III elements), have received great attention in recent years due to their potential applications as electrodes for hydrogen production by PEC water splitting and transparent conductive oxides (TCOs) in optoelectronic devices [1,2]. The p-type conductivity and good hole mobility are what make the Cu delafossites so unique and more attractive in these applications than other metal oxides. For instance, due to their p-type nature, the Cu delafossites are resistive against oxidative corrosion. Some recent experimental studies demonstrated that Cu delafossites are stable in solution and are capable of H₂ evolution from water [1,2].

Among the two Cu delafossite families, [CuM⁷⁺O₂ (M⁷⁺=Al, Ga, In) and CuM⁶⁺O₂ (M⁶⁺=Sc, Y, La)], the CuM⁷⁺O₂ family (particularly M⁷⁺=Al) has mostly been considered for p-type TCOs. On the other hand, the focus on the CuM⁶⁺O₂ family has been limited and specifically on the application on H production by solar water splitting. Until now, there has been no solid understanding of which family is better suited for which of the applications.

Despite the similar structures, the CuM⁷⁺O₂ and CuM⁶⁺O₂ families exhibit significantly different electronic properties. The optical measurements indicate that the group-IIIA delafossite family has indirect bandgaps [3,4], and can hardly be doped p-type by extrinsic dopants [5]. On the other hand, the group-IIIB delafossite family has been exclusively reported to have direct wide bandgaps and can be doped by extrinsic dopants.

It is also important to note that the main difference between the requirements for PEC electrodes and TCOs is as follows: PEC electrodes require smaller bandgaps (in the visible region) and an appropriate band-edge alignment, whereas TCOs require larger bandgaps (in the ultraviolet region). We therefore needed to conduct...
a detailed comparative study on the electronic structure between the CuMIIIO₂ and CuMIIIBO₂ families so that these materials can be used for their best-suited applications in optoelectronic devices. Furthermore, we need to develop a method to enhance the optical absorption for the Cu delafossite families.

BiVO₄ has shown particular promise for water photodecomposition with the presence of both a low bandgap (2.4–2.5 eV) and reasonable band-edge alignment with respect to the water redox potentials [6]. It has been reported to exhibit both n- and p-type semiconducting properties [7], in addition to high photon-to-current conversion efficiencies. However, to date, the effects of dopants on the electronic properties of BiVO₄ have not been well explored.

Approach

We have employed density functional theory (DFT) to study the electronic properties of the delafossite materials and BiVO₄. Generalized gradient approximation (GGA) to DFT and the projected augmented wave (PAW) basis as implemented in the Vienna ab initio simulation package (VASP) [8] are used. A plane-waves cut-off energy of 400 eV was used, and the ion positions were always relaxed until the force on each of them is 0.01 eV/Å or less. To correct the DFT+GGA underestimation of electron correlation of the cation d band, an $U_{\text{eff}} (U=7$ eV) parameter was added to the DFT Hamiltonian for all the valence Cu-d, Sc-d, and Y-d bands. No U was added for the group-IIIA elements because their filled 3d bands are fully occupied shallow core states, which is situated more than 15 eV below the top of the valence band (Al has no d-band). Also, we found that adding an additional U, for example, on the Ga-3d band resulted in a much smaller in-plane lattice a parameter compared to the experimental value. In the case of CuLaO₂, an empty and highly localized f-band is present just above the conduction-band minimum (CBM), and a localized band with d-character is seen in the lower edge of the conduction band. This overall presence of f on top of d character at the CBM makes it particularly sensitive on the choice of U parameter in the DFT+U scheme. In fact, we found that a small U value on the La d-band highly overestimates the bandgap relative to experiment. So, for CuLaO₂, no U potential has been used to La-5d. The choice of U parameter was not found to affect the relative stability of the hexagonal and rhombohedral delafossite structures. For BiVO₄, we found that U parameters were not needed.

Results

We first discuss the structure preferences for the group-IIIA and -IIIB delafossites. The delafossite structure can have either $P6/mmc$ ($#194$) or $R3m$ ($#166$) space-group symmetry, depending on the stacking sequencing of the O–M (M = group-IIIA and -IIIB) octahedron layers. Our total energy calculation revealed that group-IIIA delafossites prefer the rhombohedral group (R3m), whereas group-IIIB delafossites favor the hexagonal group (P6/mmc), which is in good agreement with experimental observation. In both symmetries, O and Cu form linear bonding structure along the c-axis, which is considered to be the main channel for the hole transport, whereas O–M bonds form distorted octahedra.

Figure 1 shows the calculated band structure for the group-IIIA and group-IIIB delafossites in rhombohedral and hexagonal structures, respectively. Our results reveal that although the CuMIIIO₂ and CuMIIIBO₂ delafossites have a similar local structure environment, they have very different electronic properties. Comparing the band structures for the CuMIIIO₂ and CuMIIIBO₂ delafossites, we find that the nature of the valence band is similar for both group-IIIA and -IIIB families. As mentioned earlier, the valence-band maximums (VBMs) are mainly composed of Cu-d and O-p orbitals. However, for hexagonal CuMIIIO₂ band structures (lower panel in Figure 1), the occurrence of the VBM at the H point is no longer observable in all cases. For example, for CuScO₂, the VBM is still at H-point, but for CuYO₂ and CuLaO₂, the VBM appears to be at the Γ point. Larger variations are seen between the CBM of the group-IIIA and group-IIIB delafossites.

**FIGURE 1.** Calculated electronic band structure of group-IIIA (upper panel) and group-IIIB (lower panel) delafossites along the high-symmetry lines of the first Brillouin zone.
The biggest difference is that at the $\Gamma$ point, the $s$-band-derived CBM in the Cu$^{III}$BO$_2$ family is not as deep as compared to that in the Cu$^{II}$BO$_2$ family. First, comparing the band structure of CuScO$_2$ and CuGaO$_2$, we clearly see the much lower CBM due to Ga-4s band in the later at $\Gamma$ point. For CuScO$_2$, the presence of unoccupied Cu-3$d$ states at the CBM ($\Gamma$ point) makes it much less dispersive. Secondly, for Ga, all its 3$d$ bands are occupied and are situated at much higher binding energy below the Fermi level, and they do not contribute much to the conduction band. At the L point, significant Ga-$s$ contribution along with $p$ character is seen for CuGaO$_2$. In contrast, for CuScO$_2$, the $d$ contribution is significant at the L point of the conduction band because of its partially filled Sc-3$d$ nature. In addition, unoccupied $f$ bands are present in the conduction band in CuLaO$_2$ which affect the CBM significantly. In principle, all the differences identified above can be attributed to the differences in electronic configurations between group-III and -IIIB elements. The detailed discussions can be found in Ref. [9]. Our results explain well the experimentally reported bandgap trends for Cu$^{III}$BO$_2$ delafossites.

We have also calculated the optical transition matrix elements for the band edges of group-IIIB delafossites at the special symmetry points as shown in Figure 1. Only the diagonal components (direct gap) of the momentum matrix were calculated, because the off-diagonal elements would not contribute significantly to optical absorption. In all cases, the transition between VBM and CBM at the $\Gamma$ point is forbidden (zero transition matrix elements), because of mainly $d$ character for both VBM and CBM and transition would result in a parity violation. Therefore, for the application for PEC water splitting, Cu delafossites have too weak absorption, particularly for visible light.

The zero contribution to the optical absorption at the $\Gamma$ point is due to the inversion symmetry of the delafossite structure. For efficient PEC water splitting, the optical absorption of Cu delafossites must be enhanced significantly. We found that significant band-structure modification can be achieved by isovalent alloying of Cu-based delafossites. This alloying significantly improves the optical absorption at lower energy because it reduces the crystal symmetry; thus, it lifts the parity-forbidden transition near the band edge, which exists in the pure delafossite compounds. Moreover, the bandgap of the quaternary delafossite alloy can be further tuned through alloy composition and ordering, thus improving the flexibility in designing delafossite-based PEC photo-electrodes. Figure 2 shows a few examples of mixed Cu delafossites. Figure 2(a) shows the structure of Cu(Y,Ga)O$_2$, where Ga substituted at Y site with a 1:1 ratio. The crystal structure (type-I), Ga- and Y-based octahedrons are separated by the O-Cu-O chain, i.e., Ga and Y are not present in the same octahedron layers. Figure 2(b) shows the structure (type-II) with the same composition of the structure shown in Figure 2(a). However, Ga and Y are present in the same octahedron layers. Figure 2(c) shows the structure of Cu(Y,Ga,In)O$_2$, where the ratio of Y:Ga:In is 2:1:1.

Figure 3 shows the calculated optical absorption coefficient for the three isovalent alloys. For comparison, the optical absorption coefficient of pure CuYO$_2$ is also given. Due to this mixed nature of the CBM, the transition matrix element is no longer zero. However, the matrix element is still not very large because for this isovalent alloy, the wavefunction mixing is relatively small. Nevertheless, the breakdown of the inversion symmetry should help to improve the near-band-edge absorption. The 50%-50% alloy, however, has an indirect bandgap with its VBM away from $\Gamma$, which may not be desirable for PEC application. However, this can be remedied by further band engineering, e.g., by reducing the Ga concentration. The absorption onset
of the type-II alloy is slightly lower in energy; however, the absorption increase is faster for the type-I layer structure, and both show remarkable improvements over bulk CuYO\textsubscript{2}. The direct bandgap for Cu(Y,Ga,In)O\textsubscript{2} at Γ point is 1.725 eV. Close inspection of the absorption curve also shows the onset of absorption at the same energy. This indicates that first, the bandgap is reduced further from the type-I and type-II alloys, and second, the absorption at the Γ point is not suppressed.

BiVO\textsubscript{4} is a promising photocatalyst for hydrogen generation, with demonstrated experimental potential in terms of bandgap, stability, and conductivity. Recent experiments have shown that doping of W can significantly enhance the PEC performance of BiVO\textsubscript{4}. Therefore, we have calculated the doping effects of W in BiVO\textsubscript{4}.

Figure 4 shows our preliminary results of doping of W in BiVO\textsubscript{4}. Figure 4(a) shows the calculated band structure of a BiVO\textsubscript{4} supercell with one W at a V site. We found that the band structure is very similar to that of pure BiVO\textsubscript{4}, indicating that substitutional W at V sites do not create any deep level in the bandgap and the W’s states are much higher in energy than the CBM. This is seen in the site projected density-of-state plot shown in Figure 4(b). These results indicate strongly that substitutional W atoms at V sites are degenerate donors, which are the most preferred donor states. We have also considered substitutional W atoms at Bi sites. We found that they are also shallow donors. However, our preliminary results indicate that W prefers the V site more than Bi due to better atomic size matching.

**Conclusions and Future Directions**

We have calculated the electronic structure of Cu delafossites and W doping in BiVO\textsubscript{4} using DFT. We have provided a detailed understanding on the different electronic structure for group-IIIA and group-IIIB delafossites. We have understood why the Cu delafossites have insufficient optical absorption in the visible-light regime, and we have demonstrated that significant bandgap modification can be achieved by isovalent alloying of Cu-based delafossites. This alloying significantly improves the optical absorption at lower energy because it reduces the crystal symmetry, thus lifting the parity-forbidden transition near the band edge, which exists in the pure delafossite compounds. Moreover, the bandgap of the quaternary delafossite alloy can be further tuned through alloy composition and ordering, thus improving the flexibility in designing delafossite-based PEC photo-electrodes. Our preliminary results have shown that W doping in BiVO\textsubscript{4} may enhance the n-type conductivity. In future study, we will provide a detailed understanding of defect physics in BiVO\textsubscript{4}, including the formation energies and transition energies of intrinsic and extrinsic defects.

Future directions will include the following:

- Perform a detailed study of defect physics in BiVO\textsubscript{4}.
- Design new metal oxides with desirable optical absorption, band-edge positions, and transport properties.
- Extend our study to non-oxide materials, such as nitrides, carbides, and sulfides.

Accomplishments

- Improvement in a hybrid photovoltaic (PV)/a-SiC device consisting of amorphous silicon (a-Si) tandem solar cell and amorphous silicon carbide (a-SiC) photoelectrode, which exhibits the following PEC performance:
  - Photocurrent of a solid-state PV/a-SiC/indium tin oxide (ITO) (illuminated through ITO) device exhibited ~5 mA/cm².
  - Photocurrent of an actual PV/a-SiC PEC device increased to 1.26 mA/cm², or equivalent to a STH efficiency of ~1.6%.
  - Good durability in pH_2 buffered electrolyte for up to 200 hours.

Objectives

- Work closely with the DOE Working Group on PEC Hydrogen Production to develop and employ new theoretical, synthesis and analytical techniques for optimizing PEC materials and devices.
- Develop new PEC film materials compatible with high-efficiency, low-cost hydrogen production devices based on amorphous-silicon-compound, tungsten-compound and copper-chalcopyrite compound classes of thin films.
- Demonstrate functional multi-junction device incorporating best-available PEC film materials developed.
- Explore avenues toward manufacture-scaled devices and systems.

Technical Barriers

This project addresses the following technical barriers from the “Photoelectrochemical Hydrogen Production” section of the Fuel Cell Technologies
Introduction

Based on its potential to meet long-term goals, research and development (R&D) centering on multijunction hybrid photoelectrode technology defines the scope of this collaborative project. Within this scope, particular emphasis is placed on the most critical materials-research components in terms of efficiency, durability and cost. To achieve 7.5% STH conversion efficiency and up to 500-hour operational life along with production cost goals, the development of low-cost photoactive materials with photocurrents >6 mA/cm² and with sufficient durability to meet the lifetime requirement is the key focus. Development of specific thin-film materials classes with promising PEC potential, including tungsten-based compounds (such as metal and mixed-metal oxides, oxy-nitrides, oxy-sulfides, etc.), copper-chalcopyrite compounds (including CIGSe₂, CGSe₂, etc.) and silicon-based compounds (such as silicon carbide and silicon nitride) is the specific focus of this R&D project. In addition to the materials R&D activities, development of laboratory-scale demonstration devices and generation of preliminary commercialization studies is included in the project scope as second-level priorities. To support the device-demonstration activities, appropriate auxiliary components have been developed for incorporation in the PEC photoelectrode designs (i.e., the hybrid PV/a-SiC PEC cells). It is the central objective of the MVSystems project team to work closely with the DOE Working Group on PEC Hydrogen Production to develop pathways for successful PEC hydrogen technologies.

Approach

The general approach of this collaborative effort focuses on the DOE PEC Working Group’s “feedback” philosophy integrating state-of-the-art theoretical, synthesis and analytical techniques to identify and develop the most promising materials classes to meet the PEC challenges in efficiency, stability and cost. Materials modeling, bulk-film optimization, film-surface enhancement, along with comprehensive material and device characterization is being employed to facilitate the R&D process. Specifically, the feedback approach is being applied to our focus material classes, including the tungsten-, copper-chalcopyrite- and silicon-based compounds, to enhance understanding of fundamental performance parameters, and expedite development of process-compatible forms of these materials. The primary objective of the materials research efforts is the development of films which meet photocurrent and durability goals and which are compatible with device fabrication. The most promising candidate materials will be identified, with the short-term goal of demonstrating laboratory-scale water-splitting devices, and with a long-term goal of transferring the fabrication processes toward the commercial-scale.

Results

During this reporting period (June 2009–June 2010), extensive studies of the three materials classes under investigation have focused on understanding and improving photoelectrochemical behavior, specifically by applying our theoretical, synthesis and analytical techniques in identifying relevant aspects of structural, optoelectronic and electrochemical properties. Progress in developing of amorphous silicon carbide-based compound films is detailed in the following subsections.

During this project period, further improvement of the PEC performance of the hybrid PV/a-SiC device has been made. Figure 1 shows a schematic diagram for the solid-state version of the hybrid PEC device, with ITO as the top contact. Using this configuration, we aimed to optimize both the a-SiC photoelectrode and the a-Si tandem solar cell beneath the photoelectrode. Under AM1.5 Global spectrum, we have so far achieved a photocurrent of ~4.2 mA/cm² (at 1.23 V), indicating a potential STH efficiency of >5%.

In actual hybrid PV/a-SiC devices, due to existence of interfacial barrier at a-SiC/electrolyte interface, extraction of photocurrent is found to be severely suppressed, leading to a very low photocurrent of <1 mA/cm² (see Annual Report 2009). To overcome the over-potential loss, we have performed a wide variety of surface modifications on the hybrid device, including hydrofluoric acid (HF) etch (to remove thin SiOₓ on the surface) and metal nanoparticle treatment. As a result, photocurrent of the hybrid device is increased. Figure 2(a) shows current vs. potential characteristics of devices performed before and after HF etching. The testing conditions were: set-up - 2-electrode; light source - AM1.5G (calibrated with a reference cell); counter
electrode: RuO$_2$ (ruthenium oxide); electrolyte: pH$_2$ buffer + Triton-X; HF etch: using HF 5% for 1.5 minutes. It is seen that photocurrent at zero potential reaches ~1.3 mA/cm$^2$, or an equivalent STH efficiency of ~1.6%.

In addition, we also performed surface treatment on the a-SiC photoelectrode and the hybrid PV/a-SiC device using metal nanoparticles, including platinum (Pt), gold/palladium (Au/Pd) and titanium (Ti). Figure 2(b) shows a scanning electron microscope photo image on a Ti nanoparticle coated sample. The metal nanoparticle layer was fabricated using sputtering method, and the size of nanoparticles is of a few nanometers. We have observed that the metal with lower metal function (e.g., Ti) is more effective in enhancing photocurrent than those metals with high work function (e.g., Pt, Au/Pd). This behavior is probably due to the surface barrier caused by the high work function metals. Work is currently underway to understand the mechanism, and to explore other surface modification methods in order to further enhance the photocurrent.

We have also made progress in further increasing the durability of the hybrid devices, which exhibits good durability for up to 200 hours. Figure 3 shows the current vs. potential characteristics of a hybrid device, measured during the course of the durability test. Compared with the initial current density-voltage (J-V) curve (black), the dark current shows virtually no increase, indicating no corrosion on the device; whereas the photocurrent shows a slight increase, possibly due to changes in the surface structure (the mechanism behind these changes is not well understood). The surface of the device shows a color change but remains largely smooth (not shown here).

**Conclusions and Future Directions**

This project is accelerating the development of three important PEC thin-film materials classes (a-SiC, WO$_3$ and CGSe) with high potential for reaching DOE goals of practical PEC water-splitting. The project benefits from existing knowledge of the three PEC thin-film materials and their PV performances to apply them to a PEC system for hydrogen production. For each material, barriers were identified and major improvements are currently being made to improve PEC performances. New surface modification techniques were investigated, surface treatments (a-SiC, CGSe, WO$_3$), bilayer formation (WO$_3$) and new device integration schemes (CGSe and WO$_3$). Bulk modifications were also investigated, such as partial copper replacement with silver to form ACIGSe film to modify energy band position. Resulting interface and bulk energy band positions will be characterized using advanced spectroscopic techniques. These new information will guide our research on device fabrication and device matching efforts effectively.

It is the central objective of the MVSystems project team to work closely with the DOE Working Group on PEC Hydrogen Production to develop pathways for successful PEC hydrogen technologies.

**Approach**

The general approach of this collaborative effort focuses on the DOE PEC Working Group’s “feedback” philosophy integrating state-of-the-art theoretical, synthesis and analytical techniques to identify and develop the most promising materials classes to meet the PEC challenges in efficiency, stability and cost. Materials modeling, bulk-film optimization, film-surface enhancement, along with comprehensive material and device characterization is being employed to facilitate the R&D process. Specifically, the feedback approach is being applied to our focus material classes, including the tungsten-, copper-chalcopyrite- and silicon-based compounds, to enhance understanding of fundamental performance parameters, and expedite development of process-compatible forms of these materials. The primary objective of the materials research efforts is the development of films which meet photocurrent and durability goals, and which are compatible with device fabrication. The most promising candidate materials will be identified, with the short-term goal of demonstrating laboratory-scale water-splitting devices, and with a long-term goal of transferring the fabrication processes toward the commercial-scale.

**Results**

During this reporting period of the project (June 2009–June 2010), extensive studies of the three materials classes under investigation have focused on understanding and improving photoelectrochemical behavior, specifically by applying our theoretical, synthesis and analytical techniques in identifying relevant aspects of structural, optoelectronic and electrochemical properties. Specific progress in developing tungsten oxide-based compound films is detailed in the following subsections.

In our general approach, each component of the PEC electrode is addressed, from the absorber (bulk) to the surface energetics (near-surface) and catalysis (surface). This year, progress was achieved toward foreign element incorporation to reduce tungsten oxide bandgap. Here, we proposed to fabricate in our laboratory our own sputtering targets made of blended powders. With this method, the amount of both WO₃ and foreign elements can be easily controlled, leading to a much easier elaboration process when compared to co-sputtering techniques. Preliminary tests were done with WO₃ nanopowder only. After compaction and sintering at 1,200°C for 3 hours, the solid WO₃ body (2-inch diameter disc) was transferred to the sputtering chamber and several depositions were performed. Initial results indicated that WO₃ optoelectronic properties (optical transmission and bandgap) were easier to control when compared to initial process where a pure tungsten target is used. Photo-electro-chemical tests pointed out also that comparable performances were obtained with this method. In a second phase, powder blends were sintered to form new sputtering targets. Since nitrogen has been evaluated as possible foreign element candidate to decrease WO₃ bandgap, our research was initially focused on nitride-based powder. A top-view scanning electron microscopy (SEM) micrograph of a WO₃:BN (95 wt% / 5 wt%) is presented in Figure 1. Again, a very good powder sintering is observed (coalesced grains), leading to a solid body. Depositions of WO₃:BN materials are currently being performed to define optimum process parameters.

Research on tungsten oxide surface catalytic treatment continued and major improvements on RuO₂ nanoparticles and nanorods synthesis were achieved. Preliminary research in our laboratory on reactively sputtered RuO₂ thin films already demonstrated high catalytic activity for oxygen evolution reaction, where O₂ was generated with overpotential as low as 0.2 V. Nanoparticles (4-8 nm in diameter) were synthesized on WO₃ thin film using similar reactive sputtering process (Ru pure target, O₂/Ar ambient, 250°C). Current vs.
voltage characteristics measured on WO₃ PEC electrode covered or not with RuO₂ nanoparticles are presented in Figure 2. No modification of both the dark current and saturated photocurrent was observed in this experiment. However, one can notice that the presence of RuO₂ nanoparticles on WO₃ thin films yield a better “fill-factor” when compared to the WO₃ witness sample, with a photocurrent increase of about 20% at 1.2 V vs. the saturated calomel electrode. Current research is focused on ruthenium oxide nanorods (120 nm long, 20 nm wide) synthesis. It is believed that extended contact area between nanorods and the electrolyte could improve charge carriers injection at the WO₃/electrolyte interface.

Finally, the possible use of highly textured substrates (HTS) in PEC applications to increase the photocurrent density was evaluated in our laboratory. With this technique, the developed area is expected to be larger than the projected one, increasing the overall photocurrent density (normalized to the sample area). HTS used were obtained by anisotropic etching of silicon wafers using potassium hydroxide (KOH) solution. Because of orientation-dependant etching ([110]>[100]>[111]), KOH treatment leads to a textured Si substrate made of pyramids with base width ranging from 5 to 20 µm. Tungsten oxide was then deposited on HTS using reactive sputtering technique. Figure 3 presents a cross-section SEM micrograph of one of this sample. The PEC performances of WO₃ thin films deposited on HTS are presented in Figure 4. Also presented in this graph are the PEC performances measured on a WO₃ deposited on flat silicon substrate (control sample). To allow a direct comparison, photocurrent density values were normalized to the maximum photocurrent density measured in the case of a flat silicon substrate at 2.5 V vs. SCE. First, one can directly observe the net photocurrent density increase when HTS are used. It is also interesting to note that a higher fill factor is achieved with HTS. Thus, it is believed that, in addition to the geometric factor, the HTS enable better harvesting of incoming normal irradiance, either by limiting the surface reflection or simply by increasing the optical path in the tungsten oxide thin film.
Conclusions and Future Directions

This project is accelerating the development of three important PEC thin-film materials classes (a-SiC, WO$_3$, and CGSe) with high potential for reaching DOE goals of practical PEC water-splitting. The project benefits from existing knowledge of the three PEC thin-film materials and their PV performances to apply them to a PEC system for hydrogen production. For each material, barriers were identified and major improvements are currently being made to improve PEC performance. New surface modification techniques were investigated, surface treatments (a-SiC, CGSe, WO$_3$), bilayer formation (WO$_3$) and new device integration schemes (CGSe and WO$_3$). Bulk modifications were also investigated, such as partial copper replacement with silver to form ACIGSe film to modify energy band position. Resulting interface and bulk energy band positions will be characterized using advanced spectroscopic techniques. These new information will guide our research on device fabrication and device matching efforts effectively.

Contract Number: DE-FG36-07GO17105

Subcontractor: University of Hawaii at Manoa (UH), Honolulu, HI

Project Partner: National Renewable Energy Laboratory (NREL), Golden, CO

Project Start Date: November 1, 2007
Project End Date: August 31, 2011

Objectives

• Work closely with the DOE Working Group on Photoelectrochemical (PEC) Hydrogen Production to develop and employ new theoretical, synthesis and analytical techniques for optimizing PEC materials and devices.
• Develop new PEC film materials compatible with high-efficiency, low-cost hydrogen production devices based on amorphous-silicon-compound, tungsten-compound and copper-chalcopyrite compound classes of thin films.
• Demonstrate functional multi-junction device incorporating best-available PEC film materials developed.
• Explore avenues toward manufacture-scaled devices and systems.

Technical Barriers

This project addresses the following technical barriers from the “Photoelectrochemical Hydrogen Production” section of the Fuel Cell Technologies Program Multi-year Research, Development and Demonstration Plan:

(Y) Materials Efficiency
(Z) Materials Durability
(AA) PEC Device and System Auxiliary Material
(AB) Bulk Materials Synthesis
(AC) Device Configuration Designs

Technical Targets

The specific targets of this project are (a) the demonstration of a PEC solar-hydrogen production system with 7.5% solar-to-hydrogen (STH) conversion efficiency (b) operational life up to 500 hours and (c) the identification of commercialization paths toward a $22/kg-$5/kg by 2015. Table 1 shows detailed milestones year by year.

Accomplishments

• Material photocurrents are in excess of goals.
• Surface and bulk modifications are improving feasibility of completed device.
• Planned device can achieve 5% STH efficiency.
Introduction

Based on its potential to meet long-term goals, research and development (R&D) centering on multijunction hybrid photoelectrode technology defines the scope of this collaborative project. Within this scope, particular emphasis is placed on the most critical materials-research components in terms of efficiency, durability and cost. To achieve 7.5% STH conversion efficiency and up to 500-hour operational life along with production cost goals, the development of low-cost photoactive materials with photocurrents >6 mA/cm² and with sufficient durability to meet the lifetime requirement will be the key focus. Development of specific thin-film materials classes with promising PEC potential, including tungsten-based compounds (such as metal and mixed-metal oxides, oxy-nitrides, oxy-sulfides, etc.), copper-chalcopyrite compounds (including CIGSe, CGSe, etc.) and silicon-based compounds (such as silicon carbide and silicon nitride) are the specific focus of this R&D project. In addition to the materials R&D activities, development of laboratory scale demonstration devices and generation of preliminary commercialization studies is included in the project scope as second-level priorities. To support the device-demonstration activities, appropriate auxiliary components have been developed for incorporation in the PEC photoelectrode designs (i.e., the hybrid PV/a-SiC PEC cells). It is the central objective of the MVSystems project team to work closely with the DOE Working Group on PEC Hydrogen Production to develop pathways for successful PEC hydrogen technologies.

Approach

The general approach of this collaborative effort focuses on the DOE PEC Working Group’s “feedback” philosophy integrating state-of-the-art theoretical, synthesis and analytical techniques to identify and develop the most promising materials classes to meet the PEC challenges in efficiency, stability and cost. Materials modeling, bulk-film optimization, film-surface enhancement, along with comprehensive material and device characterization is being employed to facilitate the R&D process. Specifically, the feedback approach is being applied to our focus material classes, including the tungsten-, copper-chalcopyrite- and silicon-based compounds, to enhance understanding of fundamental performance parameters, and expedite development of process-compatible forms of these materials. The primary objective of the materials research efforts is the development of films which meet photocurrent and durability goals and which are compatible with device fabrication. The most promising candidate materials will be identified, with the short-term goal of demonstrating laboratory-scale water-splitting devices, and with a long-term goal of transferring the fabrication processes toward the commercial scale.

Results

Progress in the study of copper chalcopyrite-based thin films of the formula \( (\text{Cu} \text{Ag}_{1-x}) \text{In}_{y} \text{Ga}_{1-y} \text{Se}_{1-z} \) for PEC water splitting this period has been focused on device integration. While copper chalcopyrite-based films are capable of high photocurrents, band misalignments currently preclude current extraction without superfluous external voltages. This particular problem has been addressed through bulk, surface and device modifications.

The typical baseline absorber film is CuGaSe₂ (CGSe), which has the highest attainable bandgap in the Cu(InₓGa₁₋ₓ)Se₂ system of ~1.68 eV. CGSe is capable of high photocurrents but only at an impractically high external voltage bias. Bulk modification has led to the best cells produced in this material class which are CuInGaS (CIGS) films (fabricated at the Helmholtz Zentrum Berlin in 2009). While performing well, these “sulfide” cells are still inadequate for a monolithically integrated hybrid (photovoltaic [PV]/PEC) photoelectrode (HPE) device shown in Figure 1 where voltage is supplied by underlying PV cells harvesting passed sub-bandgap photons.

Bulk modification was also pursued by replacing Cu with Ag, which can raise the bandgap and more properly align the band edges. Films were fabricated with a formula of Ag(InₓGa₁₋ₓ)Se₂ (AIGSe) with a bandgap only slightly lower than CGSe showing an expected n-type conduction, which is not ideal but, with a sufficient voltage, photocurrents nearly as high as that in typical CGSe films (~15 mA/cm²) could be extracted from AIGSe films (Figure 2). These films showed that Cu replacement with Ag did indeed move the band edges, but full replacement moved them an extreme amount beyond our desired levels. Further tests exploring partial replacement of Cu with Ag will
Surface modifications were also performed with PdAu nanoparticles sputtered onto the surface of CGSe films. The results, shown in Figure 3, show an improvement in the “fill factor”, however, onset voltage remains unchanged. These surface treatments can be used to extract a few more mA/cm² of any as-fabricated film in this material class.

Currently unable to monolithically integrated devices, Figure 4 shows a co-planar HPE device. The DOE goal of 5% STH can be theoretically (from numerical calculations) achieved using available materials. This device is of course impractical, however it develops a pathway towards creating a viable device. Work is underway to both fabricate these cells as standalone devices and improve upon their design.

Conclusions and Future Directions

The MVSystems/UH project is accelerating the development of three important PEC thin-film materials classes (a-SiC, WO₃, and CGSe) with high potential for reaching DOE goals of practical PEC water-splitting. The project benefits from existing knowledge of the three PEC thin-film materials and their PV performances to apply them to a PEC system for hydrogen production. For each material, barriers were identified and major improvements are currently being made to improve PEC performances. New surface modification techniques were investigated, surface treatments (a-SiC, CGSe, WO₃), bilayer formation (WO₃) and new device integration schemes (CGSe and WO₃). Bulk modifications were also investigated, such as partial copper replacement with silver to form CAIGSe film to modify energy band position. Resulting interface and bulk energy band positions will be characterized using advanced spectroscopic techniques. These new information will guide our research on device fabrication and device matching efforts effectively.

Contract Number: DE-FG36-05GO15028
Subcontractors:
• University of Toledo, Toledo, OH
• National Renewable Energy Laboratory (NREL), Golden, CO

Project Start Date: April 1, 2005
Project End Date: December 31, 2011

Objectives
• To develop critical technologies required for cost-effective production of hydrogen from sunlight and water using thin-film silicon (tf-Si)-based photoelectrodes.
• Two approaches are taken for the development of efficient and durable photoelectrochemical (PEC) cells:
  – An immersion-type PEC cell in which the photoelectrode is immersed in electrolyte.
  – A substrate-type PEC cell in which the photoelectrode is not in direct contact with electrolyte.

Technical Barriers
This project addresses the following technical barriers from Photoelectrochemical Hydrogen Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (MYPP):
(Y) Materials Efficiency
(Z) Materials Durability
(AB) Bulk Materials Synthesis
(AC) Device Configuration Designs
(AD) Systems Design and Evaluation

Technical Targets
This project focuses on the development of photoelectrode materials and tf-Si-based PEC cells required to achieve or exceed DOE's technical targets. The status of this project towards achieving the DOE MYPP technical targets for PEC production of hydrogen for 2015 is:

</table>

TCCR = transparent, conducting and corrosion-resistant; PAS = photoactive semiconductor; PV = photovoltaic

Accomplishments
• A 12”×12” substrate-type PEC cell model was fabricated and has been tested twice so far, however leaks exist in the framework.
• TCCR coatings and H₂ evolution catalysts were developed (Task 1).
For use as TCCR material In$_2$O$_3$-Fe$_2$O$_3$ work was completed and published in the Journal of Materials Research.

Large-area electroplating of porous Ni as H$_2$ evolution catalyst has been developed using precursor salts in order to improve and optimize the porous structure of the films for improved performance.

Facilities for large-area processing of substrate-type PEC cells have been established; processes for PEC components are under development (Task 5).

The effect of back reflector on amorphous silicon (a-Si) photoelectrodes was studied and material properties were optimized.

The current collection grid for a-Si photoelectrodes, which will incorporate a PAS layer, was optimized considering optimal bus bar thickness.

---

**Introduction**

This project and its subcontractors are jointly developing the critical technologies required for cost-effective production of hydrogen from sunlight and water using tf-Si-based photoelectrodes. These triple-junction tf-Si-based electrodes include triple cells with either amorphous silicon germanium alloy (a-SiGe) or microcrystalline silicon (μc-Si) as the narrow band gap absorber material.

In this project two separate approaches have been pursued for the development of immersion- and substrate-type PEC photoelectrodes:

- In one approach, triple-junction tf-Si-based photoelectrodes (a-Si/a-SiGe/a-SiGe or a-Si/a-SiGe/μc-Si) are used to generate the voltage bias necessary for hydrogen generation. A TCCR coating is deposited on top of the photoelectrode for protecting the semiconductor layers from corrosion while forming an ohmic contact with the electrolyte.

- The second approach uses a hybrid structure, in which two tf-Si-based junctions (middle and bottom junctions of the present triple-junction tf-Si cell) provide a voltage bias of about 1.1 V, and a third junction (the top junction) forms a rectifying junction between a PAS and the electrolyte.

State-of-the-art a-Si/a-SiGe/a-SiGe and/or a-Si/a-SiGe/μc-Si devices are used as photoelectrodes. The corrosion resistance and PEC mechanisms for a range of oxide-, nitride- and carbide-materials, and II-VI compounds are under investigation. High-performance, durable PEC cells and systems will be developed, optimized and demonstrated in this project.

---

**Approach**

Five technical tasks are being performed under this grant in order to accomplish the project objectives:

- Task 1: Transparent, conducting and corrosion resistant coating for a triple-junction tf-Si-based photoelectrode.
- Task 2: Hybrid multi-junction PEC electrode having semiconductor-electrolyte junction.
- Task 3: Understanding and characterization of photo-electrochemistry.
- Task 4: Development of device designs for low-cost, durable and efficient immersion-type PEC cells and systems.
- Task 5: Development of device designs for large area, substrate-type PEC cells.

---

**Results**

Tasks 1 focuses on the preparation of TCCR coatings deposited onto the top of the tf-Si photoelectrode. During this reporting period emphasis was focused on the completion of work on fabricating and characterizing In$_2$O$_3$-Fe$_2$O$_3$ films; results and findings were published in the Journal of Materials Research. The TCCR films were deposited using radio-frequency magnetron sputter deposition in argon and oxygen using multiple sputter guns simultaneously. From the completed work, the results indicate that samples made at 250°C with 30 W of In and 100 W of InFe$_2$O$_4$ and a sputter deposition time of ninety minutes produced optimal results.

Under Task 2 a method for large-area electroplating of porous Ni used as H$_2$-evolution catalyst has been developed. Over the past year work has focused on the addition of precursor salts such as zinc chloride, zinc nitrate, and copper sulfate to the plating solution in order to improve micro- and macro-structures of the porous nickel films. The method uses the co-deposition of Ni and Zn (or another precursor metal) onto the back-side of tf-Si photoelectrodes; after Ni/Zn electrodeposition Zn is leached out leaving a porous Ni-structure behind. At this stage of research, zinc chloride shows the best results, which is shown in Table 2. The goal of electroplated nickel project is to develop materials that meet or exceed the performance of the industry standard of platinum-coated nickel. Table 2 is presented to show results from our latest experiments to improve upon the standard that we have developed previously in our lab.

Under Task 2 a method for large-area electroplating of porous Ni used as H$_2$-evolution catalyst has been developed. Over the past year work has focused on the addition of precursor salts such as zinc chloride, zinc nitrate, and copper sulfate to the plating solution in order to improve micro- and macro-structures of the porous nickel films. The method uses the co-deposition of Ni and Zn (or another precursor metal) onto the back-side of tf-Si photoelectrodes; after Ni/Zn electrodeposition Zn is leached out leaving a porous Ni-structure behind. At this stage of research, zinc chloride shows the best results, which is shown in Table 2. The goal of electroplated nickel project is to develop materials that meet or exceed the performance of the industry standard of platinum-coated nickel. Table 2 is presented to show results from our latest experiments to improve upon the standard that we have developed previously in our lab.

Task 5 focuses on the development of processing procedures for large-area photoelectrodes. Under this task sintered electrocatalysts employed as anodes in substrate-type PEC cells were developed. Thin film Si-based PEC cells employ preferentially back reflectors for re-directing unabsorbed incident light back through
the semiconductor layer enhancing the solar-to-hydrogen conversion efficiency of the device. A study was conducted addressing the long-term reliability of the back-reflector: tests conducted in a high humidity environment were used for evaluating the device stability. The fill factor for devices employing different back-reflector films were measured after numerous hours of highly accelerated stress test exposure. The experimental variable in this study is the composition of the back-reflector the tf-Si material is deposited onto. We tested numerous back-reflector compositions and we identified a specific composition providing the best stability under hot and humid conditions, which will translate into improved long-term reliability of PEC cells. We are planning to use this back-reflector for fabricating large-area PEC systems.

Conclusions and Future Directions

The proposed future work will include:

- Continue optimization of present oxide materials suitable for TCCR coatings:
  - Material class studies will be focusing on In$_2$O$_3$-Co$_2$O$_3$.
- Continue optimization of present oxide materials suitable for PAS coatings:
  - Material class studies will be focusing on Fe$_2$O$_3$-WO$_3$.
- Develop chemical plating for materials suitable for PAS and TCCR coatings for immersion-type hybrid PEC cells.
- Leveraging our resources on building a prototype for large-area (1 ft×1 ft) substrate-type PEC.
- Design of final substrate-type PEC will employ porous Ni as H$_2$ evolution catalyst electroplated onto the backside of stainless steel substrates with a triple junction a-Si device on the front-side.
- Long-term reliability studies and solar-to-H$_2$ efficiency measurements will be performed.
- Develop 4”×4” immersion-type PEC cells:
  - Long-term reliability studies and solar-to-H$_2$ efficiency measurements will be performed.
- Improve performance of large-area photoelectrodes.
- Complete techno-economic analysis and energy analysis for the PEC systems for hydrogen production.

II.G.11 Photoelectrochemical Generation of Hydrogen*

Technical Targets

- Solar-to-hydrogen (STH) efficiency: 10% by 2015 by developing photoanodes having efficient light absorption in the visible range and a long-term corrosion resistance.
- Hydrogen production cost: $3.00/gge (approximately 1 kg of H₂) by 2018 by optimizing the generation process and the storage of hydrogen.

Accomplishments

- Plasma treatments of photoanodes for (a) minimizing charge carrier traps and contaminants, (b) doping the photoanode surface with nitrogen, and (c) creating oxygen vacancies for achieving high photocurrent density.
- Optimization of the surface structure of the nanotubes to improve light absorption.
- Use of layered electrodes of titanium disilicide (TiSi₂) and titanium dioxide (TiO₂) for light absorption in the visible range.
- Development of processes for synthesizing layered patterned nanotubular electrodes.
- Increased photocurrent density by more than 80% by plasma treatments and enhanced light absorption by 55% with modified nanotubular structure.
- Patent application and publication of papers reporting our work.

Introduction

During the last four decades, PEC production of hydrogen has been intensively investigated due to the advantages of the PEC method: (1) potential for direct conversion of sunlight for generating pure hydrogen, (2) high quantum efficiency of several semiconductors over nearly the entire spectrum of solar radiation, (3) possible application of inexpensive and environmentally safe materials for large scale operation, and (4) relatively low capital and operating costs.

The current barriers that prevent commercialization of the PEC technology for hydrogen production are: (1) lack of semiconducting materials that will have two essential properties: (a) bandgap for harvesting sunlight from 360 to 860 nm in wavelength for splitting water into hydrogen and oxygen and (b) high corrosion resistance of the semiconducting photoanodes during electrolysis of water, and (2) poor transfer efficiency of the photo-generated charge carriers at the interface between the solid electrode and the liquid electrolyte.
No single or compound semiconductor photoanode has been found which satisfy these critical requirements [1-3]. Several nanostructural designs have emerged as are the choices of materials, but an efficient process with optimal photo-conversion efficiency is yet to be realized for commercialization of the PEC process. The aim of our project is to engineer chemically stable photoanodes which will have a bandgap with high light absorption efficiency and yet straddle the reduction and oxidation chemical potentials of water and meet the DOE goals for hydrogen production.

**Approach**

To address the current barriers, our approach is to develop a hybrid nanostructured photoanode comprised of thin-film layers of TiO₂ covering nanotubes of TiSi₂. The latter has a high efficiency in light absorption covering the visible solar spectrum. The layered nanotubular electrodes can be arranged in a patterned array for trapping sunlight, providing large effective area for electrolysis, and corrosion protection by the titania film.

The photoactive materials from the silicide and titania family have the potential to overcome deficiencies of single metal oxide photoanodes. While the nanostructure greatly improves the reaction surface area and light absorption, the efficiency of the charge carrier transport and the corrosion resistance need to be investigated for different heterostructures including layered films, nanotubes and nanoparticles.

Interfacial charge carrier transfer phenomena govern the PEC-based hydrogen generation process. While the role of surface and interface states in the charge carrier transport and the necessity for matched lattice structure in using heterostructured semiconductors (such as TiO₂ and TiSi₂) have been reported in the literature, the chemical and physical control mechanisms for mitigating the losses due to the presence of charge carrier traps and minimization of photocorrosion of the electrodes are yet to be established. Fundamental studies are needed in the design of the PEC process, including the synthesis of nanostructured photoanodes to provide the desired bandgap, surface structure, and corrosion resistance. Optimization of operational parameters such as the optical system for collecting sunlight, collection, storage of hydrogen, and the control system for monitoring the safety and production efficiency of the process needs to be pursued. Our experimental studies are aimed to: (1) remove surface contaminants [3-8] and surface states that act as charge carrier traps, (2) apply plasma surface modification [9-11], using a reactor as shown in Figure 1, for surface cleaning as well as for surface doping of the photoanodes with n-type dopants (N), (3) optimize the structure of the nanotubes by varying anodization voltage for increasing light absorption, (4) use layered electrodes of TiSi₂ and TiO₂, and (5) evaluate surface-modified nanostructured layered photoanodes for photoelectrochemical generation of hydrogen.

**Experimental Studies**

TiO₂ semiconductor has been extensively used for PEC-based hydrogen production. It has an ionic crystal structure and its surface lattice oxygen ions are not surrounded by Ti cations on a clean surface. These surface oxygen atoms act as donor surface states in the gap region above the valence band edge. These donor states can increase the production of photogenerated electrons in the visible range but the donor states at the surface act as efficient traps for the holes and reduces the PEC oxidation of water. Similarly, the adsorbates on the electrode surface can form chemical bonds with the atoms of surface contaminants forming extrinsic surface states. We have used helium plasma treatment for minimizing the density of these extrinsic surface states which improved the charge carrier transport significantly.

As the surface adsorbates [9-13] were removed by helium plasma cleaning, the surface atoms of TiO₂ are exposed. The dangling bonds of the metal and the oxygen atoms on the surface give rise to acceptor and donor states respectively. For an n-type semiconductor like TiO₂, it is desirable to have vacant acceptor states to increase the barrier height φ. Nitrogen plasma treatment was used to increase vacant acceptor states and the barrier height enhancing the migration of holes from the electrode surface to the electrolyte for oxidizing water.

A self-assembled vertically ordered nanotubular TiO₂ array, which has been considered to be an ideal architecture for photoelectrolysis, was synthesized and used in this study. The development of nanotubular electrode structure resulted in a significant improvement of electron conduction, rapid diffusion of holes for oxidation, and an increase of the effective surface area of the photoanodes. The nanotubular structure increases the effective surface area for light absorption.
as well as for photocatalysis, however, nanostructured surface increases the density of surface states which can affect photoactivity either positively or negatively depending upon if these sites are electron traps or hole traps. Minimizing the surface density of the hole traps is essential for oxidizing water with n-type photoanodes. We used nitrogen plasma for minimizing the hole traps.

Recent studies report that TiSi₂ (a) has a significant absorption of light over most of the AM 1.5 solar energy spectrum ranging from 1.4 eV (λ≈860 nm) to 3.4 eV (λ≈360 nm), (b) is photoactive in generating hydrogen by splitting water, but (c) has a low photocorrosion resistance. Our experiments showed light absorption of TiSi₂ micro-particles in the visible range of the solar spectrum providing a photocurrent density of 3.0 mA/cm² when we used TiSi₂ particles along with TiO₂ nanotubular photoanode. We are investigating different structures of TiSi₂ photoanodes covered by a thin TiO₂ film to maximize light absorption while protecting the electrodes against photocorrosion.

The test photoanodes prepared for evaluating the photoelectrolytic properties were annealed under both oxygen and nitrogen atmospheres achieve crystallization of TiO₂ in its anatase form.

The PEC apparatus used for measuring photocurrent density of the test photoanodes under dark and illuminated conditions consisted of (1) a potentiostat/galvanostat electrochemical instrument model 283, (2) a Xenon lamp (30 mW), (3) a 60 mm-diameter quarts optical window, and (4) a reference electrode (Ag/AgCl) placed close to the photoanode. The electrolyte used was 1M potassium hydroxide (pH~14) + deionized water solution.

**Results**

X-ray photoelectron spectroscopy (XPS) analysis indicated the incorporation of N in titania lattice structure of the photoanode surface. As shown in Figure 2, the narrow scan N 1s spectrum is demonstrated at 400 and 396 eV, which has been ascribed to the presence of nitrogen in the lattice structure either as substitutional dopants for O, or as interstitial dopants in the TiO₂ crystal structure.

Nitrogen plasma treatment of titania photoanodes resulted in 80% increase in photocurrent density as shown in Figure 3. Plasma surface cleaning with helium plasma and surface doping by nitrogen plasma increased photocurrent density of titania nanotubular electrodes.

Stepped-voltage anodization was used to synthesize titania nanotubes of variable diameters. Photocurrent density vs bias voltage plotted for samples anodized at different voltages. Annealing of the photoanodes was modified. The results (Figure 4) showed enhanced light absorption and increased photocurrent density by 55%. Several deposition processes for developing heterojunction TiO₂/TiSi₂ photoanodes have been
studied; an e-beam deposition system has been installed for depositing thin films of different photoanode materials. An electrospray system has been designed and constructed for electrostatic coating of \( \text{TiSi}_2 \) particles with nanoparticles of \( \text{TiO}_2 \).

**Conclusions and Future Directions**

Our experimental studies with plasma surface treatments with helium and nitrogen gas show clearly an increase of photoanode current density compared with the untreated surface of the electrodes. The nitrogen plasma treatment increased acceptor surface states and improved performance of the \( \text{TiO}_2 \) photoanodes. Surface cleaning of the photoanode by low-temperature helium plasma treatment removed a major fraction of the contaminants (adsorbates) from the surface.

The present work reports the importance of systematic investigations of (1) the geometric structure of the nanotube arrays, (2) the plasma treatment process for surface doping of \( \text{TiO}_2 \) nanotubular photoanode with \( \text{N} \) for increasing oxygen vacancies and (3) annealing process for crystallization for improving photocatalytic generation of hydrogen from water. The test results show promising aspects of tuning several parameters involved in PEC processes in improving conversion efficiency.

**Plan for Future Studies**

- Develop patterned nanotubular layered \( \text{TiSi}_2 \) and \( \text{TiO}_2 \) photoanodes.
- Study methods for (1) optimizing the film thickness (in the nm range, to improve tunneling) of \( \text{TiO}_2 \) (2) matching the crystalline structures of the layered semiconductors and (3) reducing the interface states in the heterojunction semiconductors and the electrolyte by passivating the surfaces involved.
- Characterize interfacial states between the \( \text{TiSi}_2/\text{TiO}_2 \)/electrolyte junction by determining the optical absorption spectrum, durability and photocurrent density.
- Develop multi-junction (\( \text{TiSi}_2 \) and \( \text{TiO}_2 \)) nanotubular electrodes to enhance the absorption of solar radiation in the visible range. Measure light absorption vs. \( \lambda \).
- Measure photocurrent conversion efficiency (incident photon conversion efficiency vs \( \lambda \), corrosion resistance, and photo-generated carrier concentration decay rate by using a radio frequency conductivity probe.
- Optimize the PEC process for developing layered photoanodes and minimize the density of interfacial charge carrier traps by hydrogen plasma passivation followed by nitrogen plasma treatments.

Phone: (202) 287-5829
E-mail: Eric.Miller@hq.doe.gov

Project Start Date: March 1, 2010
Project End Date: Project continuation and direction determined annually by DOE

Objectives

- Understand the underlying mechanism of surface corrosion of semiconductor-based photoelectrochemical (PEC) cells.
- Understand the dynamics of water dissociation and hydrogen evolution at the water-photoelectrode interface.
- Understand the electronic properties of the water-electrode interface.
- Identify the relationship between corrosion and catalysis.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(Y) Materials Efficiency (Photoelectrochemical Hydrogen Production)
(Z) Materials Durability (Photoelectrochemical Hydrogen Production)

Technical Targets

This project is conducting fundamental theoretical studies of mechanisms of corrosion and catalysis in III-V semiconductor-based photoelectrode materials for PEC hydrogen production. Insights gained from these studies will be applied toward the optimization and design of semiconductor materials that meet the following DOE 2013 PEC hydrogen production targets:

- Usable semiconductor bandgap: 2.3 eV
- Chemical conversion process efficiency: 10%
- Plant solar-to-hydrogen efficiency: 8%
- Plant durability: 1,000 hrs.

Accomplishments

- Discovered that spontaneous dissociative adsorption of water could be observed in simulations of oxide-decorated InP(001) surfaces.
- Discovered that oxide reactivity can be categorized generally according to oxygen bond topology.
- Isolated possible mechanism for water dissociation on oxide surfaces with In–O–In bond topology.
- Determined that hydroxide bridges are more stable than oxides, and demonstrated that conversion between hydroxide topologies is facilitated by hydrogen-bond network in water.
- Isolated two possible mechanisms for corrosion nucleation in InP(001), both of which will be tested further for compatibility with experimental measurements.

Introduction

Development of efficient processes for the carbon-free production of hydrogen is key to sustainable realization of a future hydrogen economy. One particularly promising approach is to use sunlight to catalyze direct evolution of hydrogen from water in a PEC cell. Semiconductor-based PEC devices are particularly attractive, thanks to a relatively simple device design and a wealth of data available for engineering efficient photon harvesting [1]. Results have demonstrated that one can achieve solar-to-fuel conversion efficiency in excess of the 2013 DOE targets (>12% using a tandem GaAs/GaInP₂ cell); however, this has come at the expense of short device lifetime due to fast degradation of the electrode [2]. Further progress has been hindered by a poor understanding of the fundamental hydrogen evolution processes operating at the electrode-water interface. Our research addresses this need from a theoretical perspective, leveraging realistic ab-initio simulations to determine the key mechanisms governing corrosion and catalysis at the water-semiconductor interface.
Approach

Further progress in semiconductor-based PEC photoelectrodes requires in-depth understanding of the complex relationship between surface stability and catalytic activity. This in turn relies on knowledge of the fundamental nature of the electrode-water interface, and of the chemical pathways explored during surface-active hydrogen evolution. As such, we have been carrying out finite-temperature ab-initio molecular dynamics simulations and energetics calculations based on density functional theory to understand the chemical, structural, and electronic properties of water/electrode interfaces under equilibrium conditions, as well as to understand the competing chemical reaction pathways visited during photocatalysis. Our approach uses InP(001), which has known water-splitting activity, as a model semiconductor electrode. Currently, our chief interest is in investigating the role of oxygen at the semiconductor surface, in response to experimental observations of high oxygen contaminant concentration in the samples evaluated by our collaborators in J. Turner’s group at the National Renewable Energy Laboratory [3] and suggestions that this oxide may play a key role in motivating both the surface photocorrosion and the catalytic water splitting reaction [4,5]. Accordingly, we are evaluating the stability and reactivity of the InP(001) surfaces in the presence of oxide and hydroxide species, correlating results to oxide topology and surface morphology. In each instance, the role of the surrounding water is also assessed.

Results

To evaluate the role of oxygen contaminants in the reactivity and stability of the InP(001) surfaces, we extracted low-energy oxide configurations by adsorbing atomic oxygen on high-symmetry sites of an initially unreconstructed In-rich surface slab. The atoms were then allowed to relax to their local-minimum configuration. Atop, hollow, and both bridge sites were tested at single-monolayer coverage limit, giving rise to several relaxed oxide structures. All tested configurations show that incorporation of oxygen is strongly thermodynamically favored with respect to the clean surface in the presence of gaseous O₂ (by an average of 2.5 eV per oxygen atom), in agreement with experimental observations of high surface oxygen contamination. Several of the tested configurations resulted in the oxygen in the subsurface layer rather than the surface layer. These generally feature oxygen simultaneously bonded to one indium and one phosphorous. Surface oxygens, on the other hand, generally bridge two indium atoms. Oxygen is more stable in the subsurface than on the surface (by 0.5 eV per oxygen, on average), reflecting the strength of the In–O–P complex with respect to In–O–In.

To test whether oxide formation affects reactivity for water dissociation, single water molecules were adsorbed near the oxygen sites on each of the morphologies. In each case, oxygen bond topology proves an excellent predictor of gas-phase dissociative adsorption of water: oxygen sites in In–O–P bonds bind water weakly and do not encourage dissociation, whereas sites in In–O–In bonds promote spontaneous dissociative adsorption. For morphologies containing both types of oxide bonds, reactivity depends on the specific dissociation site. To illustrate this point, the results of water adsorption on three representative oxide surfaces are shown in Figure 1.

Figure 1 indicates that the result of water reaction with certain bridge oxide structures is local surface hydroxylation. Accordingly, we also examined hydroxylated InP(001) surfaces, generated by placing OH in high-symmetry sites. Only three unique relaxed configurations were found for OH coverage, although we are currently mining additional morphologies for further study. Hydroxide formation is thermodynamically favored with respect to oxide formation (by an average of 1.3 eV per oxygen). This reflects the thermodynamic driving force for the dissociation of water on the reactive oxide surfaces, which results in surface hydroxylation. Interestingly, the bridge configuration, which was the least stable oxide configuration we tested, proved the most stable hydroxide configuration.

![Figure 1](image)

**FIGURE 1.** Result of gas-phase water molecule adsorption on representative oxide-contaminated In-rich InP(001) surfaces. For oxides consisting exclusively of In-O-P oxygen bond topologies (a), the water molecule does not dissociate. For oxides consisting exclusively of In-O-In oxygen bond topologies (b), the water molecule dissociates, resulting in local surface hydroxylation. For oxides containing both In-O-P and In-O-In oxygen bond topologies (c and d), dissociation of the water molecule does not occur if adsorption is near the In-O-P site (c), whereas dissociation does occur if adsorption is near the In-O-In site (d). Color scheme: hydrogen = small white spheres; oxygen = small dark red spheres; phosphorous = medium gold spheres; indium = large green spheres.
We have also been running ab initio molecular dynamics calculations of the full semiconductor-water interface to examine the influence of dynamics on the reactivity and stability of the surface. In order to isolate the two oxide bond topologies and examine them individually, we have been running two oxide surface simulations, one using a low-energy configuration with 100% In–O–P bond topology and the other using a higher-energy bridge-site configuration with 100% In–O–In bond topology. For the hydroxide surface, we have been running only one simulation (bridge-site hydroxide), recognizing the fact that the shallow free energy surface should mean realization of the other morphologies in the course of the dynamics.

As expected, the In–O–In surface oxide demonstrated much higher reactivity than the In–O–P subsurface oxide. The mechanism of dissociative water adsorption on the reactive In–O–In oxide is depicted in Figure 2. The reaction begins with the adsorption of a water molecule on a surface indium site to form a bond between the water oxygen (O1) and the indium. The water molecule is initially oriented such that one of the O1–H bonds lies generally parallel to the surface, with the other pointing upwards into the solution. The parallel-lying O1–H bond is thereby free to engage in hydrogen bonding with one of the surface oxygens (O2). The subsequent cleavage occurs via proton transfer across the O1–H· · ·O2 complex, such that the covalent and hydrogen bonds are exchanged. The result is the hydroxylation of two neighboring indium atoms, the first of which (the one to which the water O1 was originally bound) forms an atop-site hydroxide, and the second of which forms either an atop- or bridge-site hydroxide. In vacuum calculations, the atop and bridge sites were nearly isoenergetic. Therefore, the choice between the two is determined by the local structure visited during the dynamics and appears to be strongly dependent on number and strength of the hydrogen bonds formed with neighboring water molecules.

For many water cleavage events, the reaction culminates in two surface hydroxyl groups. However, there are also instances in which one oxygen atom further binds to a second-layer phosphorous and is pulled into the subsurface. This phenomenon can be seen in Figure 2e and f. Since subsurface oxygen that bridges In and P is not generally reactive, the choice the system makes could have significant consequences on further surface catalytic activity. In summary, there is a competition between three possibilities for the product hydroxide groups: first, formation of a bridge-site hydroxide configuration; second, formation of an atop-site hydroxide which strongly hydrogen-bonds with the solution; and third, a subsurface hydroxide that bridges In and P. Qualitatively, the choice between these three seems to be related to the nature of the surrounding hydrogen-bond network. To be pulled into the subsurface, the product oxygen must not be engaged in significant hydrogen bonding. On the other hand, to be converted into the atop hydroxyl configuration, a product oxygen must be engaged in very strong hydrogen bonding.

Although we start the simulation with all hydroxide groups in the bridge-site configuration, we quickly see conversion of several of these to the atop-site configuration, consistent with the zero-temperature predictions of facile exchange between the two. This exchange is bidirectional, indicating a dynamic equilibrium between the two configurations. As with the oxide simulations, whether a conversion takes

---

FIGURE 2. Mechanism of water dissociation on a bridge-site oxide of In-rich InP(001). O1 and O2 refer to the oxygen atoms originally associated with the water molecule and the oxide surface, respectively. (a) and (b) O1 binds to indium, and a hydrogen bond is formed with O2. (c) The water molecule transfers a hydrogen across the O1–H· · ·O2 complex. (d) The In–O2 bond breaks. (e) and (f) Optionally, O2 is pulled below the surface to form a bond with P. Color scheme: white = hydrogen; dark red = oxygen; light green = In; medium gold = phosphorous. The thin purple lines represent hydrogen bonds.
place seems to largely depend on the structure of the hydrogen-bond network surrounding the hydroxide group. If the group is involved in strong hydrogen bonding, the atop-site configuration is preferred, whereas the converse is true for the bridge-site configuration.

Occasional dissociative adsorption of water is observed in the hydroxide simulations, although it is generally associated with temporary breaking of an O–H surface bond to form bridge-site In–O–In. Water cleavage then proceeds via an identical mechanism to that observed in the reactive In–O–In oxide (Figure 2). Since these local-oxide configurations are relatively rare, the rate of water dissociation is significantly slower than for the reactive oxide (almost an order of magnitude). In addition, hydrogen atoms can sometimes transfer from a water molecule in solution across a hydrogen bond to OH groups on the surface. This turns surface OH into an indium-adsorbed H₂O, which may then be released back into the solution to free up an indium for further reactions. This also leaves one OH in the solution for further surface reactions, such as the surface hydroxide-to-oxide conversion via further water dissociation. The suitability of this reaction depends on temporary stabilization via local fluctuations in the hydrogen-bond network.

Conclusions and Future Directions

- We investigated oxides and hydroxides of InP(001) and found that surface reactivity can be correlated with local oxygen bond topology.
- Our ab initio molecular dynamics simulations of the oxide- and hydroxide-decorated surfaces show possible mechanisms for corrosion and catalysis.
- Dynamics appear to be very important in understanding surface behavior, particularly in reference to the water structure at the interface. Further analysis of the water structure to identify the nature of these correlations is currently underway.
- These mechanisms will be tested further by running additional simulations, and the results will be compared with X-ray absorption spectroscopy spectra currently being obtained by our collaborator, Prof. Clemens Heske.
- We have yet to assess the effect of surface and solution treatments on stability and reactivity. These include modification of the water pH and inclusion of nitrogen additives.

II.G.13 Photoelectrochemical Generation of Hydrogen from Water Using Visible Light Sensitive Ferro-Electric BiFeO$_3$ and Semiconductor Nanotubes*

Objectives

- Develop high-efficiency metal oxide nanotubular array photo-anodes for generating hydrogen by water splitting.
- Develop density functional theory to understand the effect of morphology of the nanotubes on the photoelectrochemical (PEC) properties of the photo-anodes.
- Develop kinetics and formation mechanism of the metal oxide nanotubes under different synthesis conditions.
- Develop combinatorial approach to prepare hybrid photo-anodes having multiple hetero-atoms incorporated in a single photo anode.
- Improve the durability of the material.
- Scale up the laboratory demonstration to production unit.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(Y) Materials Efficiency
(Z) Materials Durability

Technical Targets

This project investigates potential application of hybrid TiO$_2$ nanotubes for hydrogen generation by water photoelectrolysis. Insights gained from these studies will be applied toward the design and synthesis of high efficiency materials for hydrogen generation from water splitting that meet the following DOE targets:

- Usable semiconductor bandgap: 2.3 eV by 2013
- Chemical conversion process efficiency: 10% by 2013
- Plant durability: 1,000 h by 2013

Approach

In this current project, utilization of hybrid metal (Ti, W, Fe, Ta) oxide nanotubular arrays for generation of hydrogen from water using sunlight is being studied. The metal oxide nanotubular arrays have been found to be robust, photo-corrosion resistant, and can be used efficiently to generate hydrogen and most importantly are active in the visible light portion of the solar spectrum. It is envisioned that the process will be efficient and economical in the production of solar hydrogen. The nanotubular arrays were prepared by electrochemical anodization of solid metal in different inorganic and organic electrolytes in the presence of fluoride ions. The effect of voltage, time, and solution chemistry on the size, uniformity, and self-assembly of nanotube formation was studied. It was found that materials prepared in organic solvents such as ethylene glycol by an ultrasonic assisted process were stable and form an efficient pattern of nanotubes that have excellent photo-efficiency. We have already developed processes to synthesize metal oxide nanotubes in inorganic, organic and ionic liquids as electrolytes. This process is also suitable to prepare mixed metal oxide nanotubes e.g. TiFe, TiMn and TiW. In addition to the...
preparation of metal oxide-based photoanodes, we have also shown that these nanotubes can work efficiently as a cathode by nanoparticle modification. In addition to the anodization process, we have also developed new mixed metal oxide compounds by sol-gel method. In this project, a highly efficient photoanode, a cathode, and a modified electrolyte will be integrated to design a PEC cell to generate hydrogen with at least 10% efficiency by 2013. The scale up process looks highly promising for large-scale hydrogen generation.

The hydrogen generation work was conducted using a hybrid metal oxide nanotubular or mixed metal oxide photoanode in alkaline solutions in the presence of simulated solar light. The material stability and photo-efficiency was determined as a function of time, electrochemical and analytical measurements. The photo-efficiency was determined by measuring current as well as volume of the hydrogen generated by gas chromatograph.

In the future our main focus for the research will be to understand:

- The formation mechanism and kinetics of metal oxide nanotubes prepared by various anodization methods and electrochemical solutions.
- Synthesis of visible light active metal oxide nanotubular photocatalysts for PEC applications and analysis of their various phases while annealing by X-ray diffraction (XRD) measurements followed by density functional theory (DFT) calculations.
- Synthesis of visible light active mixed metal oxide photocatalysts for PEC applications.
- Develop quantum dot sensitized nanotubular oxide hybrid photo-anodes based on DFT modeling.
- Stability of the catalysts for 1,000 h.

On the basis of fundamental and applied research, a scaled-up experiment in the laboratory will be performed to elucidate the viability of the new catalysts for PEC generation of hydrogen using sunlight.

**Accomplishments**

- The UNR team has designed a low-cost process for synthesis of nanostructured bismuth iron oxide (BiFeO$_3$) as a multiferroic material for PEC applications. The experimental band gap of BiFeO$_3$ was found to be 2.1 eV (Figure 1(I)). The synthesis conditions were optimized and it was found that a highly crystalline nanostructured material could be obtained when BiFeO$_3$ is annealed under N$_2$ at 600°C for 2 h (Figure 1(II)).
- BiFeO$_3$ was found to be an efficient photocatalyst generating hydrogen under AM 1.5 light illumination conditions in 1 (M) KOH as electrolyte (Figure 2).
The band structure and optical properties of BiFeO$_3$ were estimated using generalized gradient approximation with Hubbard-type interaction parameter and spin polarized approach (GGA+U-SP) approximation considering the unoccupied Fe 3d orbital state. The calculated band gap was 1.61 eV (Figure 3).

UNR has developed an innovative ultrasonically mediated fabrication process to synthesize crystalline tantalum oxynitride (TaON) nanotube (NT) arrays (Figure 4). TaON NTs have been synthesized by a two-step process, firstly by forming Ta$_2$O$_5$ NTs (anodizing Ta foil) followed by heating them in an atmosphere of flowing NH$_3$ at 700°C for 6 h. It should be mentioned here that TaON nanoparticles (NPs) are not formed when Ta$_2$O$_5$ NPs are heated at 700°C for 6 h under identical synthesis conditions as TaON NTs.

- TaON NTs have a band gap 2.07 eV (Figure 5(A)) and show excellent visible light activity (47%) compared to TiO$_2$ nanotubes (0.39%) (Figure 5(B)).
- The first principle computational calculations of Ta$_2$O$_5$ and TaON have been carried out based on DFT using plane wave assumption (Figure 6). The calculated band gaps are smaller than the experimentally determined values. In our current simulation, the calculated band gap of Ta$_2$O$_5$ is 3.6 eV, while the experimental value is 4 eV. The calculated band gap of TaON is about 1.9 eV.

Conclusions and Future Actions

In the past year, we have developed new metal oxide based mixed nanotube arrays. We have also got an expanded idea on the formation conditions of metal oxynitride NTs and metal oxynitride NPs. TaON NTs prepared by single nitridation and annealing step are found to be efficient photocatalysts for hydrogen generation by water splitting using visible part of the solar spectrum. Preliminary studies on BiFeO$_3$ as a multiferroic material for photocatalysis has shown positive results. Theoretical studies on bandgap calculations are in accordance with the experimentally determined values. The following bulleted list is indicative of the areas we will pursue in the coming year of the project:

- Synthesis of one-dimensional mixed metal oxide and metal oxynitride materials for PEC applications.
- Synthesis of photoanodes composed of multiferroic materials.
Incident photon to current conversion efficiency measurements.

Design large PEC system for on field testing under real solar irradiation.

Scale up testing for solar light harvesting.

Special Recognitions & Awards/Patents Issued

FY 2010 Publications/Presentations

II.H.1 Maximizing Light Utilization Efficiency and Hydrogen Production in Microalgal Cultures

Objectives

- Minimize, or truncate, the chlorophyll antenna size in green algae to maximize photobiological solar conversion efficiency and H₂-production.
- Demonstrate that a truncated chlorophyll (Chl) antenna size would minimize absorption and wasteful dissipation of sunlight by individual cells, resulting in better light utilization efficiency and greater photosynthetic productivity by the green alga mass culture.

Technical Barriers

This project addresses the following technical barriers from the Biological Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(AG) Light Utilization Efficiency

Technical Targets

The Fuel Cell Technologies Program Multi-Year Plan technical target for 2005 for this project was to reach a 10% utilization efficiency of absorbed light energy (out of a theoretical maximum of 30% possible) in unicellular green. Progress has currently achieved a green alga utilization efficiency of absorbed light energy of about 25%.

Approach

- Employ deoxyribonucleic acid (DNA) insertional mutagenesis, screening, biochemical and molecular genetic analyses for the isolation of “truncated Chl antenna size” mutants in the green alga *Chlamydomonas reinhardtii*.
- Clone and characterize the gene(s) that affect the “Chl antenna size” property in *Chlamydomonas reinhardtii*.
- Apply such genes to generate a “truncated Chl antenna size” in this and other green algae.

Accomplishments

1. Published manuscript on the utility of the truncated light-harvesting chlorophyll antenna (*tla1*) gene in conferring a truncated chlorophyll antenna size and on the mechanism by which it maximizes light utilization efficiency and hydrogen production in microalgal cultures.
2. Deposited two versions of the *tla1* truncated antenna mutant in the strains library of the Chlamydomonas Center (http://www.chlamy.org/), Accession Numbers CC-4169 and CC-4170. These *tla1* strains are openly available to the interested public.
3. Isolated and characterized new “truncated chlorophyll antenna size” mutants *tla2* and *tlaR*. Properties of these strains are given in Tables 1 and 2.

| TABLE 1. *Chlamydomonas reinhardtii* cellular chlorophyll content, photosystem chlorophyll antenna size and energy utilization efficiency in wild type, *tla1*, *tla2* and *tlaR* mutant mutant strains, as determined by spectrophotometric kinetic analysis (n = 5, ±standard deviation). |

Introduction

The goal of the research is to generate green algal strains with enhanced photosynthetic productivity and $H_2$-production under mass culture conditions. To achieve this goal, it is necessary to optimize the light absorption and utilization properties of the cells [1-4]. A cost-effective way to achieve this goal is to reduce the number of Chl molecules that function in the photosystems of photosynthesis. Thus, efforts are under way to isolate microalgae mutants with a truncated chlorophyll antenna size.

The rationale for this work is that a truncated light-harvesting Chl antenna size in green algae will prevent individual cells at the surface of the culture from over-absorbing sunlight and wastefully dissipating most of it (Figure 1). A truncated Chl antenna size will permit sunlight to penetrate deeper into the culture, thus enabling many more cells to contribute to useful photosynthesis and $H_2$-production (Figure 2). It has been shown that a truncated Chl antenna size will enable about 3-4 times greater solar energy conversion efficiency and photosynthetic productivity than could be achieved with fully pigmented cells [5].

Approach

The focal objective of the research is to identify genes that control the Chl antenna size of photosynthesis and, further, to elucidate how such genes confer a truncated Chl antenna size in the model green alga *Chlamydomonas reinhardtii*. Identification of such genes in *Chlamydomonas* will permit a subsequent transfer of this property, i.e., “truncated Chl antenna size”, to other microalgae of interest to the DOE Fuel Cell Technologies Program. This objective is currently being approached through DNA insertional mutagenesis/screening and biochemical/molecular/genetic analyses of *Chlamydomonas reinhardtii* cells.

Results

The *tla*2 mutant plasmid insert site has been cloned and a gene of interest has been tentatively identified as causing the *tla*2 mutation. This molecular and genetic analysis is currently in progress. Work further described the isolation and biochemical and physiological characterization of a new mutant of *Chlamydomonas reinhardtii*, termed *tlaR*. Properties of the *tla* “truncated Chl antenna size” strains so far isolated are summarized in Tables 1 and 2, and Figure 3. The *tlaR* mutant has the smallest yet Chl antenna size known in green algae.

Future efforts will be directed toward the cloning and characterizing the genes responsible for the *tla* phenotype in *tla2* and *tlaR* mutants.
Conclusions

- Significant, ahead-of-schedule progress was achieved in terms of acquiring “truncated Chl antenna size” mutants. This demonstrates feasibility of the approach chosen and success of the methods employed.
- A truncated light-harvesting chlorophyll antenna size in the tla-type mutants enhanced solar conversion efficiencies and photosynthetic productivity under bright sunlight conditions.
- Insights on the molecular mechanism for the regulation of the Chl antenna size by the Tla1 gene were obtained (results not shown pending publication of these findings in a peer reviewed journal).

Future Directions

- Advance the biochemical and molecular characterization of the tla2 and tlaR strains.
- Clone the genes that confer the tla2 and tlaR phenotypes.
- Establish transformation (sense and antisense) protocols with Tla-type genes to enhance the down-regulation of the Chl antenna size in Chlamydomonas reinhardtii.

II.H.2 Biological Systems for Hydrogen Photoproduction

Objectives

- Engineer an [FeFe]-hydrogenase that has an extended half-life following exposure to O₂, as part of an aerobic algal H₂-production system being developed with other Fuel Cell Technologies Program-sponsored groups.
- Optimize and use a platform for testing algal mutants with improved H₂-production properties and higher light-conversion efficiencies.
- Address individual components of an innovative H₂-production system based on integrating fermentative and photosynthetic H₂-producing organisms.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies (FCT) Program Multi-Year Research, Development and Demonstration Plan:

(AI) Continuity of Photoproduction

(AH) Rate of Hydrogen Production

(AT) Feedstock Cost

Technical Targets

<table>

N/A - not available

Accomplishments

- Extended the computational modeling techniques used to identify gas diffusion to the Desulfovibrio gigas [NiFe]-hydrogenase.
- Confirmed that the reduced state of the [FeFe]-hydrogenase is more tolerant to O₂ in vitro than the oxidized state; detected an “O₂-insensitive” state.
- Identified positive Chlamydomonas transformants transcribing the Ca1 hydrogenase gene.
- Simulated fusions between the petF ferredoxin and algal/clostridial hydrogenases to test optimal interactions and performed in vitro tests of fusions.
- Observed that increased thickness of the alginate film improves O₂ tolerance but decreases H₂-production rates.
- Designed adenosine triphosphate (ATP) synthase inducible mutants.
- Demonstrated that an anaerobic clostridial consortium ferments algal biomass, pure algal lipids, pure proteins and unpolymerized alginate.
- Optimized fermentative H₂ production from potato waste.
- Demonstrated sequential H₂ production from dark- and light-driven processes.

Introduction

Green algae can photoproduce H₂ using water as the source of electrons. This property requires the coordinated operation of the photosynthetic apparatus (splits water, producing O₂, electrons, and protons) and [FeFe]-hydrogenases (recombine protons and
electrons, producing $\text{H}_2$ gas). The catalytic center of [FeFe]-hydrogenases is composed of a unique 2Fe2S metal center that is sensitive to $\text{O}_2$, a by-product of photosynthetic water oxidation. This inactivation prevents sustained $\text{H}_2$ production by the organism in the light. The continuity of $\text{H}_2$ photoproduction is one of the major technical barriers to developing photobiological $\text{H}_2$-production systems, as listed in technical barrier AT.

A second major barrier to efficient algal $\text{H}_2$ photoproduction is the low rate of the reaction (technical barrier AH), which is dependent upon many factors: the competition for photosynthetic reductant between the $\text{H}_2$-production and the $\text{CO}_2$-fixation pathways; the down-regulation of photosynthetic electron transport from water under $\text{H}_2$-producing conditions; and the predominance of cyclic, unproductive electron transport over linear electron transfer under anaerobiosis.

Our current project addresses: (a) the $\text{O}_2$ sensitivity of $\text{H}_2$-producing algae and the low rates of $\text{H}_2$ production by using molecular engineering (both site-directed and random mutagenesis) to alleviate these barriers; (b) the further development of a platform, based on the induction of $\text{H}_2$ production by sulfur deprivation, to test biochemical and reactor engineering factors required to improve the rates and light-conversion efficiencies of algal $\text{H}_2$-photoproduction; and (c) the performance of different components of a proposed system that integrates fermentative with photobiological processes for more cost-effective, biological $\text{H}_2$ production. The latter addresses the technical barrier AT (feedstock cost in an integrated system).

**Approach**

**Task 1. Molecular Engineering of [FeFe]-hydrogenases**

This task has three objectives: (a) the engineering of increased $\text{O}_2$ tolerance in [FeFe]-hydrogenase through site-directed or random mutagenesis of region(s) that control $\text{O}_2$ access to the catalytic site; (b) the functional expression of clostridial [FeFe]-hydrogenases in *Chlamydomonas reinhardtii*; and (c) the evaluation of strategies for decreasing the competition between the $\text{CO}_2$-fixation and the $\text{H}_2$-production pathways, which are being implemented in cooperation with a research group at MIT. The efforts being conducted under the first objective have been guided by an extensive computational study of gas diffusion in the clostridial Cpl [FeFe]-hydrogenase, which identified four amino acids that form a “barrier” for $\text{O}_2$ migration into the catalytic site. Up until now, our experimental strategy had been to increase the energy required for $\text{O}_2$ to migrate through this barrier by changing its amino acid composition. Targets for mutagenesis were selected based on static and dynamic computational simulations of gas diffusion and identification of energy barriers. A random mutagenesis approach, though more labor- and time-intensive, will create a more comprehensive library of mutants, increasing the likelihood of finding one with improved tolerance.

The efforts being conducted under the second objective involve the design of a genetic construct for expression, activation, and translocation of a clostridial [FeFe]-hydrogenase into the stromal compartment of the algal chloroplast. Clostridial [FeFe]-hydrogenases are ~100x more $\text{O}_2$ tolerant than algal hydrogenases, yet both undergo the same activation process. The progress made through this approach will lead to the development of expression constructs and techniques that will be essential to expressing engineered [FeFe]-hydrogenases in *C. reinhardtii*, and will provide data on the effects of a more $\text{O}_2$-tolerant enzyme on the kinetics and metabolism of photo-hydrogen production.

In order to control the flow of photosynthetic reductant away from $\text{CO}_2$ fixation and towards $\text{H}_2$ photoproduction, we are working with Prof. Zhang’s research group at MIT to engineer fusions between ferredoxins, the final electron acceptor in photosynthesis, and the HYDA1 algal hydrogenase. This work should prove the hypothesis that it is possible to decrease the competition between these two electron transport pathways and thus increase $\text{H}_2$ photoproduction even in the presence of $\text{CO}_2$.

**Task 2. Optimization of the Sulfur-Deprivation Platform to Test the Performance of Various Algal Mutants**

With our collaborators at the University of California, Berkeley, we developed a method, based on depriving algal cultures of sulfate, to induce continuous $\text{H}_2$ photoproduction. This procedure has become a platform for testing the performance of a variety of algal mutants, as well as to study process engineering parameters that affect the light-conversion efficiency of the system. These will become important once an $\text{O}_2$-tolerant hydrogenase system (see Task 1) becomes available.

**Task 3. An Integrated Biological $\text{H}_2$-Production System**

The FCT Hydrogen Biological Production working group identified a novel system for biological $\text{H}_2$ production that depends on the coordinated activity of photosynthetic (oxygenic and non-oxygenic) and fermentative organisms. An integrated system has the potential for circumventing the shortcomings of each of the individual $\text{H}_2$-producing components in terms of limitations in their overall light-conversion efficiencies and substrate dependence. The two particular configurations being pursued at NREL...
involve: (a) stacked reactors of sulfur-deprived green algae and photosynthetic bacteria that produce H₂ in the light, followed by a fermentative component consisting of anaerobic bacteria that degrade the algal and photosynthetic bacteria biomass and produce H₂ and acetate as products. The latter is the source of reductant for H₂ production by the photosynthetic bacteria; and (b) fermentors that utilize potato waste to produce H₂ and organic acids, followed by organic acid-dependent photosynthetic H₂ production by photosynthetic purple non-sulfur bacteria.

**Results**

**Task 1. Molecular Engineering of [FeFe]-hydrogenases**

Our initial approach to engineer an O₂-tolerant [FeFe]-hydrogenase focused on *site-directed mutagenesis* of the amino acids that comprise a single barrier region controlling O₂ access from the hydrogenase’s central cavity to its catalytic site. One mutation of this region in the clostridial Ca1 [FeFe]-hydrogenase possessed high O₂ tolerance when expressed and purified from *E. coli* in the absence of reducing agents. However, this property was also found to be shared by the wild-type enzyme when purified under similar conditions, suggesting that gas accessibility alone may not be the sole determinant of O₂ sensitivity in [FeFe]-hydrogenases. This year, we showed that the ability of the enzyme to transition between redox states is critical for O₂ tolerance, and that hydrogenases isolated in the reduced state are more tolerant to O₂ than those isolated in the oxidized state. We also observed the presence of an apparently “O₂-insensitive” state that may be related to similar states described for *Desulfovibrio* [FeFe]-hydrogenases. We are preparing a manuscript describing these observations.

We also observed that, based on the recently published crystal structure of the algal hydrogenase by the Peters’ group, our targets for mutagenesis could interfere with the appropriate folding and assembly of the enzyme’s catalytic center, resulting mostly in inactive mutants, which agrees with our results. Thus, while considering different mutagenesis strategies for generation of O₂-tolerant Ca1 mutants, we also initiated efforts to introduce the Ca1 hydrogenase gene into the *C. reinhardtii* genome in a manner that is intended to result in the expression of an active hydrogenase. Since Ca1 is already more O₂ tolerant than the algal hydrogenase, these studies will provide evidence that increased *in vitro* O₂ tolerance does result in increase *in vivo* tolerance. For these purposes, we introduced the Ca1 gene into the *C. reinhardtii* strain CC-849 genome and identified by polymerase chain reaction (PCR) transformants that show the presence of the entire Ca1 codon-optimized gene. The presence of the Ca1 transcript was demonstrated by reverse transcriptase polymerase chain reaction in at least one transformant, and it is anaerobically induced in a similar manner as expression of the endogenous *C. reinhardtii* HYDA1. Future efforts will be directed towards confirming that in these transformants the Ca1 protein is also expressed, localized and active. In addition, once Ca1 is confirmed to be active, preliminary O₂-sensitivity results will be confirmed and physiological characterization will be pursued.

In order to understand the partitioning of photosynthetic reductant among different metabolic pathways, we measured H₂ evolution and its competitive reaction, reduced nicotinamide adenine dinucleotide phosphate (NADPH) production (required for CO₂ fixation), in a series of *in vitro* reactions with purified thylakoids, Ferredoxin (Fd), FD/NADPH oxidoreductase (FNR) NADP⁺ and hydrogenases. In agreement with previous studies, we found that light-mediated H₂ evolution by algal hydrogenase with thylakoid membranes is blocked in the presence of FNR, Fd and oxidized NADP. When free hydrogenase was replaced with a Fd-hydrogenase fusion, H₂ was evolved at near maximal rates with NADPH as a co-product. Some of the NADPH was also recycled back into H₂. This tunable, catalytic complex led to partitioning of photosynthetic electron transport to H₂ even under conditions that support CO₂ fixation and will be investigated as a way to improve light-conversion efficiencies in algae under photosynthetic growth for scale-up development.

**Task 2. Optimization of the Sulfur-Deprivation Platform to test the Performance of Various Algal Mutants**

Our major accomplishments on this task this past year were the discoveries that: (a) a decrease in film thickness improves maximum specific rates and yields of H₂ production under anaerobic conditions but decreases H₂ production rates under aerobic conditions due to protection from O₂ inactivation; (b) the addition of acetate to alginate-immobilized algal cells stimulates H₂ production; (c) alginate-immobilized ATP synthase mutants show increased H₂ production under both low and high illumination, as predicted from uncoupled preparations; and (d) new ATP synthase mutants have been designed and are being introduced in *C. reinhardtii* behind an inducible promoter to allows us to regulate its expression.

**Task 3. An Integrated Biological H₂-Production System**

We demonstrated that our anaerobic bacterial consortium metabolizes algal biomass with a H₂/glucose ratio higher than 4, suggesting that components other than carbohydrates are being utilized. This
hypothesis was confirmed by the observation that the same consortium is capable of degrading pure algal lipid and protein. Finally, we demonstrated that the consortium also metabolizes un-polymerized alginate, thus underlining its usefulness in consuming residual immobilized algal biomass from an integrated photobiochemical/fermentative H₂-production system.

Working with a different integrated system that links fermentation of potato waste to photosynthetic H₂ production by purple non-sulfur bacteria, our collaborators in Russia optimized the fermentative component by examining factors such as exclusion of ammonium; addition of Fe ions, peptone and zinc; and increased phosphate buffering capacity. They reported final yields of 1.6 moles H₂/glucose. Finally, they demonstrated sequential H₂ production from the integrated system with maximum yields at this point of 5.6 moles H₂/glucose if the fermentation effluent is feed to the non-sulfur bacteria.

Conclusions and Future Directions

Task 1: (a) Continue to characterize positive algal transformants expressing the bacterial Ca1 gene; (b) measure the in vivo O₂ tolerance of those transformants; (c) devise a different mutagenesis approach to generate O₂-tolerant [FeFe]-hydrogenase mutants; and (d) complete in vitro studies of Fd/hydrogenase fusions in collaboration with MIT and attempt in vivo expression of the fused promoters.

Task 2: (a) Test the effect of the volume of the photobioreactor’s headspace on the H₂-production properties of algal cultures; (b) adapt and improve on the methods previously used to induce photoautotrophic cultures to produce H₂ in the absence of added acetate; (c) test more advanced truncated antenna mutants from the University of California, Berkeley; and (d) construct and test the performance of an ATP synthase gene expressed in C. reinhardtii behind an inducible promoter.

Task 3: (a) Scale up and further optimize fermentation of suspended and immobilized algal biomass by the fermentative consortium using new fermentors; (b) optimize the integration of the fermentative/photobiological H₂-production system using potato waste as the feedstock.

Objectives

- Perform hydrogen fermentation using cellulolytic bacteria and lignocellulosic biomass to lower feedstock cost.
- Perform metabolic pathway engineering to improve hydrogen molar yield via fermentation.
- Develop microbial electrolysis cell to improve hydrogen molar yield using waste from the fermentation of lignocellulosic biomass.

MEC = microbial electrolysis cell

- Yield of H₂ from glucose: DOE has a 2013 target of an H₂ molar yield of 4 using glucose as the feedstock. In Fiscal Year (FY) 2010 we achieved a molar yield of 3.2, accomplished by Clostridium thermocellum fermenting avicel (commercial cellulose) via fermentation only.
- Feedstock cost: The DOE Biomass Program is conducting research to meet its 2013 target of 10 cents/lb biomass-derived glucose. NREL's approach is to use cellulolytic microbes to ferment cellulose and hemicellulose directly, which will result in lower feedstock costs.

Accomplishments

- Determined effects of substrate loadings on both rates and yields of H₂ production in scale-up bioreactor experiments using the cellulose-degrading bacterium C. thermocellum fermenting various amounts of avicel cellulose and lignocellulose, the latter prepared from the acid-hydrolysis of corn stover biomass.
- Tested genetic transformation protocols with a custom-designed plasmid in collaboration with University of Manitoba (Canada). Initial finding is promising which warrants further improvement.
- Designed, constructed and tested a bench-scale prototype microbial electrolysis cell of 2.5 L in volume that contained eight pairs of electrodes. The reactor produced H₂ gas at a rate of up to 1,250 mL/d, and produced a steady current of 155 to 180 mA demonstrating the usefulness of this design.

◊ ◊ ◊ ◊ ◊
Introduction

Biomass-derived glucose feedstock is a major operating cost driver for economic H₂ production via fermentation. The DOE Fuel Cell Technologies Program is taking advantage of the DOE Biomass Program’s investment in developing inexpensive glucose from biomass to meet its cost target of 8 cents/lb by 2015. Meanwhile, one alternative and valid approach to addressing the glucose feedstock technical barrier (AT) is to use certain cellulose-degrading microbes that can ferment cellulose directly for hydrogen production. One such example is the cellulose-degrading bacterium Clostridium thermocellum 27405 (C. thermocellum), which was reported to exhibit the highest growth rate using crystalline cellulose [1]. Another technical barrier to fermentation is the relatively low molar yield of hydrogen from glucose (mol H₂/mol sugar; technical barrier AR), which results from the simultaneous production of waste organic acids and solvents. Biological pathways maximally yield 4 mole of hydrogen per 1 mole of glucose (the biological maximum) [2]. However, most laboratories have reported a molar yield of 2 or less [3,4]. Molecular engineering to block competing pathways is a viable option toward improving H₂ molar yield. This strategy had resulted in improved hydrogen molar yield in Enterobacter aerogenes [5].

A promising parallel approach to move past the biological fermentation limit has been developed by a team of scientists led by Bruce Logan at PSU. In the absence of O₂, and by adding a slight amount of negative potential (—250 mV) to the circuit, Logan’s group has produced H₂ from acetate (a fermentation byproduct) at a molar yield of 2.9-3.8 (versus a theoretical maximum of 4) in a modified microbial fuel cell (MFC) called an MEC [6]. It demonstrates for the first time a potential route for producing 8 or more moles of H₂ per mole glucose when coupled to a dark fermentation process. Indeed in FY 2009, the team reported a combined molar yield of 9.95 when fermentation was coupled to MEC in an integrated system. Combining fermentation with MEC could therefore address technical barriers AR and AS (waste acid accumulation) and improve the techno-economic feasibility of H₂ production via fermentation.

Approach

NREL’s approach to addressing feedstock cost is to optimize the performance of the cellulose-degrading bacterium C. thermocellum. To achieve this goal, we are testing various amounts of cellulosic substrates and optimizing reactor parameters to improve longevity, yield, and rate of H₂ production. We are selectively blocking competing metabolic pathways in this organism via developing a genetic method to accomplish this goal. Via a subcontract, PSU is testing the performance of an MEC using both a synthetic effluent and the real waste stream from lignocellulosic fermentation generated at NREL.

Results

Lignocellulose Fermentation

We tested effects of substrate loadings on rates and yields of H₂ production in C. thermocellum. Two types of substrates were tested: avicel cellulose and the dilute-acid pretreated corn stover lignocellulose, the latter with a composition of 59.1% cellulose, 25.3% lignin, 6.4% residual hemi cellulose-derived sugars, and 3.7% ash. We performed fermentation in scale-up bioreactors with automated temperature (55°C), pH (7.0), and pressure controls. The bioreactor was bubbled with nitrogen (N₂) gas (10 cc/min) to allow real-time sampling of H₂ and carbon dioxide (CO₂) via an online gas chromatograph. Clostridium thermocellum, previously cultured in crystalline avicel cellulose, was inoculated into a 1.5 L (working volume) bioreactor fed with various amounts of the individual substrates described above. Table 2 summarizes rates, molar yields of H₂, production, and carbon mass balance during a period of 80 hours. Calculation of the carbon mass balance did not account for those carbon substrates assimilated into bacterial cell mass. These experiments conclude that higher carbon loading leads to faster rate of H₂ production whereas lower carbon loading results in higher H₂ molar yield. The molar yield of 3.2 obtained with 1 g/L avicel was the average of two experiments. Overall, these experiments provide the parameters (hydraulic and solid retention time) to conduct fermentation in fed-batch mode in the more realistic scale-up process. Typical compounds found in the fermentation waste are: acetic, formic, lactic, and ethanol, which are ideal substrates for the MEC reaction.

Metabolic Engineering

The ultimate goal of this approach is to develop tools to inactivate genes encoding competing metabolic pathways, thus redirecting more cellular flux to improve...
H₂ molar yield. Transformation in this organism has been unsuccessful thus far in the literature likely due to either an inefficiency of the plasmids used or an active restriction system in the host that is destroying the incoming plasmid. To ascertain any restriction endonuclease activity in *C. thermocellum*, crude cell extracts were prepared from a 20-mL culture grown to late-exponential phase, and adjusted to contain 50% (v/v) glycerol. For restriction assays pIKM1 plasmid deoxyribonucleic acid (DNA, isolated from TOP10 cells) were incubated with a buffer (10 mM Tris/HCl, pH 7.5, 50 mM NaCl, 10 mM MgCl₂, 1 mM dithiothreitol, and 0.01% bovine serum albumin) at 55°C for 2-3 hr. The products were analyzed on 1% agarose gel (Figure 1). Gel electrophoresis analysis indicated that cellular extract indeed digested the pIKM1 DNA in the cellular extract confirming our previous speculation about the *C. thermocellum* endonuclease activity on the plasmid DNA (Figure 1, lane 2). Plasmid DNA incubated without the cellular extract remained undigested (data not shown). To test the endonuclease activity of *C. thermocellum* crude extract on methylated DNA, plasmid PIKM1 was treated with GpC methyltransferase (M.CviPI) that selectively methylate all cytosine residues at the 5° carbon position within the double stranded DNA sequence. Our results indicated that the methylated PIKM1 DNA was protected from the endonuclease activity of *C. thermocellum* (Figure 1, lane 1). Methylated *C. thermocellum* DNA without cell extract or methylated PIKM1 DNA both serve as the controls (Figure 1, lanes 3 and 5, respectively). The outcomes warrant the importance of plasmid DNA methylation to improve overall transformation efficiency.

**Microbial Electrolysis Cell**

Previously examined MECS contained a single set of electrodes and were relatively small (0.03 L) in volume. In order to examine the scalability of the existing single-chamber MEC designs, a multiple-electrode system was designed, constructed and tested for hydrogen production and current density achievable using acetate as a feedstock. The bench-scale MEC was 2.5 L in volume when empty, and contained eight separate electrode pairs made of graphite fiber brush anodes (pre-acclimated for current generation), and 304 stainless steel mesh cathodes (64 m²/m³) (Figure 2). Under continuous flow feeding conditions, and a one-day hydraulic retention time, a maximum current of 181 mA was produced within three days of operation. This is 1.18 A/m² of cathode surface area, and equivalent to 74 A/m³. The maximum hydrogen production (day 3) was 0.53 L/L-d, reaching an energy efficiency relative to electrical energy input of $\eta_E = 144\%$. Current production remained relatively steady (days 3 to 18), but the gas composition dramatically shifted over time from hydrogen to methane. After 16 days of operation, only small amounts of H₂ gas were recovered, and methane production had increased to 0.118 L/L-d. When considering the energy value of both hydrogen and methane, efficiency relative to electrical input remained above 100% until near the end of the experiment (day 17) when only methane gas was being produced. These results showed that MECS could be scaled up primarily based on cathode surface area, but that hydrogen produced in the single-chamber MEC can be completely consumed in a continuous flow system unless methanogens can be completely eliminated from the system.

**Conclusions and Future Direction**

- Using both avicel cellulose and corn stover lignocellulose as the substrate and a sequenced strain of *C. thermocellum*, we found that low substrate loading gives rise to higher H₂ molar yield while high substrate loading yields faster rate of H₂ production.
- We determined that plasmid DNA methylation is necessary for successful transformation in *C. thermocellum*. 
Hydrogen production was successful in a larger-scale (2.5 L) continuous flow MEC, but eventually all hydrogen production was converted to methane. In the future, we will conduct fed-batch fermentation to optimize solid and hydraulic retention time for more realistic scale-up application. We will continue to develop tools for molecular engineering in \textit{C. thermocellum}. In the MEC area, a new reactor design is now in progress to better capture hydrogen gas produced in these systems to avoid its loss to methanogens.

II.H.4 Hydrogen from Water in a Novel Recombinant Oxygen-Tolerant Cyanobacterial System

Objectives

Develop an O₂-tolerant cyanobacterial system for sustained and continuous light-driven H₂-production from water.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(AH) Rate of Hydrogen Production

(AI) Continuity of Photoproduction

Accomplishments

JCVI

- Transferred the genes of the *Thiocapsa roseopersicina* stable hydrogenase to *Synechococcus elongatus* PCC 7942 and detected activity from the heterologously-expressed hydrogenase.
- Cloned a novel NiFe-hydrogenase from Sargasso Sea environmental deoxyribonucleic acid (DNA), expressed it in *T. roseopersicina*, and detected activity from the purified protein in 1% oxygen.
- Transferred the genes of this novel environmental hydrogenase into *S. elongatus*, and detected activity from the heterologous hydrogenase.

NREL

- Cloned the O₂-tolerant *Rubrivivax gelatinosus* hydrogenase genes in two plasmids suitable for expression in *Synechocystis* sp. PCC 6803. One plasmid will integrate *Rubrivivax* genes into the genome of *Synechocystis* via the homologous recombination mechanism. Genes cloned into the second plasmid will be expressed off the plasmid. Expression from both plasmids is driven by a native promoter in *Synechocystis*.
- Protein western blots revealed the expression of three *Rubrivivax* hydrogenase subunits using the above two expression systems.

Introduction

Photobiological processes are attractive routes to renewable H₂ production. With the input of solar energy, photosynthetic microbes such as cyanobacteria and green algae carry out oxygenic photosynthesis, extracting energy from water oxidation. The resulting energy can couple to a hydrogenase system yielding H₂. However, one major difficulty is that most hydrogen-evolving hydrogenases are inhibited by O₂, which is an inherent byproduct of oxygenic photosynthesis. The rate of H₂ production is thus limited. Certain photosynthetic bacteria are reported to have an O₂-tolerant evolving hydrogenase, yet these microbes do not split water, requiring other more expensive feedstock.

To overcome these difficulties, we propose to construct novel microbial hybrids by genetically transferring an O₂-tolerant hydrogenase from other...
bacteria into cyanobacteria. These hybrids will use the photosynthetic machinery of the cyanobacterial hosts to perform the water-oxidation reaction with the input of solar energy, and couple the resulting reducing equivalents to the O$_2$-tolerant bacterial hydrogenase, all within the same microbe. This addresses one of the key technological hurdles to cost-effective photobiological production of H$_2$, overcoming the sensitivity of the hydrogenase enzyme to O$_2$, which limits the production of hydrogen in current algal systems.

**Approach**

Our goal is to construct a novel microbial hybrid taking advantage of the most desirable properties of both cyanobacteria and other bacteria, to serve as the basis for technology to produce renewable H$_2$ from water. To achieve this goal, we use the following two approaches. The first approach is to transfer known O$_2$-tolerant hydrogenases from anoxygenic photosynthetic bacteria *Thiocapsa roseopersicina* and *Rubrivivax gelatinosus* to cyanobacteria. Since only a very limited number of O$_2$-tolerant hydrogenases are available, our second approach is to identify novel O$_2$-tolerant hydrogenases from environmental microbial communities and transfer them into cyanobacteria.

**Results**

**JCIV: Expression of HynSL hydrogenase from *Thiocapsa roseopersicina* in Cyanobacteria**

We have introduced the O$_2$-tolerant hydrogenase from *T. roseopersicina* into cyanobacteria along with various combinations of accessory genes. These constructs were introduced into a mutant strain of *Synechococcus elongatus* PCC 7942 (Hoxmut) which lacks the HoxYH hydrogenase and has no native hydrogenase activity. The *T. roseopersicina* hydrogenase structural genes, *hynSL*, were introduced into Hoxmut along with the known *T. roseopersicina* accessory genes in plasmids pHyn4, pHyn5, and pHup (Figure 1). Proteins encoded by the accessory genes are necessary to assemble a functional active site for NiFe hydrogenases. While not all accessory genes are known for *T. roseopersicina* because the genome has not been sequenced, the available 16 genes were co-expressed in cyanobacteria to determine whether a hydrogenase with a functional active site could be assembled.

The *T. roseopersicina* hydrogenase was expressed upon isopropyl β-D-1-thiogalactopyranoside (IPTG) induction in the cyanobacterial strains (Figure 2), but no active hydrogenase was produced (Figure 3). However, when the accessory genes from a novel environmental hydrogenase (construct Wav10 described in the following) were co-expressed with the *T. roseopersicina* genes in Hyn4 or Hyn5, a *T. roseopersicina* hydrogenase with a fully assembled active site was produced and possessed activity upon *in vitro* assay (Figure 3).

**Identifying Novel O$_2$-Tolerant Hydrogenases from Marine Microbes and Expression in Cyanobacteria**

We have previously identified sequences of large and small NiFe hydrogenase subunits from the Global Ocean Sampling expedition. One of these environmentally-derived NiFe hydrogenase sequences was expressed in *T. roseopersicina* and found to encode a functional hydrogenase. When the genes encoding the small and large subunits of the hydrogenase and the adjacent accessory genes were transferred to the Hoxmut strain of the cyanobacterium *S. elongatus* (strain RC41, Figure 2), an active hydrogenase expressed (Figure 3). The heterologously-expressed hydrogenase possessed roughly

![FIGURE 1. Constructs used to express *T. roseopersicina* (T. r.) and environmental (Envi) hydrogenases in cyanobacteria.](image-url)
II.H Hydrogen Production / Biological

With the T. roseopersicina HynSL hydrogenase described above, this is the first report describing heterologous expression of active NiFe hydrogenases in cyanobacteria.

Purifying Hydrogenases Expressed in T. roseopersicina and Testing O2-Tolerance

We have previously described purification of the T. roseopersicina HynSL hydrogenase described above, this is the first report describing heterologous expression of active NiFe hydrogenases in cyanobacteria.

FIGURE 2. Expression of T. roseopersicina hydrogenase in cyanobacteria. Proteins from wild-type and HynSL-expressing strains were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis and Western blots were performed using antiserum raised against HynL.

FIGURE 3. In vitro H₂ evolution assays were performed on crude cell extracts from cyanobacterial strains containing T. roseopersicina constructs (Hyn4, Hyn5, Hyn5/Hup) or constructs Hyn4 and Hyn5 in combination with the environmental hydrogenase accessory gene construct (Wav10). Cells were induced with isopropyl β-D-1-thiogalactopyranoside, lysed, and assays were performed under Ar atmosphere using the synthetic electron donor methyl viologen.

one-tenth the activity of the native cyanobacterial hydrogenase (Figure 3). With the T. roseopersicina HynSL hydrogenase described above, this is the first report describing heterologous expression of active NiFe hydrogenases in cyanobacteria.

the hydrogen-deuterium exchange assay. The environmentally-derived hydrogenase maintained 20% activity in 1% O₂, 5% activity in 5% O₂, and did not possess activity at 5% O₂. This indicates that the novel, environmental hydrogenase is active in the presence of O₂.

NREL: The goal for this part of the work is to construct a cyanobacterial recombinant harboring the O₂-tolerant hydrogenase from Rubrivivax gelatinosus, using Synechocystis sp. PCC 6803 as the model host. We used two plasmids to accomplish this goal. Plasmid pPETE SigD was provided by Prof. Robert Burnap (Oklahoma State University) which enables light-regulated gene expression and homologous recombination. We cloned four structural genes cooLXUH encoding the Rubrivivax O₂-tolerant hydrogenase into the pPETE_SigD plasmid followed by its transformation into a Synechocystis mutant host lacking background hydrogenase activity (Hox⁺ provided by Prof. Teruo Ogawa). Protein western blot confirmed the expression of Rubrivivax hydrogenase subunits CooH (catalytic subunit), CooL (small subunit), and CooU (unknown function) in one of the three LXUH transgenic lines tested (Figure 4A). Expression of CooX is likely but not yet confirmed due to poor quality of its antibody. Since the transfer of up to 12 genes is likely needed to express a functional Rubrivivax hydrogenase, we employed a broad host range plasmid pRL1342 (provided by Prof. Peter Wolk, Michigan State University) to express additional genes. We constructed and transformed the Synechocystis Hox⁻ strain the plasmid carrying codon-optimized Rubrivivax cooL gene alone (pRL1342_L), or cooL as well as the hypA (hydrogenase maturation; pRL1342_LA) genes. As shown in Figure 4B, CooL protein is detected in both transgenic lines, demonstrating the utility of this broad host range plasmid in expressing foreign genes in Synechocystis. It is likely that the HypA protein was also expressed in the +LA line, which will be confirmed once we have the HypA-specific antibody.

Conclusions

JCVI: We have heterologously expressed two NiFe hydrogenases in cyanobacteria, one from T. roseopersicina and the other cloned from environmental DNA, and demonstrated that they are expressed with fully assembled and functional active sites. We have also purified these hydrogenases and verified that the environmentally-derived hydrogenase...
maintains activity in the simultaneous presence of up to 3% O₂. This work demonstrates that novel hydrogenases with potentially useful properties can be isolated from environmental DNA.

**NREL:** The NREL research confirmed the expression in *Synechocystis* of three genes, via homologous recombination, encoding subunits of the O₂-tolerant hydrogenase from *Rubrivivax*. Moreover, we also detected the expression of a *Rubrivivax* hydrogenase subunit via a plasmid-based approach in *Synechocystis* which could be used to express additional genes for building the recombinant.

**Future Directions**

- Re-engineer plasmid constructs and demonstrate increased expression of hydrogenase in vitro (JCVI).
- Test electron mediator requirement of hydrogenase expressed in cyanobacteria strains with increased hydrogenase expression (JCVI).
- Optimize conditions and transfer additional hydrogenase structural and maturation genes of *Rubrivivax* to express a functional O₂-tolerant hydrogenase in *Synechocystis* (NREL).

II.I.1 Photoelectrochemical System for Hydrogen Generation

Objectives

- Optimize and refine selection of A2B6 semiconductor photoelectrode materials.
- Synthesize and characterize the A2B6 semiconductor photoelectrode materials.
- Develop large-area photoelectrode panels.
- Develop a scaled-up prototype of a photoelectrochemical (PEC) reactor cell.
- Integrate the scaled-up prototype reactor cell with photoelectrodes and evaluate its performance.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(Y) Materials Efficiency
(AC) Device Configuration Designs
(AD) Systems Design and Evaluation

Technical Targets

Accomplishments

- Fabricated A2B6 photoelectrodes using low-cost electrodeposition to produce two distinct architectures: a CdS/ZnS bilayer (n-type) and a ZnTe (p-type).
- Demonstrated CdS/ZnS absorption band edge at 2.2 eV and performed photoelectrochemical testing of samples.
- Designed, fabricated, and tested two generations of photoelectrochemical (PEC) reactor cells.
- Conducted preliminary economic analysis for PEC reactor system.

Introduction

Sunlight is an abundant, renewable and domestically available energy source that can provide a significant proportion of carbon-free energy in the future, particularly if sunlight can be harnessed to generate hydrogen fuel for transportation. PEC hydrogen generation is an approach to generate hydrogen fuel directly from water by using sunlight to drive a water-splitting reaction on the surface of novel semiconductor materials. The primary technical barriers to the development of these semiconductor materials are that they absorb a sufficient amount of the incoming solar energy, efficiently transfer that energy to drive the water-splitting reaction, and remain durable and efficient for long operational times while remaining cost-competitive with other hydrogen generation approaches. In this project, Physical Optics Corporation (POC) is developing an approach for the low-cost fabrication of A2B6 semiconductor photoelectrode architectures and building a prototype PEC reactor cell for testing and demonstration.

Approach

The approach of this project is to increase the solar-to-hydrogen efficiency by using lower band gap A2B6 semiconductor materials (addressing the Materials Efficiency technical barrier). Using a lower band gap enables increased solar absorption due to capturing the abundant lower energy photons inaccessible to traditional high band gap PEC materials. Through a review of potential A2B6 material combinations we selected CdS and ZnTe absorbing materials with band gaps in the 2.2-2.4 eV range. Both materials can be deposited using the low cost, solution process of electrochemical deposition, which is also highly scalable for manufacturing. To address the well-known lack of
durability of CdS we designed a Type-II heterojunction architecture which uses wide band gap ZnS as a capping or window layer to provide photocorrosion protection (addressing the Device Configuration Designs technical barrier). A process for co-depositing CdS with the ZnS capping layer from a single solution was adopted and refined for photoelectrode fabrication.

In addition to fabricating photoelectrode materials, a series of generations of prototype systems to house the photoelectrodes, the PEC reactor cell, were designed, assembled, and tested as part of an iterative design process. Ultimately the photoelectrodes and PEC reactor housing will be assembled as a final prototype for testing and demonstration purposes. Technoeconomic evaluations of the hydrogen production cost will be made based on the prototype fabrication costs, the material costs, and the projected photoelectrode efficiency and lifetime of the mature system. This work directly addresses the Systems Design and Evaluation technical barrier.

Results

Our efforts on this project have focused on the development of the two major cell components: the semiconductor photoelectrode structure and the photoelectrochemical reactor cell housing.

Electrodeposited A2B6 Photoelectrode Development

We developed and refined the process for co-deposition of an n-n CdS/ZnS bilayer film using electrochemical deposition. The bilayer film shown in Figure 1, consists of an approximately 2 micron thick layer of CdS capped with roughly 100 nm of ZnS. After a base layer of CdS is deposited, the incorporation of ZnS is gradual starting around the third hour of the deposition process. Due to the large band gap of ZnS (E_g = 3.5 eV) the CdS/ZnS bilayer films are visibly and spectroscopically (for absorption spectroscopy) indistinguishable from CdS single layer films. Figure 2 shows the Tauc plot for an electrodeposited CdS/ZnS film showing a direct band edge around 2.2 eV, which achieves the DOE target. The reduction in band gap compared to bulk CdS (E_g = 2.4 eV) is attributed to a reduced amount of strain present in the solution deposited film. The influence of different substrate materials on the growth of CdS/ZnS was investigated, which revealed that due to the process by which CdS deposits (i.e., mediated by proton reduction on the cathode) more uniform CdS films were deposited using substrate materials that had slow proton reduction kinetics (e.g., Ti and ITO).

Zinc telluride films were also fabricated using electrochemical deposition which showed a strong dependence on the substrate and growth potential due to the large difference in reduction potential between Zn and Te. Films with an excess of one material or another were typical, as confirmed by energy dispersive X-ray (EDX) and X-ray diffraction (XRD) measurement.

The electrodeposited CdS/ZnS were characterized following standard PEC procedures. The open circuit potential measurement confirmed the n-type doping with an estimated flatband potential of -0.50 V vs. Ag/AgCl in 0.1 M H_2SO_4. Results of PEC testing are shown in Figure 3, which shows the 3-electrode current density-voltage (IV) and unbiased photocurrent characteristics for electrodeposited CdS/ZnS. Air annealing (at 200-300°C) has been investigated as a means of improving crystallinity. Initial results showed similar PEC properties with a decrease in durability attributed to the formation of cracks in the film during
annealing due to the mismatch in thermal expansion between the substrate and film. PEC characterization of ZnTe films are in progress and are expected to offer increased photocorrosion stability due to being p-type and generating hydrogen during the water-splitting reaction (i.e., due to being the photocathode).

PEC Reactor Cell Development

We have designed and fabricated a second generation prototype for the PEC reactor cell which will house the photoelectrode, counterelectrode, water and evolved H₂ and O₂ gases. The second generation design shown in Figure 4 was developed based on the testing of the first generation design performed by using electrolysis on metal electrodes installed in the unit in the locations where the photoelectrode and counterelectrode would sit. Through this testing we observed H₂/O₂ gas evolution and identified potential bottlenecks, weak seals, and other drawbacks. The resulting second generation design improved on the first by including a drastically reduced number of seals, eliminating bottlenecks, and improving the layout of the photoelectrode and counterelectrode configuration to better utilize space. The new design is both scalable (by increasing the size of the basic unit cell) and modular (by allowing multiple cells to be combined together) while providing easy maintenance. While awaiting system level tests with photoelectrodes, the second generation design is being further refined through studies of the durability of the materials (plastics, metals, etc.) to extended exposure to harsh electrolytes and ultraviolet light. This study includes both a literature review and laboratory lifetime testing of various reactor materials in electrolyte solutions.

Conclusions and Future Directions

POC has applied a novel CdS/ZnS bilayer electrodeposition approach to fabricate a semiconductor architecture for photoelectrochemical hydrogen generation. The resulting films exhibit broad absorption of the solar spectrum with a band gap of 2.2 eV. The characterization of the bilayer film using PEC methods demonstrated a photocurrent of 27 µA at 0 V vs. Ag/AgCl under AM1.5 illumination. Future work aims at improving the photocurrent through investigation and optimization of the carrier transport properties of the electrodeposited films to be achieved by optimizing the deposition process. Verification of PEC test results through collaboration with other members of the PEC workgroup are planned. In addition to developing...
photoelectrode materials, we constructed a small-scale prototype PEC reactor, based on the testing of the first generation prototype. The second generation prototype improved on the collection and partitioning of gases, an improvement of the counterelectrode-photoelectrode arrangement, the durability of the materials used in the system, and the modularity and scalability of the design. The future development of the PEC reactor system will include integration with photoelectrodes for full system testing and evaluation. Based on the final prototype system, an evaluation of the commercial potential for the system will be performed including the calculation of the cost of hydrogen production through technoeconomic analysis. The results of the system development and economic analysis will provide a strong basis for further commercial development of photoelectrochemical hydrogen production components or systems in the future while working to overcome DOE technical barriers.

**FY 2010 Presentations**

II.I.2 Nanotube Array Photoelectrochemical Hydrogen Production

Objectives

- Determination of optimal template geometry for photoelectrochemical (PEC) water splitting using TiO₂ as a test bed material.
- Development of additional absorber materials with required composition and architecture to achieve 5,000+ hour lifetime, 2.0 eV bandgap, and >10% conversion efficiency in the prototypes.
- Evaluation of approaches for integration of developed materials into a self-contained system.
- Formation of partnerships for bringing the technology to the market.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(AA) PEC Device and System Auxiliary Material
(AC) Device Configuration Designs

Technical Targets

This project is conducting studies of PEC hydrogen production by creating a hybrid design that combines multiple layers of materials to simultaneously address issues of durability and efficiency. As part of this effort, techniques are being developed that can manufacture devices at commercial scales. The overall goal of this project is to create a PEC device that meets or exceeds the following DOE 2018 PEC hydrogen production targets:

- Usable bandgap: 2.0 eV
- Chemical conversion efficiency: 12%
- Solar to hydrogen efficiency: 10%
- Plant durability: 5,000 hours

Accomplishments

- Produced conformal transparent conductive oxide (TCO) and TiO₂ nanotubes in a layered manner inside pores of anodic aluminum oxide (AAO).
- Demonstrated photocurrent on PEC devices without applying an external potential.
- Demonstrated ability to reduce bandgap of TiO₂ to 2.5% without affecting conductivity.
- Demonstrated conformal deposition of GaN inside AAO as a separate light absorbing material.

Introduction

The cleanest method of hydrogen production is the use of sunlight to electrochemically split water into hydrogen and oxygen. Advances in photoelectrode materials are required to make PEC hydrogen production practical. Current materials representing the state-of-the-art in this area suffer from significant lifetime limitation, bandgaps poorly matched with the solar spectrum, and low conversion-efficiency. The project aim is to develop and commercialize next-generation PEC materials that incorporate an innovative three-dimensional nanostructured architecture and a tailored bandgap.

Approach

The material architecture includes high-density, high-surface-area arrays of nanotubes formed inside the pores of the honeycomb-like, self-organized matrix of nanoporous AAO. The approach utilizes a synergistic combination of two technologies developed by the project team: (1) synthesis and integration of AAO with the required porous structure; and (2) conformal atomic layer deposition (ALD) of materials inside the high-aspect-ratio pores to produce nanotubes with atomically controlled thickness of coaxial layers. The approach
results in up to a 1,000-fold increase of the cross-section available for light absorption and the surface area available for electrochemical reactions, thus significantly increasing the hydrogen yield per area of the electrode.

The PEC materials developed in this project include a catalytic layer, surrounded by a layer of light absorbing material, surrounded by an outer shell of TCO (Figure 1). In addition, the light absorbing material can also have a vertically graded composition to allow for a vertically graded bandgap for maximum light absorption. The architecture provides a long vertical path length for light absorption with a short lateral path length for efficient charge separation.

Results

During this project we have produced AAO membranes with a variety of pore dimensions and pore densities. Pore diameters ranged from 13 to 300 nm, with corresponding pore periods from 20 to 500 nm. Subsequently, TCO and TiO$_2$ were deposited conformally inside the pores to form hollow PEC tubes and the materials were tested for PEC efficiency. These studies showed that the larger pore periods were more effective as PEC scaffolds and all subsequent tests were performed on these larger period samples.

In order to meet the cost targets for hydrogen from PEC, we also performed a scale-up effort to increase the size of our AAO membranes. Figure 2 shows an anodization cell of sufficient capacity to support large membranes (up to 10”x17”) as well as large batches of smaller membranes. Further membrane production of larger format membranes will be completed in this cell.

In addition to our efforts to scale up the anodization cell, we also expanded our ALD reactor to accommodate up to seven different precursors. Two of these precursors are on a separate dosing line specifically designed to handle the low vapor pressure precursors used for TiO$_2$ deposition. The efficacy of this new reactor design has been demonstrated by depositing highly conformal, pinhole-free layers inside the pores of AAO.

Figure 3 shows the photocurrent in chopped light as a function of the applied potential for our nanostructured PEC samples as well as flat samples with...
materials deposited in identical conditions. Peaks in the current are due to the light incident on the sample and the valleys between are due to no illumination on the sample. A Ag/AgCl reference electrode was used which has a potential of ~0.22 V vs standard hydrogen electrode. Therefore, the far left axis in Figure 3 represents zero applied bias. For the flat sample, there is no current when the applied bias is low, however, for the nanostructured sample there is an appreciable current even without an applied bias. This is a very promising result for this architecture.

In earlier efforts we explored nitrogen and carbon doping of TiO₂ to reduce the bandgap of the material. We were able to reduce the bandgap from 3.1 eV to 2.5 eV using nitrogen doping (Figure 4). These samples were prepared before the ALD reactor was modified and this was the best that could be achieved at the time. In more recent efforts we have developed a chemistry for the deposition of TiN. By combining this chemistry with the TiO₂ chemistry, we anticipate that we will be able to achieve larger doping densities and lower the bandgap to the required 2.0 eV.

In addition to modifying the TiO₂ bandgap, we have also explored the use of a separate absorber material, as shown in Figure 1. We used the expanded ALD reactor to manufacture PEC samples consisting of an outer conductor, a GaN absorber, and a TiO₂ catalytic layer. These samples were extensively tested by our collaborators at the National Renewable Energy Laboratory.

The open-circuit potential (OCP) (measured vs. the reference electrode) shifted negative with the application of broadband illumination from a 250-Watt tungsten lamp. The negative shift in OCP indicates these material configurations behave n-type, making them photoanodes.

Photocurrent spectroscopy was performed and indicated an indirect bandgap transition for these materials. GaN (bulk) is known to have a direct electronic transition at an energy of 3.4 eV, so the absorption of visible light is an encouraging result. That the transition is indirect is less encouraging. One possible explanation for the low-energy indirect transition observed could be mid-gap defect states in the GaN. These defect states limit the utility of the as-deposited GaN as an absorber material.

The reason the GaN/TiO₂ electrodes didn’t generate significant photocurrent is likely due to non-ideal band alignment at the GaN/TiO₂ heterojunction. If the valence band (VB) of the GaN is above the VB of TiO₂, holes from the GaN have an energy barrier that would prevent them from injecting into the VB of TiO₂, where they would be available for oxidation on the electrode surface. A similar argument could be made for electrons in the conduction band (CB) if the CB of GaN is above the CB of TiO₂. X-ray photoelectron spectroscopy measurements by Hansen [1] of a GaN/TiO₂ heterojunction suggest the latter.

The visible light absorption in GaN is intriguing. It is likely that the GaN has defects or impurities that lead to the visible absorption. There are reports that solid solutions of ZnO/GaN can absorb into the visible region, but not as far into the visible as we see with these electrodes. From the two data points we have (5 nm, 10 nm) the thicker the GaN, the better the photoresponse. Though these GaN samples can absorb visible light and generate reasonable photocurrent densities, the band edges appear to preclude these electrodes as unbiased water splitting electrodes.

Currently the lifetime of the materials is low, less than 100 hours. Techniques to increase the lifetime are currently being explored.

Conclusions and Future Directions

Conclusions

We have developed a nanostructured PEC material that is manufactured using scalable techniques. The material shows a significant enhancement in photocurrent over flat anodes, and is active without the need for an applied bias. We have shown that we can lower the bandgap of TiO₂ while increasing the efficiency of PEC. We have also produced samples with GaN as the absorber, and shown that it absorbs visible light; unfortunately, the band edges are misaligned for water splitting.

Future Directions

- Investigate WO₃ as a PEC material.
- Revisit N-doping of TiO₂ as a means to push bandgap down to 2 eV.
- Measure long-term stability of nanostructured films.
• Investigate other absorber materials.
• Explore techniques for increasing robustness of films and their lifetimes.

Special Recognitions & Awards/Patents Issued

1. On May 1st 2009 we submitted a U.S. Provisional Patent Application No. 61/174,577 entitled “ENERGY CONVERSION DEVICES AND METHODS FOR MAKING SAME.” This patent covers the architecture described in this project as well as related architectures for photovoltaics and other applications.

* Preliminary.
b Linearly scaled down from a 2 tons per day modular production system.
c In 2005USD, includes only H2 production costs, using H2A standard economic assumptions.

Accomplishments

- Developed continuous reactor concept with a fixed-bed catalyst design thereby eliminating the need for complicated particle separation subsystem.
- Achieved similar hydrogen yields on pre-dissolved feedstock thereby allowing a continuous reactor system design to be based on a liquid medium rather than a slurry.
- Experimentally validated that similar hydrogen yields are possible at higher reaction temperatures and lower NaOH concentration which will assist in the precipitation process.

Introduction

Approximately 100-150 million tons per year of municipal solid waste (MSW) are potentially available for hydrogen production [1]. This equates to ~14-22 million tons of hydrogen per year from a source that is normally considered a nuisance or, in some cases, even a hazard. The main advantages of using MSW as a feedstock are its low (or even negative) cost, its already established collection system, and its proximity to population centers which are also hydrogen demand

Objectives

- Experimentally demonstrate a continuous BFR reactor with similar performance to the Phase 1 batch system.
- Experimentally determine the appropriate operating parameters specific to our reactor design.
- Develop a system which allows for reuse of catalysts.
- Determine, through experiments, the appropriate operating parameters specific to our precipitator design.
- Validate process feasibility by correlating experimental results with economic analysis.

Technical Barriers

This project addresses the following technical barriers from Section 3.1 – Hydrogen Production of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Reformer Capital Costs
(B) Reformer Manufacturing
(D) Feedstock Issues
(E) Greenhouse Gas Emissions

Accomplishments

- Developed continuous reactor concept with a fixed-bed catalyst design thereby eliminating the need for complicated particle separation subsystem.
- Achieved similar hydrogen yields on pre-dissolved feedstock thereby allowing a continuous reactor system design to be based on a liquid medium rather than a slurry.
- Experimentally validated that similar hydrogen yields are possible at higher reaction temperatures and lower NaOH concentration which will assist in the precipitation process.

Introduction

This equates to ~14-22 million tons of hydrogen per year from a source that is normally considered a nuisance or, in some cases, even a hazard. The main advantages of using MSW as a feedstock are its low (or even negative) cost, its already established collection system, and its proximity to population centers which are also hydrogen demand

Accomplishments

- Developed continuous reactor concept with a fixed-bed catalyst design thereby eliminating the need for complicated particle separation subsystem.
- Achieved similar hydrogen yields on pre-dissolved feedstock thereby allowing a continuous reactor system design to be based on a liquid medium rather than a slurry.
- Experimentally validated that similar hydrogen yields are possible at higher reaction temperatures and lower NaOH concentration which will assist in the precipitation process.

Introduction

Approximately 100-150 million tons per year of municipal solid waste (MSW) are potentially available for hydrogen production [1]. This equates to ~14-22 million tons of hydrogen per year from a source that is normally considered a nuisance or, in some cases, even a hazard. The main advantages of using MSW as a feedstock are its low (or even negative) cost, its already established collection system, and its proximity to population centers which are also hydrogen demand
centers. Disadvantages include separation of the heating value constituents of MSW (paper, wood, grass, food) from the non-heating value constituents (rocks, plastic, metal, etc.).

One solution is to use a process not limited by feedstock type such as BFR. The chemical reaction within BFR has been found to produce hydrogen from most MSW materials. BFR allows one to produce highly pure hydrogen gas (>98% purity) in a simple one-step process with no need for water-gas shift systems and minimal, if any, additional gas purification. In Phase 1 of this Small Business Innovation Research project, we investigated process parameters, evaluated case studies of various commercial system scenarios, and performed system analysis using laboratory data to confirm economic feasibility. In Phase 2 we are addressing the hurdles associated with a continuous prototype system to better understand the operation and viability of a commercial product.

Approach

The continuous BFR system is being developed using an iterative test and design approach. As different operating conditions are tested, the results from those experiments influence the design of the feedstock preparation, BFR reactor, and causticizing reactor. Major subsystems are being designed and experimentally tested individually and will not be linked in a complete system as part of this project. Thus current work focuses on developing a system design and defining operating conditions that will optimally work together when all subsystems are linked. This is particularly challenging as the reactor and precipitation subsystems optimum performance are at contradictory conditions.

Results

The main activity conducted to date has been exploration of the integrated BFR system configuration and operating conditions. The complete BFR system consists of four main subsystems (Figure 1). The first subsystem is feedstock preparation which modifies the form of the feedstock so it is more easily handled and reacts best with the catalyst. The second subsystem is the hydrogen generation which takes place in the BFR reactor. The aqueous Na₂CO₃ waste stream from the BFR reactor is transferred to the third subsystem, the causticizing reactor, in order to reconstitute NaOH from the Na₂CO₃. The NaOH is recycled to the feedstock preparation and the CaCO₃ precipitate is transferred to the final subsystem, the calcium carbonate recycle. Here, CaO is reconstituted from the CaCO₃ precipitate and recycled to the causticizing reactor for the slaking reaction. While hydrogen production takes place in the second subsystem, economic studies indicate that the recycling of the reaction components is necessary to lower the cost of hydrogen.

Major subsystems are being designed and individually tested. The optimum feedstock preparation
procedures are being refined. The hydrogen generation subsystem is being fabricated (Figure 2). The major components are a feedstock holding tank, a heating section to bring the fluid up to the reaction temperature, the BFR reactor which contains the catalyst, a hydrogen gas cooling and collection section, and a waste stream cooling and collection section. Using a pump and having sufficient storage at each end point makes this subsystem continuous over a period of time. Once assembled, test will be performed replicating batch BFR reactor conditions to validate hydrogen production capabilities on this subsystem. The reactor hardware will not be linked to the other subsystems previously identified as part of this project. This work’s key results, rather, are the design of a continuous BFR reactor, its fabrication, and validation testing. Additionally, subsystem designs will be developed and tested at the component level. Upon project completion, the team will deliver a future system design, including all four subsystems, and the process parameters necessary for the optimal operation of the system.

In Phase 1 of the project all tests were performed in batch mode on solid feedstock using powder catalysts. While these conditions provided favorable results, a continuous flow system is desirable to allow convenient system scale-up and to achieve high thermal and pressure efficiency. However, the movement of solid feedstock through a continuous system creates complexity and fouling concerns. Consequently, a portion of Phase 2 testing has focused on investigating if the feedstock can be completely liquefied prior to entering the BFR reactor.

Over 40 different tests were completed to determine the extent to which feedstock could be liquefied under various heating profiles. Testing reveals that ~97% (wt) of the wood feedstock dissolves to a liquid1 at 220°C within 10 minutes when combined with NaOH and water (but no catalyst) in a pre-reactor (Figure 3). Pre-dissolving the feedstock in a pre-reactor enables multiple simplifying design elements. First, the liquid feedstock permits use of fixed-bed monolithic catalysts since the absence of solid particles ensures that the catalyst will not foul. This permits repeated use of the catalyst without costly separation equipment. Second, a liquid feedstock allows use of inexpensive, conventional liquid pumps as opposed to costly slurry pumps. Third, pre-liquefying the feedstock allows operating conditions to be easily varied between the pre-reactor and main BFR reactor. Last, hydrogen production can be located independently of the feedstock source and its processing.

Another portion of our experimental work has been focused on lowering the vapor pressure of the BFR solution so that we can operate at lower pressures for a given temperature. Batch testing in Phase 1 confirmed that hydrogen yield2 is proportional

\[ \text{Hydrogen yield} = \frac{\text{Volume of } H_2 \text{ gas obtained}}{\text{Theoretical maximum gas available}} \]

1Dissolves into liquid or liquid-like slurry strainable with a glass-fiber filter having 2.7 micron pore size.

2Hydrogen yield (%) = Volume of H₂ gas obtained / Theoretical maximum gas available
to reaction temperature. In general, higher BFR reaction temperature leads to higher hydrogen yield. Consequently, a high temperature (~340°C) is desired. However, the necessary pressure to raise the boiling point and keep the water in liquid phase at elevated temperature can easily exceed 1,500 psi, a level undesirable for safe, low-cost industrial operation. In Phase 1 equipment was pressure-limited so high NaOH concentrations were used to keep reaction pressures low. However, the causticizer subsystem operates best at low NaOH concentrations which typically result in high operating pressures. Experiments have been conducted in Phase 2 to determine if additional solution constituents are able to suppress pressure while not increasing NaOH concentration. Testing reveals that these additives have a similar effect on vapor pressure as increasing the NaOH concentration. Most importantly though in our experimentation thus far it appears that these additives have no negative impact on the hydrogen production capabilities of the BFR process (Figure 4). These tests were performed in a batch reactor and thus heating and reaction time could not be decoupled. In the case of the Phase 2 continuous BFR reactor the heating section is separated from the catalyst bed and thus we expect lower catalyst residence time and the ability to computed reaction time with respect to hydrogen yield.

Conclusions and Future Directions

- In collaboration with our project team we are building a continuous reactor in which to test various operating conditions and validate batch-mode results.

Contract Number: DE-SC0001179
Project Start Date: July 2009
Project End Date: January 2010

Objectives

The main objective was to examine the real-world technical, operational and market factors that are associated with implementing the hydrogen home refueler (HHR). The detailed effort was comprised of:

• a feasibility study,
• an analysis identifying the technical, operational, and safety requirements of the appliance,
• a preliminary design,
• estimates of energy use and environmental emissions,
• a detailed analysis of the process economics for the proposed technology, and
• a technology development plan.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section (3.1.14.3) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(G) Capital Cost
(H) System Efficiency

Technical Targets

This project addressed the issue by providing an analysis of the feasibility of an alternative, HHR, where consumers can refuel their cars at home for a competitive price of gasoline.

• HHR production capacity sufficient to support 500,000 vehicles would reduce hydrogen costs to between $3.55 and $4.25 per kg
• Cost of HHR installation to support 500,000 vehicles is between $2,425 at present and $1,336 for future.

Accomplishments

• Preliminary Design – developed specific system designs that meets the system requirements for product operation and commercial acceptance.
• Design Analysis – three different designs were evaluated based on technical, operational, safety and cost.
• Process Analysis – made an economic analysis detailing the process economics.
• Technology Development Plan – defined technical plans to address specific technical factors important to the successful development of the HHR.

Introduction

ElectroChem examined in detail the potential for a novel HHR to provide the daily hydrogen needs for fuel cell passenger vehicles. The HHR appliance uses ElectroChem’s innovative integrated flow field (IFF) stack design in a highly reliable proton exchange membrane (PEM) based electrolyzer system [1]. The appliance is clean, safe, and cost-effective, and provides a significant infrastructure cost savings during the growth phase of the fuel cell vehicle market.

A system design proposed in the report was examined in detail for safety, cost, performance, and market acceptance. Manufacturing costs were examined under the assumptions of a highly automated mass production capacity of 500,000 units annually, commensurate with vehicle manufacturing. The H2A model was used to examine total operating costs and the effective price of fuel to the consumer.

Approach

The key design elements of the proposed HHR appliance are:

• The HHR provides 1 kg of H₂ directly to the vehicle storage tank, using lower cost, off-peak electricity, over an 8-hour period. (Sufficient for a 65-mile driving range.) This effectively “tops-off” the vehicle every night.
• No high-pressure $H_2$ is stored in the appliance and the inherent system design is simplified for maximum safety and minimum cost.
• Appliance installation costs are modest and typical homes already have sufficient electrical capacity to support the unit.
• HHR operation is simple and computer controlled for maximum safety, efficient operation, and can be as easy to use as recharging a cell phone.

Results

The HHR appliance creates a paradigm shift. Hydrogen is generated at night using off-peak electricity and fed directly to the vehicle tank at 5,000 psi for daily commuting. Forecourt hydrogen refueling stations are then only needed to facilitate long distance travel greater than 300 miles. The cost advantage of hydrogen production of ElectroChem’s HHR over forecourt hydrogen station states in the fact that:

a) no manpower is required for operation,
b) no real estate is required for installation,
c) the simple design has few components, and
d) no additional infrastructure is required (electrical power lines, delivery trucks, or natural gas lines).

A system design analysis has found that the safety is readily assured by the adaptation of existing design rules applied to home refueling systems for compressed natural gas, and electric vehicle rechargers [2]. In addition, the HHR is based on ElectroChem’s IFF Electrolyzer (as shown in Figure 1) which passively manages the water content of each cell, guaranteeing reliable performance (enhanced efficiency and superior operational stability) and greatly reducing the number of moving parts. The significant system simplifications also reduce manufactured cost.

Manufacturing costs were examined under the assumptions of a highly automated mass production capacity of 500,000 units annually, commensurate with vehicle manufacturing. The cost estimates partially leveraged the benefits of using materials that are also produced for fuel cell vehicles. Several approaches to cost estimation were used, with each providing similar results, concluding that the HHR can be manufactured for between $1,000 and $2,000.

Because the number of HHR units manufactured is very large (one per vehicle) the manufactured costs are quite low. (The HHR unit is nearly as low a cost on a per kg hydrogen basis as the much larger forecourt station.) This is because, the HHR unit makes up its cost disadvantage by not requiring the excess station costs. It is seen that the total installed cost of the two approaches are nearly the same.

Our primary finding is that HHR production capacity sufficient to support 500,000 vehicles would reduce hydrogen costs to between $3.55 and $4.25 per kg, a cost and energy equivalent that is competitive with gasoline. One gallon of gasoline has nearly the energy equivalent of 1 kg of hydrogen. However, it is also noted that hydrogen vehicles are expected to be twice as efficient on a cost per mile basis. Therefore, it costs half as much to drive a mile with hydrogen.

The forecourt approach to hydrogen refueling was critiqued in detail, particularly during the period of fuel cell vehicle market growth. The problem in the forecourt approach is that large quantities of high-pressure hydrogen must be stored on-site to enable fast vehicle refueling [3]. It is concluded that the serious underutilization of capacity during market growth makes the use of forecourt based fuel very expensive, no matter what technology is used to produce the hydrogen. It is estimated that the perceived need for subsidies to
support infrastructure development can be reduced by a factor of four, if the HHR system is successfully deployed.

The environmental impact of the PEM-based HHR system is minimal because of its inherent use of safe materials, few moving parts, and no toxic emissions. The mass deployment of the HHR refueling system will also reduce carbon emissions. The material components are highly recyclable and the owner will be financially incentivized to recycle by the modest content of precious metal (approx. $100 per unit).

Conclusions and Future Directions

The HHR appliance is a key enabler of fuel cell vehicles. The HHR is seen as a means to rapidly expand the fuel cell vehicle market to all locations simultaneously, without geographic limitations, and with minimal infrastructure cost. Two specific technology development recommendations are made to enable the HHR to achieve its potential of low system cost and high reliability. 1) IFF electrolyzer development to achieve its system cost and reliability potential, and 2) electrolyzer membrane development to reduce hydrogen gas crossover to enable 5,000 psi IFF electrolyzer operation. Additional effort should be placed on low-cost, reliable hydrogen compressor designs, as a fallback to the chance that reduced crossover membrane development only partially meets its goals.

II.I.5 Unitized Design for Home Refueling Appliance for Hydrogen Generation to 5,000 psi

Objectives

Develop conceptual design for a unitized electrolyzer system for residential refueling at 5,000 psi to meet DOE targets for a home refueling apparatus:

• Complete preliminary system and stack design of a unitized proton exchange membrane (PEM) electrolyzer.
• Evaluate PEM membrane up to 2,500 psi.
• Complete economic feasibility studies.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

Accomplishments

• Preliminary Electrolyzer Stack and System Design
  - Completed preliminary design of a 5,000 psi “unitized” stack.
    - Designed, fabricated, and tested electrolyzer stack hardware to 2,500 psi.
  - Completed preliminary design for unitized PEM electrolyzer system for home refueling applications.
  - Completed economic feasibility studies.
  - Completed survey of applicable domestic and international hydrogen generation/refueling safety codes and standards.

• Membrane Evaluation
  - Six-cell short stack built with advanced dimensionally stable membrane (DSM™).
  - Conducted testing of DSM™ at pressures of 100, 600, and 2,500 psi.

Introduction

U.S. automakers have invested significant resources in the research and development of hydrogen fuel cell vehicles. However, to enable their widespread use, an additional major investment will be required to construct an infrastructure for hydrogen production and delivery to fueling stations. In order to facilitate this transition, the DOE has recommended that high-pressure hydrogen generation for home refueling of fuel cell vehicles be implemented as an intermediary approach.

GES has developed PEM-based electrolyzer technology for producing hydrogen at moderate to high pressure directly in the electrolyzer stack, while oxygen is evolved at near-atmospheric pressure. In this system, liquid water, which is a reactant as well as coolant, is introduced into the oxygen side at near atmospheric pressure. A low-cost process for producing high-pressure hydrogen from water by electrolysis will significantly advance the development of the hydrogen economy, providing hydrogen for fuel cell vehicles at a price competitive with that of gasoline on a per-mile basis. The ability to produce hydrogen economically, the relatively low capital cost of the electrolyzer unit, and the low maintenance cost of the unit will allow widespread distribution of hydrogen home fueling appliances deemed necessary for the introduction of fuel cell vehicles.
Approach

GES is currently conducting a multi-year, development project for DOE (Contract DE-FC36-08GO18065) that aims to reduce non-military electrolyzer costs while simultaneously raising the efficiencies of the PEM-based water electrolyzer units operating in the range of 400 psi. Future extension of this technology to pressures of 5,000 psig is feasible with modifications to the electrolyzer stack, providing the ability to safely operate in a balance hydrogen/oxygen pressure mode. Based on an innovative electrolyzer stack concept and recent developments in high-strength membrane, GES has designed a PEM-based water electrolyzer system for home refueling applications that can deliver hydrogen at pressures of 5,000 psi. The design concept demonstrates a method for the generation of high-pressure hydrogen by means of “unitizing” the electrolyzer stack and a high-pressure hydrogen/water phase-separator. The combination of components eliminates the need for bulky and costly stack parts and facilitates a method for fabricating an electrolyzer system that can safely operate at a balanced hydrogen pressure of 5,000 psi. In addition, a reduction of major system components and system cost is realized.

Results

**Electrolyzer Stack Design:** The Home Refueling Appliance (HRA) has been designed for on-demand operation. The system is designed with a small six-cell 2 kWe electrolyzer stack, providing a vehicle tank fill of 0.5 kg of hydrogen over a 12-hour period. This will provide 50 miles of driving range based on current fuel cell vehicle fuel economy estimates of 60 miles/kg-H₂. The electrolyzer stack is totally enclosed in a pressure containment dome; the pressure in the pressure dome is matched to that of the electrolyzer’s hydrogen and oxygen production streams. This pressure dome-based design markedly simplifies many of the stack design requirements. Operating in the dome at pressures up to 5,000 psig, the 6-cell stack has a design pressure of 100 psid, and a proof pressure of 150 psid, meeting the requirements of the Draft International Organization for Standardization (ISO) Standard ISO_DIS_22734-2 [2].

**Preliminary Design of a 5,000 psi “Unitized” Electrolyzer System for Home Refueling:** A block diagram outlining the process configuration for the 5,000 psi (34.6 MPa) PEM HRA is shown in Figure 1. The direct production of high-pressure hydrogen in the electrolyzer is shown via combining the water storage tank, electrolyzer stack and hydrogen/water phase-separators inside a pressure-containment dome, eliminating the need for a high-pressure mechanical hydrogen compressor, along with its ancillary equipment. The simplified major subsystems of the high-pressure electrolyzer system include the electrolyzer; the electricity feed sub-system; a user accessible deionized water feed and deionized water handling system. Note that the oxygen/water phase-separator is eliminated in

---

**FIGURE 1.** Cathode Feed Process Flow Diagram
this cathode-fed design; product oxygen that is free of liquid water will be promptly reduced from its high-pressure and vented safely from the system. Figure 2 illustrates a conceptual layout of the HRA pressure dome containing the major items of equipment (electrolyzer stack, water separators, hydrogen cooling coil, and hydrogen dryer).

**Liquid-Gas Phase Separators**: As they will not be subject to any significant differential pressures, the hydrogen/water phase separators located within the dome are designed from low-cost polypropylene material. They do need to be gas-tight; to meet this requirement they will be rotationally molded in a single piece, or injection molded in two pieces, then ultrasonically welded.

**Pressure Dome**: Section VIII of the American Society for Mechanical Engineers (ASME) Boiler and Pressure Vessel Code [3] was used to calculate preliminary material thickness for the HRA pressure dome. Two primary calculations were completed – for the cylindrical shell of the dome, and for the flanged-and-dished heads used to seal both ends of the dome. The cylindrical shell of the dome requires a 2.5″ carbon steel metal thickness to contain the 5,000 psig pressure within the dome.

**Membrane Evaluation at High Pressure Operation**: Polarization scans were obtained in an operating cathode-feed six-cell electrolyzer stack with an active area of 50 cm². The membrane used for this test was DSM™, fabricated by GES personnel. Utilizing a unique structure, DSM™ is a high-performance membrane having excellent dimensional stability over a wide range of temperatures and relative humidities. Compared to conventional ionomer membranes, the supported membrane is stronger, more ionically conductive, and can be optimized for specific applications. The DSM™ used in these tests had a total dry thickness of 2.2 mils, with a polyimide reinforcement layer. Figure 3 illustrates a polarization scan obtained with this electrolyzer, with data taken while operating at 80°C and 100 and 600 psi. The DSM™ demonstrated stable short-term operation and performance superior to that of Nafion® 117 [4]. The voltage ranged from 1.512 V at 100 mA/cm², to 1.688 V at 1,600 mA/cm². At the HRA design current density of 1,200 mA/cm², the operating voltage of 1.655 V translates into a stack voltage efficiency of 75.6% LHV (89.4% higher heating value, HHV). In separate testing using the same hardware, the cell voltage measured during single-cell testing at a balanced operating pressure of 2,500 psi is 1.695 V. Although hardware development is required for 5,000 psi operation, a cell voltage of 1.701 V is achievable (accounting for the Nernst penalty loss at 5,000 psi balanced-pressure-operation) or a cell efficiency of 73.6% LHV (87.0% HHV).

**System Feasibility Studies**: The main challenge to producing commercially viable hydrogen is cost reduction. To determine the feasibility of using a ‘unitized electrolyzer’ as an HRA, it was necessary to examine the individual contributors to the cost of hydrogen production, such as the capital, feedstock
II.1 Hydrogen Production / Production

Norman – Giner Electrochemical Systems, LLC

(electrical costs), and fixed operating and maintenance costs (See Tables 1 and 2).

A comparison was made between the GES HRA cost estimates and the DOE Hydrogen Program 2015 system cost goal of $30/kWe for light-duty vehicle fuel cells [5]. Using this DOE cost basis, and a scaling factor of 0.60 [6,7], a 2 kWe HRA system would be predicted to cost $234 at a unit production volume of 1,000,000 units. Alternately, a different comparison can be made to the DOE forecourt electrolyzer cost breakdown for 2017 of $125/kWe [8]. Using this alternate DOE cost basis, and a scaling factor of 0.60, a 2 kWe HRA system would be predicted to cost $4,617 at a unit production volume of 1,000. These can be compared to the GES predicted capital costs to verify that the GES costs ($1,220/$6,994) are well above the DOE 2015/2017 scaled costs ($234/$4617). As the modeled GES costs are a factor of 1.5 to 5 above the scaled DOE costs, the magnitude of the GES capital cost predictions appear to be conservative, relative to the DOE 2015/2017 costs.

The total cost of delivered hydrogen ($/kg-H2) via DOE’s H2A analysis model (rev 2.1.1) is shown in Table 2. Our studies indicate that the most significant cost contributions are in two areas: feed stock and capital costs. The feedstock (electricity required to generate H2) contribution of an electrolyzer system operating with a 3-mil DSM™ membrane, average efficiency of 84.1% HHV and a power cost of 4 cents per kWh, is $1.98/kg-H2. Although limited by durability at elevated temperature operation, for comparison the feed stock cost of an electrolyzer system operating with Nafion® 117 (average cell efficiency of 73.7% HHV), is calculated to be >$2.30/kg-H2.

Conclusions and Future Directions

The Phase I project yielded a practical preliminary design for a 5,000-psi “Unitized” design that will be able to provide on-site residential hydrogen refueling at a cost that meets the DOE target of $3.00/kg-H2 in 2017. In addition to unitizing the major components, the design incorporates numerous cost-saving (and reliability enhancing) simplifications, such as eliminating the need for any mechanical pumps, and utilizing passive cooling for low-cost, maintenance-free heat transfer. These design features eliminate the need for bulky and costly stack and system parts, and facilitate a method for producing a low-cost electrolyzer system that can safely operate at a hydrogen pressure of 5,000 psi in a residential setting. Future objectives are:

- Detail design and fabrication of a full-scale electrolyzer stack sized for a hydrogen production rate of 0.5 kg H2 per 12-hour operational period.
- Detail design, component fabrication, and assembly of a “unitized” breadboard HRA electrolyzer system for 5,000 psi delivery pressure.
- Perform in-depth reviews of codes and standards pertinent to hydrogen generation.
- Performance testing of unitized system prototype.
- Develop marketing strategy and partnerships for wide scale adoption of the technology.

II.I.6 Design, Optimization and Fabrication of a Home Hydrogen Fueling System

Objectives

- Construct a multivariate system optimization model for a reformer-based home hydrogen fueling appliance that:
  - Provides system selection guidance for optimal system integration.
  - Determines the cost, energy requirement and CO₂ emissions for the selected system integration route.
  - Provides sensitivity analysis for the selected system integration routes with respect to critical cost and energy parameters such as natural gas price, electricity price, hydrogen production rate and bulk production volume.
- Determine the safety issues with the optimal system of choice for a hydrogen production rate of 0.5 kg/day to 3 kg/day. The safety of operation has to be evaluated for the operation of the appliance for a home owner or a person completely unskilled from technical and safety points of view.

Technical Targets

The technical target of the project is to develop an affordable and safe home hydrogen fueling appliance for a daily consumer that speeds up commercialization and general awareness of fuel cell technology. Insights gained from this project will be applied toward the design and fabrication of a home hydrogen fueling appliance in Phase II of the project. The target of the Phase I project was to design a system that meets average home-owners requirements for a fuel cell vehicle application. The specific targets are:

- H₂ production rate: 0.5-5 kg per day
- Fueling time: 2-8 hrs
- H₂ cost: $2.00 to $3.00 per kg H₂ for distributed H₂ production
- Fuel cell grade H₂ quality (SAE J2719 standard)
- H₂ delivery pressure: ≥5,000 psig
- H₂ delivery temperature: 25-40°C

Accomplishments

- Identified safety codes and standards and developed operating guidelines.
- Constructed a user-friendly multivariate model that can perform sensitivity analyses and identified best options for a home fueling station for low H₂ production rates based on cost, CO₂ emissions and electricity consumption.
- Completed preliminary system design calculations for a Phase II prototype system for 0.5 kg/day H₂ production.
- Identified Go/No-Go milestones for Phase II for the optimized system fabrication.

Introduction

Cost, safety and energy requirement are the critical barriers for realizing the concept of home hydrogen fueling for widespread recognition and commercialization of fuel cells in automotive use. Reformation of hydrocarbon fuels such as natural gas and electrolysis of water are the two best options available for hydrogen production. For fuel cell vehicle application, hydrogen at high purity and pressure (>5,000 psig) is required. This presents a system integration problem, where individual processes of hydrogen generation, purification (only for reformation...
route) and compression have to be integrated together efficiently in order to produce an affordable device. Though there have been significant efforts in advancing and optimizing individual systems for centralized and distributed hydrogen generation, there is no effort made on the understanding and optimization of system integration strategies for very low hydrogen production rates (<5 kg/day, 8 hour operation) for a typical home fueling application.

**Approach**

The target of Phase I was to identify, select and integrate the individual subsystems (desulfurizer, reformer, hydrogen purifier and compressor) for a reformer-based home hydrogen generation unit, utilizing natural gas as the fuel feed. The selection criteria were to be based on optimization of critical parameters identified for successful commercial home fueling appliance through a multivariate analysis of the system. The chosen parameters for evaluation of the system were cost, safety and in particular, the electrical energy requirement of the appliance. Lynntech approached the system optimization problem in the following steps:

- Identify and qualify the subsystem or component options and weigh them qualitatively from cost, safety and operability standpoints. This is done by creating weighting factors for each criteria (cost, safety, etc.) and determining the overall system or component score.
- Select appropriate systems for integration from the weighting parameter analysis.
- Construct a quantitative multivariate model to estimate the cost, energy requirement and CO₂ emissions for selected system integration routes.
- Conduct the sensitivity analysis with the model for cost with respect to the variation in natural gas cost, electricity cost and bulk production volume.
- Design the most optimum system from the model results for fabrication of a Phase II prototype for 0.5 kg/day H₂ production.

**Results**

In accordance with the objectives of Phase I, Lynntech developed a multivariate system optimization tool to determine the cost, CO₂ emissions and energy requirement for different system integration strategies for natural gas reformation as well as the water electrolyzer route. The significant findings for a H₂ production rate of 0.5 kg/day to 5 kg/day from the project was that a combination of natural gas reformation for H₂ production with electrochemical purification and compression offers the most economical system design. The competitive system analyzed was a low-pressure electrolyzer with a compressor. The cost of H₂ per kg, electricity requirements and CO₂ emissions are found to be less than the electrolyzer route. The results for H₂ production rate of 0.5 kg/day with 8 hours of operation per day are summarized in Figure 1.

The target of the system optimization was to develop a user-friendly system analysis tool, which allows user inputs for hydrogen production rate, selection of individual system components and their key operating or cost parameters and creates output of cost of hydrogen, CO₂ emission and electricity requirements. A weighting factor analysis procedure was formulated for comparing individual system components for initial screening of the system components for integration. The system components are scored for cost, safety, technology maturity, ease of operation, ease of integration and maintenance. A typical output from the program for comparing different system components is shown in Figure 2.

The selected system components were then linked with each other to create complete system integration strategies. The assumptions for electricity and natural gas cost are taken from H₂A analysis. Capital cost is the primary cost driver in the hydrogen production range under consideration. Figure 3 compares the capital costs of only the reactor-purifier systems under consideration, e.g. the two combinations for the reformer systems, steam methane reformer with electrochemical purifier (SMR-ECM) and steam methane reformer with pressure

![Figure 1](image-url)  
**Figure 1.** Comparison of system optimization results for 0.5 kg/day H₂ (8 hour per day operation) production for Lynntech’s proposed reformer system and a low-pressure water electrolyzer.

Compression Options

Lynntech’s Reformer System of Choice

FIGURE 2. Scoring comparison for different systems and Lynntech’s reformer system of choice.
CPOX - catalytic partial oxidation; PD - palladium; LP - low pressure

After deducing the capital and operating costs for the systems under consideration, the cost of hydrogen was determined by amortizing the capital cost over a period of 10 years. The rate of return on investment for this period was assumed to be 10%. Figure 4 shows a comparison of hydrogen cost for different production rates for the four system integration options considered under the project. System 1, a SMR-ECM was found to be the best choice among the systems analyzed. It was inferred from the bar plots that for purification and compression, the mechanical systems, PSA and mechanical compression become competitive with electrochemical systems at hydrogen production rates of 5 kg/day, but below that electrochemical systems are the preferred choice. Sensitivity analysis was then
conducted to determine the dependence of $H_2$ cost on the cost of electricity and natural gas feedstock.

Based on the optimal system integration strategy, preliminary plant design for the complete hydrogen production plant was developed for 5,000 psig $H_2$ output as per SAE J2719 quality standard. Safety analysis was then conducted as per ISO 16110, to identify critical failure modes and control strategies or equipment needed. A cheap and effective control strategy was developed to reduce the complexity and cost of the sensor and control equipments used.

Conclusions and Future Directions

- A multivariate model was developed for system optimization and sensitivity analyses of home hydrogen fueling systems.
- Model results for 0.5 to 5 kg/day hydrogen production rate:
  - Reformation of natural gas is the cost-effective way to produce hydrogen gas as compared to water electrolyzers.
  - Capital cost of purification and compression are the critical cost drivers for the reformer-based hydrogen production systems.
  - Electrochemical purification and compression technologies offer the most cost-effective route as compared to conventional PSA and mechanical compression technologies.
  - Combination of reformation for $H_2$ production with electrochemical purification and compression offers the most economical system design.

- The commercial benefits are multiple and include:
  - Small-scale hydrogen refueling stations offering significant cost and process advantages over existing designs.
  - Modeling and simulation tools for implementation of future hydrogen economy equipment items and infrastructure.

- The future task will be to refine the model and convert it into a user-friendly program that can be used as a tool for selection of subsystems for a home hydrogen fueling system.
- Lynntech plans to use the model results to develop and demonstrate a cheap (low capital cost) home hydrogen fueling appliance for 0.5 kg/day $H_2$ production in Phase II.
II.I.7 Hydrogen by Wire — Home Fueling System

Objectives
- Define critical requirements for proton exchange membrane (PEM) electrolysis home fueling system.
- Define hydrogen production capacity for a recharge time relevant to the end-user.
- Estimate the electrical service requirements and physical size.
- Estimate the capital and operating costs.
- Describe the relevant codes and standards and their impact on cost.
- Describe key elements of product safety related to energy content and electrical hazard.
- Describe the types of operation and maintenance required, and estimate costs.

Technical Barriers
This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:
(G) Capital Cost
(H) System Efficiency

Accomplishments
- Estimated required hydrogen production capacity for a range of vehicle fuel efficiency values and vehicle usage profiles.
- Estimated physical size and electricity usage.
- Developed home fueling system bill-of-materials.
- Calculated $/kg cost for a range of fuel efficiency and vehicle usage profiles using the H2A model. Demonstrated significant progress toward DOE hydrogen cost targets established for much larger scale hydrogen production systems.
- Tabulated list of relevant codes and standards.
- Estimated cost impact of municipality specific codes and standards environment.
- Defined maintenance strategy.

Introduction
The goal of this study was to develop requirements for a home-based hydrogen fueling system, design conceptual systems, compare the impacts of changing key parameters, and evaluate the feasibility of those concepts in meeting the requirements of the home fueling application. Factors considered in developing requirements included driving scenarios, electrical service requirements, recharge times, compression and storage, and codes and standards. Concepts were evaluated on the basis of capital cost, efficiency, safety, and installation and maintenance.

Approach
The approach was to gather primary data, develop a handful of scenarios representative of typical driving habits, and derive the requirements for the home fueling
system based on the fundamental information. The driving scenarios were based on primary survey data of commuting distances of average Americans including the National Household Travel Survey [1] produced by the U.S. Department of Transportation Federal Highway Administration and the Omnibus Household Survey [2] from the Bureau of Transportation Statistics. The electrical service requirements were evaluated within the context of power available in a typical residence, and compared to other devices currently found in homes. The recharge times were based on the amount of time a vehicle would be parked at home. Proton Energy Systems’ industrial electrolyzer equipment and high-pressure systems were used as sources of information to form the base bill-of-materials for the packaging studies and cost estimates. In addition, Proton’s experience servicing its fleet of fielded commercial electrolyzer products was used to inform the maintenance and service plans. In each of the areas investigated, an approach based on available data and manufacturing experience with commercial electrolyzers was used to ensure the analysis and projections were strongly grounded in practical end-use and the realities of manufacturing.

Results

The hydrogen production capacity was estimated for a range of vehicle fuel efficiency values and driving habits, including serving one, two, or three vehicles within one household. With a single 90 mile per kilogram (mi/kg) vehicle, as little as 0.4 kg of hydrogen are required on average each day (Figure 1). With three 55 mi/kg vehicles and higher driving mileage, as much as 1.8 kg of hydrogen might be required on a given day.

The effects of using an electrolyzer that generates hydrogen and directly fills the vehicles only when the vehicles are home was compared with the option of including a small amount of stationary ground storage. While the inclusion of stationary ground storage does allow the hydrogen production equipment to be smaller, as it can be operating continuously, the cost of the ground storage system outweighs the cost reduction of the electrolysis equipment. Therefore, the electrolysis direct fill configuration has the advantage over a system that includes stationary hydrogen storage.

The compression efficiency of mechanical compressors and the electrochemical compression capability of a PEM electrolysis cell were compared. Electrochemical compression from ambient to 5,000 psi and higher is more efficient than mechanical compression from the same starting pressure. A further optimization showed that there may be a marginal efficiency gain by using a combination of electrochemical compression and mechanical compression where the electrochemical portion ensures that there is only one stage of mechanical compression. The efficiency gains for the combined case may be as much as 10% over pure electrochemical compression. However, including mechanical compression in a home fueling system has several drawbacks. First, the upfront purchase cost is higher with a mechanical compressor. In addition, the life cycle maintenance costs, as well as installation costs, and noise regulations in residential neighborhoods all discourage configurations that include mechanical compression. Electrolysis-only configurations were considered for the balance of the study.

A packaging study was conducted to estimate the physical size of a PEM electrolysis hydrogen home fueling appliance. The result of the detailed packaging exercise yielded a rough sizing of the unit, not including any storage or compression, of approximately 30 to 40 inches wide by 24 to 36 inches deep by 60 to 72 inches tall, smaller than a typical refrigerator (Figure 2).

The cost analysis examined the impact of different driving scenarios, different vehicle fuel economies, the incorporation of either storage or mechanical

![FIGURE 1. Calculated Hydrogen Generation Requirement (average for vehicle driving scenarios and fuel economy)](image1)

![FIGURE 2. A packaging estimate yielded a clean, compact design based on components used in current commercial equipment.](image2)
compression, different cell stack configurations, and long-term cost reductions. Moreover, the sensitivity of the cost of hydrogen to several key factors was studied. Interestingly, for the home fueling application, the usage (as it impacts capacity factor) and the capital cost have a much greater impact on the cost of hydrogen compared to larger hydrogen production plants (Figure 3). The cost of hydrogen for a medium volume, cost reduced product is estimated to be about $5.99/kg. The relative cost reduction from an initial prototype to volume production is estimated to be greater than 50% (Figure 4).

There is a cost impact associated with the current municipality specific codes and standards environment. Based on Proton’s experience with fueling stations as either the prime equipment installer, or the electrolysis supplier, the costs of coordinating with the authority having jurisdiction can be measured from 4 to 50 hours per installation. This type of installation cost would be severely restricting in expanding the reach of a home fueling product to the residential market. The solution is to coordinate national and international standards (such as International Organization for Standardization 22734-2), to assist states and municipalities in adopting the most up-to-date standards, and to educate the local authorities on what key features they should be looking for in a typical installation of this new type of equipment.

For equipment properly designed and properly installed to the latest standards, a PEM electrolysis-based home fueling station exhibits uniquely appropriate characteristics. For example, the maximum on-board hydrogen inventory at full-pressure production is less than 0.05 kg. The amount of energy contained in that amount of hydrogen is less than 1% of what is contained in a couple of lawn mower gasoline filler tanks and less than 0.1% of that contained in two typical gasoline power vehicles. Thus, a PEM electrolysis-based fueling system minimizes the local presence of fuel by converting water directly to fuel only as it is needed.

Conclusions and Future Directions

The case for including the hydrogen home fueling concept in the overall mix of fueling infrastructure is strong. The home fueler can grow in production volume and geographic distribution with individual vehicles as they are placed in the market with more flexibility than centralized fueling stations. Existing utility infrastructure (water, electricity) can be utilized within their existing capacities to cover the distribution aspect of the fueling infrastructure.

- The hydrogen production capacity required for the practical range of home fueling needs is within the capability of existing PEM electrolysis devices.
- The ability to generate hydrogen at 5,000 psi differential pressure—that is, with oxygen at near-ambient pressure—is another significant advantage of PEM electrolysis technology, eliminating the capital cost, footprint constraints, noise, and long-term maintenance costs associated with mechanical compression equipment.
- The footprint of a PEM electrolysis-based home fueling system can fit comfortably within a typical residential garage.
- Cost reduction efforts in line with Proton’s current roadmap can help to bring the hydrogen cost from home fueling down to levels competitive with the targets for neighborhood stations.
- PEM electrolysis-based home fueling equipment has intrinsic characteristics that enhance the opportunities for safe home use, in particular by maintaining a low on-board hydrogen inventory even while operating at full production and pressure.
Proton recommends that the U.S. Department of Energy support near-term prototype fabrication and test of integrated, residential-scale, home fueling equipment based on PEM electrolysis technology.

Proton recommends the support of technology development to extend the differential pressure capability of PEM electrolysis equipment and the support of cost reduction efforts to speed the transition of this technology to initial product release.

II.I.8  Development of a Hydrogen Home Fueling System

Objectives

- Define the requirements for hydrogen home fueling system needs.
- Design and optimize process flows for the hydrogen home fueling system.
- Implement DOE's H2A model to analyze the tri-generation economics and identify barriers to be overcome.
- Setup a technology development plan to advance home application of the technologies.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(G) Capital Cost
(H) System Efficiency

Technical Targets

Verify feasibility of achieving $3.70/gasoline gallon equivalent (gge) (delivered) from distributed electrolysis (4Q, 2012).

Accomplishments

- Completed analysis of fuel-assisted electrolysis home fueling station process design.
- Showed that using current technology, with current production methods and supply costs, a gge cost of $8.75 can be achieved, with feedstock costs of $1.65/gge.
- Constructed a solid-oxide fuel-assisted electrolyzer and power production hybrid module and used the resulting performance data as input to the home fueling station process design.
- Identified safety codes to be modified for hydrogen home fueling station applications.

Introduction

A critical factor inhibiting the rollout of hydrogen vehicles is the lack of supporting hydrogen distribution and generation networks. Significant use of hydrogen vehicles is not feasible until convenient fueling is accessible to the driving public; a possible solution to this problem is the simultaneous rollout of both hydrogen vehicles and home-based (distributed) hydrogen generation. For such a system to be economical, and avoid the problems associated with on-site hydrogen production via reformation, a fuel-assisted electrolysis method can be used—pairing the purity of electrolysis generated hydrogen with the reduced cost of natural gas feedstock (replacing high cost of the electricity requirement).

Approach

In this project, several system process designs were completed for a hydrogen home fueling system using solid-oxide fuel-assisted electrolyzer cell (SOFEC) technology. Small hybrid SOFEC/solid-oxide fuel cell (SOFC) power generation modules were fabricated and tested, and the performance data were fed into the system process designs to ensure accuracy in the performance component of the cost modeling. The most cost-effective and efficient process was chosen and analyzed for major contributors to the calculated distributed hydrogen production cost.

Results

In conjunction with NREL, MSRI completed a system process design which calls for the use of distributed natural gas as a depolarizing agent to reduce the electrical cost of high-temperature steam electrolysis.
Important considerations in the completion of this design were: (a) projected demand for a fuel cell vehicle operating as a daily commuter, (b) performance of the hybrid SOFEC-SOFC modules, (c) the expected “charge time” allowable (a longer term hydrogen generation cycle allows for reduce system size and correspondingly reduced operational and capital costs), (d) planned operational lifespan of the hydrogen fueling appliance, (e) amount and cost of feedstocks, (f) operational behavior, including system shutdown/startup behavior, expected turndown, required user interaction, etc., and (g) expected subsidiary roles (power and/or heat generation).

Hybrid SOFEC-SOFC (hydrogen and power cogeneration) stacks were built and run using distributed natural gas (directly from the Questar Gas residential/commercial network) and a performance profile was established for the technology at its present state. The data (including performance at a variety of fuel and air utilizations and amperage levels) were compiled and fed into the process design to allow performance analysis according to the H2A model. Figure 1 shows a selection of the performance profiles obtained through the module testing at various utilizations, and Figure 2 shows a steady-state performance profile with set utilizations.

The completed process design included all the requisite components for a hydrogen generation system, including an autothermal reformer, a steam generator, heat recovery devices, hybrid SOFEC/SOFC (hydrogen/power generation) modules, condensers, and a hydrogen compressor. Analysis of the design allowed a current state of technology cost per gge estimate to be made (see Figure 3); it is clear that to meet DOE targets, capital costs (adding $4.51/gge to the production cost) must be reduced significantly.

Conclusions and Future Directions

Hydrogen production via SOFEC has shown to be a viable means of significantly reducing the operational costs of hydrogen generation via electrolysis. It is also clear, that in order to meet the cost goals established by the DOE it will be necessary to reduce the unit capital cost. In addition, a review of existing residential and commercial codes has shown that the regulatory structure necessary for the widespread implementation of residential hydrogen fueling stations is not yet in place.

Future work will include:

- The completion of a complete proof-of-concept hydrogen production unit (including balance-of-plant components).
- Characterization of the complete unit, including the development of practical and optimized startup, shutdown and steady-state operation.
- Recommendations on how the hydrogen home fueling unit can fit into regulatory code development efforts.
- A design for manufacture analysis targeting significantly reduced unit production cost.

II.J.1 Developing Improved Materials to Support the Hydrogen Economy*

Michael Martin
Edison Materials Technology Center (EMTEC)
3155 Research Blvd.
Dayton, OH 45420
Phone: (937) 259-1365
E-mail: hydrogen@emtec.org

DOE Technology Development Manager: Rick Farmer
Phone: (202) 586-1623
E-mail: Richard.Farmer@ee.doe.gov

DOE Project Officer: Reg Tyler
Phone: (303) 275-4929
E-mail: Reginald.Tyler@go.doe.gov

Contract Number: DE-FC36-04GO14215
Start Date: March 1, 2004
End Date: December 31, 2010
*Congressionally directed project

Objectives

- Foster the investigation and advancement of cross-cutting, breakthrough materials technologies to yield an award-winning project with active DOE Hydrogen Office participation (technology commercialization).
- Manage ongoing hydrogen infrastructure projects; collect and review monthly project reports for go/no-go results (near term commercialization of technologies, products and processes in support of the hydrogen economy).
- Prepare quarterly project reports from individual project reports; negotiate statements of work for selected projects.

Technical Barriers

The projects under this award addressed a wide range of barriers from the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan.

Technical Targets

The EMTEC solicited and funded hydrogen infrastructure related projects that have a near-term potential for commercialization. The subject technology must be related to the U.S. Department of Energy hydrogen economy goals as outlined in the multi-year plan titled, “Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan.” Preference was given to cross cutting materials development projects that lead to the establishment of manufacturing capability and job creation.

Approach

The EMTEC has used the U.S. Department of Energy hydrogen economy goals as outlined in the multi-year plan titled, “Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan” to find and fund projects with near-term commercialization potential. Our request for proposal approach specifies proposals/projects for hydrogen production, hydrogen storage or hydrogen infrastructure processing which may include sensor, separator, compression, maintenance, or delivery technologies. EMTEC is especially alert for projects in the appropriate subject area that have cross cutting materials technology with near-term manufacturing opportunities. To date, EMTEC has selected projects through our request for proposal process which develops novel technologies preparatory to commercialization. EMTEC’s overriding objective is technology commercialization.

Accomplishments

- From project start, EMTEC has funded and provided oversight to over 30 projects in various phases of development.
- EMTEC hosted and attended individual project reviews for the active projects and final site visits for the projects completed throughout the year. All capstone projects are now complete.
- EMTEC attended and presented a poster at the DOE Hydrogen Program Merit Review, June 7–11, 2010, which featured the most promising technologies.

Conclusions and Future Directions

EMTEC has leveraged DOE initiative funded on a 1 to 1 match basis on this highly successful project, resulting in strong technology advancement as well as job creation and economic development:

Individual Projects: (all complete - see previous reports)
Future Directions

- Technical governance with projects and technology outcomes.
- Seek new opportunities to continue technology development and commercialization activities as appropriate for the most promising technologies.

Conclusions

EMTEC continues to energetically pursue the near-term commercialization of the hydrogen infrastructure technologies that in many cases has been developed with previous DOE support. The EMTEC programmatic collaborative approach is well suited to accelerate technology to market. EMTEC selected high quality projects in appropriate subject areas that have cross cutting materials technology with near-term manufacturing opportunities.

EMTEC has leveraged DOE initiative and funds on a 1 to 1 match basis on this highly successful project, resulting in strong technology advancement as well as job creation and economic development.

2010 Publications/Presentations

1. EMTEC made a presentation at the 2010 Ohio Fuel Cell Coalition annual Symposium, giving a historical perspective of fuel cell involvement with some of the developmental programs and projects throughout many years.
Objectives

- Investigate and evaluate initial processes for the production of hydrogen from various waste streams using anaerobic microbial fermentation.
- Investigate paths for implementation of the research as a modular energy source initially for application in remote locations.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (Revision 2007) (see page 3.1-30 of Section 3.1.4):

- (AR) H\textsubscript{2} Molar Yield
- (AT) Feedstock Cost
- (AU) Systems Engineering

Accomplishments

- Testing of various combinations of microbial consortia was conducted with organic waste materials to determine parameters that maximize production. It was determined that pH, temperature and waste material concentration had the greatest influence on hydrogen production for the test conditions considered. A central composite design is being used to determine operating values that maximize hydrogen production.
- The automated testing system previously designed and constructed was used to determine optimal operating parameters. Fourth generation tests are now being completed.
- Tests of continuous production are ongoing for Purdue food waste and distiller's grain and inoculum samples.
- The initial design of a modular energy system for local energy production and waste treatment has been completed and is being used to optimize value.
- A 3 L batch/continuous fermentor is being implemented to enhance testing and consider scale up issues.
- The vacuum tube solar collector system is used for pre- and post-waste processing and consideration of other ancillary uses such as building heating and production of potable water.
- Steam generator tests demonstrated ability to distill water with maximum solar energy conversion efficiency of ~70%.
- Initial designs are being investigated for development of a prototype system with reduced substrate water concentration.
- Decreasing water concentration significantly increases the value for the modular energy system design. Water concentration has been decreased from 95% to 75% with little loss in hydrogen production rates.
- Significant hydrogen production was demonstrated using distiller's grain from ethanol production as substrate. Maximized operating procedure has shown significant increase in hydrogen production levels for second generation tests of distiller's grain.
Two advisory board meetings were held in the last year to continue to gain input from industry. Advisory board members include: Cargill, INEOS Technologies, BP, Advanced Power Technologies, and Ajinomoto Food Ingredients, LLC.

Introduction

This project allows the creation of a Hydrogen Research Laboratory in a unique partnership between Purdue University’s main campus in West Lafayette and the Calumet campus. This laboratory is engaged in basic research in hydrogen production and storage and has initiated engineering systems research with goals established as per the U.S. DOE Fuel Cell Technologies Program. Hydrogen production research of this project is reported in Purdue Hydrogen Systems Laboratory: Hydrogen Production.

Bio-production of hydrogen is potentially an important renewable source of energy. Using organic wastes for bio-production of hydrogen not only has the potential to generate cost-effective and renewable energy but also can reduce pollution in the environment and provide a source of fertilizer for growing crops. The purpose of the current research effort is to investigate, obtain data, and evaluate initial processes for the production of hydrogen from various waste streams using microbial fermentation and investigate possible paths for implementation of the technology as a local electric and thermal energy source. This effort is targeted to assure that the developed technology will be applicable for integration into various current and future energy supply options including the Department of Energy Road Map. This effort is investigating ways to develop a modular anaerobic biological hydrogen production and energy system for applications initially in remote locations (Figure 1). It is realized that hydrogen production levels from conventional anaerobic processes are not as great as is desired in the long term perspective for bulk production systems.

This research is focusing on a process that has multiple products and associated values. Value streams include hydrogen, waste disposal function, heat for buildings, drinking water, and possibly a marketable chemical product produced from process carbon dioxide. After it is proven, it is anticipated that the technology will be leveraged to larger applications in continuing research efforts. We have performed preliminary cost analysis studies, but factors such as the water content greatly influence the design and consequently the cost. It is also necessary to consider aspects such as the value of waste disposal, sanitized fertilizer, and ancillary energy. These aspects depend on the details of the process currently being developed. Preliminary estimates indicate that when all costs and benefits are considered, the technology has advantages over other alternatives for this application. The carbon dioxide capture portion of the process is intended principally for gas conditioning. Carbon dioxide is a co-product and hydrogen purification is usually necessary. The potential for utilization of the captured carbon dioxide in the production of chemical products is under investigation as a part of maximizing the utility of the proposed self-contained system.
**Approach**

We are considering methods to optimize hydrogen production from waste through the use of a fermentation process (Figure 2). The optimization procedure is being used to form the foundation for the subsequent development of a modular device that will use various waste streams, including garbage, animal or human waste, and distiller’s grain for the production of hydrogen. This hydrogen will be separated from the biogas stream by use of nanocatalyst or a membrane for use in a fuel cell or reciprocating engine to produce electricity locally. Methods to sequester carbon dioxide as part of the process are also being considered. Energy for the pre- and post-processing of feed streams is being obtained from a solar collector system. The steam generator of the solar system is currently producing potable water. Computer simulations of the process indicate that the system can be installed in a shipping container and used to provide local electric and thermal energy. Initial efforts have reduced the amount of water in the processed waste material from 98% to 75% with minimal decrease in hydrogen production. By reducing the fraction of water it will be possible to reduce the volume and weight of the bio reactor and increase the system efficiency.

**Results**

Additional inocula have been tested and the concentration of hydrogen in the produced gas has been correlated with the experimental variables: pH, temperature, and substrate concentration. We have preliminary indications that a new procedure for producing hydrogen with distiller’s grain may show considerable higher hydrogen production levels than any observed to date. We are currently investigating this approach. If verified, this may provide a new alternative for increasing hydrogen production levels with distiller’s grain and provide a potential enhancement to the energy balance for ethanol production. Considerable interest in these results has been shown by the Industrial Advisory Board for the project since it could be of value for multiple industrial processes.

Test samples and data are being exchanged between Purdue Calumet and Lafayette and trials to test repeatability continue. A micro gas chromatograph is used to determine gas composition. The testing is based upon a central composite experimental design. We are currently completing the third iteration for the optimization of the hydrogen production levels. This process identifies combinations of operating variables that maximizes hydrogen production. Figure 3 depicts the third generation optimization of hydrogen concentration using the Simplex methodology with an optimum point at 36.9°C, starting pH 5.9 and 1.2 g/25ml concentration. The multiple testing devices are fully operational and is being used to generate data (Figure 4). This device provides the capability to conduct multiple simultaneous tests with automated data processing and monitoring. Continuous production testing is currently being conducted at Purdue Lafayette and initiated at Purdue Calumet with the addition of a batch fermentor (New Brunswick). Initial approaches to a dry substrate design are being investigated at Purdue Calumet and Lafayette. The computer simulation model for the modular energy system was updated based upon new experimental values. Efforts using a catalyst process for capture of carbon dioxide have been initiated.

**Conclusions and Future Directions**

The biological hydrogen production work to develop optimal hydrogen production cultures for different substrates, reduce the water content in the substrate, and integrate results from the vacuum tube solar collector pre and post processing tests into an enhanced energy system model and modular energy system design will continue this year. The automated testing device developed will continue to be used to consider optimal hydrogen production conditions using statistical testing procedures. Testing with the
continuous fermentor will be expanded to consider issues associated with continuous feed of substrate and scale up of the process. A mass flow meter will continuously measure hydrogen production levels from the fermentor. We will also explore existing catalytic methods including nanocatalysts for capture of carbon dioxide from the fermentation process. The next phase of the research will involve the construction a bench top reactor based on these designs that will operate with dryer waste material and use solid material handling techniques. Funding is currently not available for the actual construction of the dry bench top test unit. This research considers hydrogen production, but also considers the leveraging of other value streams to overcome design issues that have arisen in the past. We consider this process to have significant value for waste processing and heat production as well as hydrogen production. The use of catalysis to condition the biogas stream also adds value to the process that has not been considered in the past for this application.

**FY 2010 Publications/Presentations**

III. HYDROGEN DELIVERY
Introduction

Hydrogen must be transported from the production site to the end user (e.g., a fueling station or stationary power site) or produced on-site. It also must be compressed, stored, and dispensed at refueling stations or at stationary power generation sites. Due to hydrogen's relatively low volumetric energy density, the transportation, storage, and final delivery of hydrogen as an energy carrier currently entail significant costs and inefficiencies. The Hydrogen Delivery sub-program activity focuses on developing technologies to reduce the cost and increase the energy efficiency of hydrogen delivery, to enable the widespread use of hydrogen as an energy carrier.

Three potential delivery pathways are being considered: gaseous hydrogen (trucks or pipelines), liquid hydrogen (trucks), and novel solid or liquid hydrogen carriers (trucks or pipeline). A carrier is a material that stores hydrogen at lower pressures and higher temperatures. Examples of potential hydrogen carriers include metal or chemical hydrides, nanostructures, and liquid hydrocarbons that can be easily de-hydrogenated and re-hydrogenated with a round-trip efficiency greater than 60%. In addition, research and development (R&D) activities include work on compression and off-board hydrogen storage development.

Goal

The goal of the Program’s hydrogen delivery portfolio is to develop hydrogen delivery technologies that enable the introduction and viability of hydrogen as an energy carrier for transportation and stationary power generation.

Objectives

The objective of the Program’s hydrogen delivery portfolio is to reduce the costs involved in delivering hydrogen from the point of production to the end-user and to enable hydrogen to be sold competitively (on a cents-per-mile basis) with gasoline. This overall goal applies to all delivery and dispensing technologies, including those used in centralized hydrogen production pathways and those used in both centralized production and distributed, on-site hydrogen production (e.g., on-site compression, storage, and dispensing). Interim targets and pathway-specific targets are currently being identified. Significant technological advances are needed to lower the cost of hydrogen delivery and to enable a transition to the widespread use of hydrogen. R&D objectives and priorities for hydrogen delivery include:

- **Pipelines:** Resolve hydrogen embrittlement concerns with steel pipelines, reduce capital costs by developing new steel compositions and/or welding and installation techniques, and/or develop viable composite pipeline technology with reduced capital costs.
- **Tube Trailers:** Increase gaseous tube trailer capacity and lower trailer costs to reduce overall hydrogen delivery cost, especially during a market transition.
- **Compression:** Develop more reliable, lower cost, higher efficiency hydrogen compression technology for pipeline transmission and for stationary and refueling station applications.
- **Storage:** Develop lower capital cost off-board storage technology; confirm the technical feasibility and adequate availability of geologic storage for hydrogen.
- **Liquefaction:** Reduce the capital cost and increase the energy efficiency of hydrogen liquefiers and bulk storage (reduce boil-off).
- **Carriers:** Work toward a Go/No-Go decision and leverage research for on-board storage applications to determine if a novel solid or liquid carrier might be suitable for hydrogen transport or off-board storage and result in lower delivery costs and higher energy efficiency. This technology is feasible only if the carrier is used on-board the vehicle.
• **Analysis:** Conduct comprehensive analysis of the options and trade-offs of hydrogen delivery approaches for the near-term and long-term, including: 350-bar, 500-bar, 700-bar, and cryocompressed station and upstream delivery costs.

**Fiscal Year (FY) 2010 Technology Status**

Current costs for the transport of hydrogen range from $2 to $8/gasoline gallon equivalent (gge) and are dependent on the quantity of hydrogen and the distance that the hydrogen is transported. Pipeline transport costs are at the lower end of the cost range and are also dependent on transport distance and quantities. These transport costs do not include compression, storage, and dispensing at fueling sites, which can add $2–3/gge of hydrogen. Progress toward current goals and targets is summarized below.

* Targets shown are currently under review and will be updated in FY 2010 and FY 2011.
** DOE projections—not publicly vetted. Target and Status costs are projected high-volume costs.

**FY 2010 Accomplishments**

**Pipelines**

• Savannah River National Laboratory completed a life management plan for fiber reinforced composite (FRC) pipelines, completed a review of existing FRC design specifications/standards, and initiated environmental and flaw tolerance testing of FRC.
• Sandia National Laboratories examined the fracture properties of X52 pipeline steel in high-pressure H₂ gas and established a relationship between hydrogen-assisted fatigue crack growth rate and load-cycle frequency at frequencies prototypic of a pipeline application.

**Tube Trailers and Bulk Storage**

• Lincoln Composites completed an assembly that includes an International Organization for Standardization (ISO) frame, four pressure vessels, and relevant plumbing. The American Bureau of Shipping approved the entire ISO assembly for manufacture.
• Lawrence Livermore National Laboratory designed a pressure vessel that, when incorporated into a trailer, could deliver hydrogen at a cost below $1/gge (not including forecourt expenses).
Compression and Liquefaction

- Concepts ETI Inc. completed a preliminary design of a six-stage hydrogen pipeline compressor capable of delivering 240,000 kg H₂/day at 1,250 psig.
- Five subsystems of a 290 K to 120 K active magnetic regenerative liquefier prototype were designed, fully assembled, and successfully tested by Prometheus Energy.

Analysis

- Argonne National Laboratory upgraded the Hydrogen Delivery Scenario Analysis Model to evaluate three new delivery pathways, two different station configurations for 700-bar dispensing, and an option permitting user selection of station configuration.
- The National Renewable Energy Laboratory upgraded the Hydrogen Rail Components Model with 700-bar and cryo-compressed dispensing and higher tube-trailer delivery pressure, of up to 480 atm.

Budget

The FY 2010 budget provided $5.4 million for continued hydrogen delivery research. The President’s FY 2011 budget request includes $40 million for hydrogen fuel R&D, out of which $7.2 million is planned for hydrogen delivery, with an emphasis on lower-cost, higher-efficiency compression technology and lower-capital-cost off-board storage technology.

FY 2011 Plans

Annual reports and final reports documenting progress will be issued in late FY 2010 and FY 2011, respectively. H₂A cost projections for delivery pathways, the Hydrogen Delivery Chapter of the Energy Efficiency and Renewable Energy (EERE) Fuel Cell Technologies Multi-Year Program Plan, and the Delivery Roadmap will be reviewed and updated as needed in FY 2011. The applied R&D program in EERE will coordinate with the Office of Science, which plans to include up to $50 million of basic research related to hydrogen and fuel cell technologies. Through basic science activities, a fundamental understanding of issues such as hydrogen embrittlement can help address the challenges of hydrogen technologies in the long term. In addition, through projects funded by the American Recovery and Reinvestment Act of 2009, lessons-learned and best practices related to hydrogen delivery technologies will be developed.

Partners:
• National Renewable Energy Laboratory
• Pacific Northwest National Laboratory

Project Start Date: October 2007
Project End Date: Project continuation and
direction determined annually by DOE

Objectives
• Refine technical and cost data in the Hydrogen Delivery Scenario Analysis Model (HDSAM) to incorporate additional industry input and evolving technology improvements.
• Expand the model to include advanced technologies and other pathway options leading to new versions of the models.
• Improve methodologies for estimating key aspects of delivery system operation and optimizing cost and performance parameters.
• Explore options to reduce hydrogen delivery cost, including higher pressure and/or lower temperature gases, and operating strategies.
• Provide analyses to support recommended hydrogen delivery strategies for initial and long-term use of hydrogen as a major energy carrier.

Technical Barriers
This project directly addresses Technical Barrier A (which implicitly includes barriers B, C, D, F, H and J) in the Delivery Technical Plan, as well as Barriers B, C and E in the Systems Analysis Plan of the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan. These are:
(A) Lack of H2/Carrier Infrastructure Options Analysis
(B) Stove-Piped/Siloed Analytical Capability
(C) Inconsistent Data, Assumptions and Guidelines
(E) Unplanned Studies and Analysis

Technical Targets
The project is developing a computer model to evaluate alternative delivery infrastructure systems. Insights from the model are being used to help identify elements of an optimized delivery system which could meet DOE’s long-term delivery cost target.

Accomplishments
• Completed Version 2.2 of HDSAM which is now available at http://www.hydrogen.energy.gov/h2a_delivery.html. As described in the 2009 Annual Progress Report for the DOE Hydrogen Program, additions include:
  – Three new delivery pathways:
    - High-pressure gaseous tube trailers
    - Cryo-compressed (CcH2) hydrogen dispensing
    - 700-bar gaseous hydrogen dispensing
  – Two different station configurations for 700-bar dispensing:
    - High-pressure cascade system
    - Lower pressure cascade system (with dedicated boost compressors for each hose)
  – Option permitting user selection of station configuration.
• Added a “cold gas” tube-trailer pathway to the development version of HDSAM.
• Analyzed HDSAM fuel station footprint assumptions (including setbacks, separation distances, and other safety constraints) as compared with proposed new standards from the National Fire Protection Association (NFPA). Developed revised station footprints to better reflect minimum separation distances between different components.
• Analyzed cost, energy use and greenhouse gas (GHG) emissions to bring renewable hydrogen to Los Angeles. Estimates include hydrogen production from New Mexican wind power, transmission to the Los Angeles city gate, geologic storage, local distribution, and dispensing.
Introduction

Initiated as part of the H2A project, HDSAM is an Excel-based tool that uses a design calculation approach to estimate the contribution of individual components of delivery infrastructure to hydrogen cost, energy use and GHGs. The model links the individual components in a systematic market setting to develop capacity/flow parameters for a complete hydrogen delivery infrastructure. Using that systems level perspective, HDSAM calculates the full, levelized cost (i.e., summed across all components) of hydrogen delivery, accounting for losses and tradeoffs among the various component costs. A graphical user interface permits users to specify a scenario of interest. A detailed User’s Guide and access to the Energy Efficiency and Renewable Energy (EERE) help desk also assist users in running HDSAM.

Results

Work continued on updating and expanding HDSAM. Release 2.2 includes several high-pressure/low-temperature options discussed in last year’s report. These were further refined, tested and reviewed prior to their inclusion in the new release. Results from work on HDSAM 2.21, to be released in late 2010, are described in the following.

“Cold Gas” Tube-Trailer

This high-pressure/low-temperature pathway might be particularly well suited to early markets. Characterized in Fiscal Year (FY) 2010, this pathway assumes composite tube trailers (characterized by Lawrence Livermore National Laboratory) are loaded with gaseous hydrogen (GH2) at 350-bar (90 K) in order to deliver approximately 1,500 kg of hydrogen to a station where it is compressed to 600-bar (130 K) in a cascade charging unit and dispensed at 500-bar (190 K). Figure 1 shows the major stages in this pathway as compared with three other “early market” pathways contained in HDSAM 2.2. Figures 2 and 3 show preliminary results – installed capital costs of stations and the station portion of levelized hydrogen cost.1 By eliminating the cascade system and reducing site storage and refrigeration, compression costs are much lower for CcH2 delivery (Figure 2) than for the other options. Cold gas delivery appears to get part way to the station savings of CcH2 because of reduced storage costs. Thus, station costs

1 Note that 700-bar GH2 with high pressure cascade is less expensive than the booster-compressed option (not shown). for cold gas delivery may be comparable to those for 350-bar GH2 delivery but with improved energy use and vehicle driving range. Note that some of the CcH2 “savings” is shifted upstream to terminals and tube trailers, thereby reducing the difference among delivery

FIGURE 1. HDSAM Contains Several Early Market Delivery Options Including Cold Gas Tube-Trailer Delivery with 500-Bar Dispensing, Liquid Truck Delivery with Cryo-Compressed Dispensing, and 180-Bar Delivery with 700-Bar Cascade or Booster Compressed Dispensing

FIGURE 2. Station Costs May Be Comparable for 500-Bar Cold Gas and 350-Bar Pathways, Greater for 700-Bar and Less for Cryo-Compressed Pathways
options. As shown in Figure 3, total levelized delivery cost differs by less than $0.40 among CcH2, cold gas and 350-bar delivery pathways.

Station Footprint Analyses

Default footprints in HDSAM 2.2 are approximately 110 x 130 ft for GH2 stations and 150 x 170 ft for liquefied hydrogen (LH2) stations. In response to industry concern that land areas are insufficient to accommodate required setbacks, separation distances and delivery truck maneuvers, layouts were reviewed and compared with proposed NFPA rules for setback and separation distances. Results suggest that GH2 total station land area should be increased from 3,950 to 16,500 ft² (about two-thirds of which is due to land requirements for an additional hydrogen tube-trailer bay, a cascade storage system, truck maneuvering and associated separation distances). Note that HDSAM does not allocate the cost of land occupied by convenience stores, parking, car washes or other amenities to hydrogen storage and dispensing. The impact of fully NFPA-compliant station size on levelized hydrogen cost may be seen in Figure 4. For GH2 stations, full NFPA compliance adds $1.35/kg for stations dispensing 50 kg/day but only $0.17/kg to stations dispensing 1,000 kg/day. For LH2 stations (not shown) the effect is less – full NFPA compliance adds $0.57/kg for stations dispensing 50 kg/day and only $0.07/kg for stations dispensing 1,000 kg/day.

Wind-to-LH2 Analysis

In response to the California mandate that 30% of the state’s hydrogen use must be produced from renewable sources, a study was initiated to evaluate the cost, energy use and GHG emissions of potential renewable hydrogen production/delivery options. As a first step, a “generic” site with Class 3 wind potential and relatively good access to Los Angeles (LA) was selected for analysis. Located near Albuquerque, NM, the site was assumed to include a 252-MW wind farm (i.e., 84 3-MW turbines), a 160-MW electrolyzer, a 40-tpd liquefier and 4,000 t of geologic storage. All output was dedicated to liquid hydrogen production (i.e., no electricity was exported to the grid) for 80,000 fuel cell vehicles approximately 800 miles to the west. Initially, five potential pathways, both renewable and nonrenewable were compared: Albuquerque-to-LA via wind-to-LH2, Albuquerque-to-LA via steam methane reforming (SMR)-to-LH2, Albuquerque-to-LA via electrolysis-to-LH2; centralized production in LA via SMR, and centralized production in LA via electrolysis. Preliminary results (Figure 5) show that hydrogen production tends to be the major contributor to levelized
III. Hydrogen Delivery

Hydrogen delivery infrastructure analysis seeks to identify aspects of hydrogen delivery that are likely to be especially costly (in capital and operating cost, energy and GHG emissions) and estimate the impact of alternative options on those costs. This project has developed a model of hydrogen delivery systems to quantify those costs and permit analyses of alternative technologies and operating strategies. This work has been conducted collaboratively by staff of Argonne National Laboratory, the National Renewable Energy Laboratory and Pacific Northwest National Laboratory with the advice and assistance of several industrial partners. Regular interaction has also occurred with the Fuel Pathways and Delivery Tech Teams.

Through FY 2010, results affirm that hydrogen delivery could add $4 or more to the levelized cost of hydrogen “at the pump.” The most promising options for reducing delivery cost tend to smooth demand (thereby reducing the need for hydrogen storage) or increase the energy density of delivered fuel (by maintaining low temperature or high pressure in the delivery pathway). Tasks completed through June 2010 have been discussed above. The following tasks will be completed by the end of FY 2011:

- Further analyses of hydrogen delivery cost targets.
- Completion of the wind-to-liquid hydrogen analysis and publication of results.
- Further expansion of HDSAM’s capabilities to include a cold gas tube-trailer pathway, advanced compression technologies, and revised approaches to modeling fuel station land requirements, cryo-compressed dispensing and geologic storage (the latter in conjunction with Sandia National Laboratories).
- Completion and posting of HDSAM 2.21 on the EERE Web site.
- Continued interaction and collaboration among the project partners and with the Fuel Pathways Integration Tech Team, the Delivery Tech Team, industry, and the broader hydrogen modeling community.

Conclusions and Future Directions

Hydrogen delivery infrastructure analysis seeks to identify aspects of hydrogen delivery that are likely to be especially costly (in capital and operating cost, energy and GHG emissions) and estimate the impact of alternative options on those costs. This project has developed a model of hydrogen delivery systems to quantify those costs and permit analyses of alternative technologies and operating strategies. This work has been conducted collaboratively by staff of Argonne National Laboratory, the National Renewable Energy Laboratory and Pacific Northwest National Laboratory with the advice and assistance of several industrial partners. Regular interaction has also occurred with the Fuel Pathways and Delivery Tech Teams.

Through FY 2010, results affirm that hydrogen delivery could add $4 or more to the levelized cost of hydrogen “at the pump.” The most promising options for reducing delivery cost tend to smooth demand (thereby reducing the need for hydrogen storage) or increase the energy density of delivered fuel (by maintaining low temperature or high pressure in the delivery pathway). Publications/Presentations

III.2 H2A Delivery Analysis and H2A Delivery Components Model

Accomplishments

- Upgraded H2A Delivery Components Model with 700 bar and cryo-compressed dispensing and increased tube-trailer delivery pressure to 480 atm.
- Designed seven new delivery components accommodating gaseous hydrogen delivery in composite tubes.
- Updated rail delivery components with new cost and technical input data.
- Performed comparative cost analysis of various delivery pathways for long-distance delivery.
- Completed the first stage of developing multi-node delivery scenarios.

Introduction

The H2A Delivery Components Model is an Excel-based, publicly available tool that calculates the cost of delivering hydrogen through multiple delivery pathways. The Components Model is part of a larger set of H2A or “Hydrogen Analysis” models, including the H2A Production Model, and the H2A Delivery Scenario Analysis Model (HDSAM). The H2A Production Model calculates the cost of producing hydrogen from a variety of feedstock types. The HDSAM, developed at Argonne National Laboratory, allows the user to choose between multiple production and delivery pathways to calculate total scenario costs. The H2A Delivery Components Model also calculates delivery costs but provides the user with significant flexibility in determining the costs of distinct delivery components, setting unique values for key parameters and constructing customized scenarios. The Delivery Components Model also serves as a tool for generating input delivery cost data for use in other hydrogen models, such as Scenario Evaluation and Regionalization Analysis (SERA), Hydrogen Demand and Resource Analysis (HyDRA), and the H2A Fuel Cell Power Model.

Approach

Since its start in 2004, the project has followed the general H2A approach and guidelines: closely collaborating with industry to update cost data and technical specifications, keeping consistency of the cost inputs across all H2A models, employing H2A standard assumptions, and maintaining publicly available models.
Results

Pursuing the project objectives, we upgraded the H2A Delivery Components Model with new dispensing options and an additional delivery pressure. We added a second dispensing pressure of 700 bar to the gaseous refueling station. At the 700 bar station, hydrogen can be dispensed via a cascade system or booster compressor. We also added a new dispensing option at the liquid refueling station: hydrogen can be dispensed not only as gas, but also as liquid or cryo-compressed fluid. Figure 1 shows the impact of the refueling station upgrade on the station share of hydrogen cost, as well as station capital cost. The gaseous truck-trailer component was upgraded with the second tube pressure of 480 atm. As Figure 2 reveals, pressure boost from 180 atm to 480 atm enables an increase in tube-trailer capacity by 140% and a decrease in the truck-trailer share of hydrogen cost by 37%.

Addressing the barrier (A) - Lack of Hydrogen/Carrer and Infrastructure Option Analysis, we are developing new rail delivery components. Six new rail delivery components include gaseous and liquid production site terminals, rail transport in rail cars and rail tankers, and city gate terminals for both gaseous and liquid hydrogen. At the production site terminal, hydrogen is loaded into rail cars (or tankers). Every day a single train leaves the production site terminal with a sufficient supply of hydrogen to meet city daily demand. At the city gate terminal hydrogen is reloaded from the rail cars to trucks, which deliver hydrogen

![FIGURE 1](image1.png)

**FIGURE 1.** Hydrogen refueling station costs: a) station share of hydrogen levelized cost; b) station capital cost. Station capacity is 100 kg/day. (GH2 – gaseous hydrogen, LH2 – liquid hydrogen)

![FIGURE 2](image2.png)

**FIGURE 2.** Gaseous truck-trailer: a) capacity (kg of hydrogen); b) truck share of hydrogen levelized cost ($/kg). The cost analysis is made for delivery to the refueling station with an average capacity of 100 kg/day.
to the refueling station. Whenever possible, the H2A default sizes have been preserved in designing both types of terminals. This year our update of the rail components concerned freight data, rail car leasing data, and intermodal facility crane technical specifications and cost. The updated rail components were used to perform comparative delivery cost analysis. Figure 3 demonstrates the hydrogen delivery cost sensitivity to the distance. For the distances longer than 1,500 km, liquid hydrogen rail and truck delivery outperform all other options, becoming serious candidates for delivery of hydrogen produced from renewable sources.

Addressing the barrier (F) - Gaseous Hydrogen Storage and Tube Trailer Delivery Costs, we analyzed the possibility for delivering gaseous hydrogen in composite tubes instead of metal tubes. Using composite tubes with a pressure of 250 bar decreases the cost of delivery via gaseous truck-trailer by 20-30% (see Figure 3). Also, preliminary analysis has shown that with a pressure increase to 550 bar, delivery costs drop by 33% for gaseous rail delivery and up to 50% for gaseous truck-trailer delivery.

Barrier (F) also was addressed through developing a novel method of hydrogen delivery: when a hydrogen plant not necessarily serves only one city, but can accommodate demand from multiple cities. By introducing these multi-node delivery scenarios, we can model pipeline and hydrogen storage systems shared between multiple cities, which potentially can decrease the cost of storage designed for plant outage and demand surge. For designing multi-node delivery networks, we have used the SERA Model. This model is a geographical information system-based dynamic optimization tool that determines optimal production and delivery infrastructure build-outs and their evolution. The first stage of SERA scenario development was completed this year. We coded four delivery components directly into the SERA model in order to gain extensive flexibility of placing delivery components at different geographical locations. Also, we added transmission pipeline branching to allow sharing a production plant between multiple cities. Figure 4 displays an optimized pipeline network, demonstrating mature multi-node delivery at the Midwestern region.

Conclusions and Future Direction

- In Fiscal Year 2010, by introducing new dispensing and delivery options, we reached the following conclusions:
  - Gaseous hydrogen tube-trailer capacity can be increased by 140%, and its share of the total cost of hydrogen delivery can be decreased by 37%.
  - The cost of gaseous hydrogen delivery via truck can be decreased by 50% by the introduction of composite tubes.
  - Liquid rail and truck delivery are the least cost long-distance options for delivering hydrogen produced from remote renewable sources.
  - Multi-node delivery configurations have the potential to reduce the cost of storage by sharing systems between two or more production plants.
In the upcoming year, the major effort for the H2A Delivery Analysis and H2A Delivery Components Model will focus on:

- Developing go/no-go decision on delivering hydrogen via existing natural gas pipeline network.
- Refining rail delivery components.
- Continuing multi-node delivery scenarios design.
- Developing scenarios for delivering hydrogen that has been produced from wind.
- Maintaining and updating the H2A Delivery Components Model.

**FY 2010 Publications/Presentations**

III.3 Oil-Free Centrifugal Hydrogen Compression Technology Demonstration

Objectives

Demonstrate key technologies needed to develop reliable and cost-effective centrifugal compressors for hydrogen transport and delivery:

- Eliminate sources of oil/lubricant contamination.
- Increase efficiency by using high rotational speeds.
- Reduce system cost and increase reliability.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(B) Reliability and Costs of Hydrogen Compression

(i) Hydrogen Leakage and Sensors

Technical Targets

This project is directed towards the design, fabrication and demonstration of the oil-free centrifugal compression technology. This project will identify the key technological challenges for development of a full scale hydrogen/natural gas centrifugal compressor. The project addresses the following DOE technical targets from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (see Table 1).

Accomplishments

- Completed compressor design with nine compression stages and established the impeller diameter, blade design and desired rotational speed.
- Conducted stress analysis to determine the range of stresses developed in the rotor for several selected materials and established the safety margin for each material.
- Conducted rotor dynamic analysis to ensure dynamic stability of the rotor at the operating speed.
- Prepared preliminary drawings of the compressor frame and the overall system layout, including the drive system and transmission.

Introduction

One of the key elements in realizing hydrogen economy is the deployment of a safe, efficient hydrogen production and delivery infrastructure on a scale that can compete economically with current fuels. The challenge, however, is that hydrogen, the lightest and smallest of gases with a lower viscosity than natural gas, readily migrates through small spaces. While efficient and cost effective compression technology is crucial to effective pipeline delivery of hydrogen, today’s positive displacement hydrogen compression technology is very costly, and has poor reliability and durability, especially for components subjected to wear (e.g., valves, rider bands and piston rings). Even so called “oil-free” machines use oil lubricants that migrate into and contaminate the gas path. Due to the poor reliability of compressors, current hydrogen producers often install...
duplicate units in order to maintain on-line times of 98-99%. Such machine redundancy adds substantially to system capital costs. Additionally, current hydrogen compression often requires energy well in excess of the DOE 2% goal. As such, low capital cost, reliable, efficient and oil-free advanced compressor technologies are needed.

**Approach**

The MiTi® team will meet project objectives by conducting compressor, bearing and seal design studies; selecting components for validation testing; fabricating the selected centrifugal compressor stage and the corresponding oil-free bearings and seals; and conduct testing of the high-speed, full-scale centrifugal compressor stage and oil-free compliant foil bearings and seals under realistic pressures and flows in a hydrogen gas environment. Specific tasks include: (1) Preliminary oil-free, multi-stage, high-speed centrifugal compressor system design; (2) Detailed design of a full-scale centrifugal compressor stage; (3) Mechanical component detailed design of the oil-free bearings, seals and shaft system needed to test the compressor stage; (4) Test hardware fabrication; (5) Dynamic test; (6) Compressor performance test; (7) System design refinement; and (8) Program management and reporting.

**Results**

The goal of the compressor design analysis was to determine the number of stages necessary to reach a discharge pressure of 1,200 psig and 500,000 Kg/day mass flow. The investigation began by using the maximum allowable tip speed (1,600 ft/s), as determined by earlier finite element analysis (FEA) stress analysis. This condition is labeled “Full Speed” in Figure 1. While higher tip speeds are possible in a non-hydrogen environment, the potential reduction in material strength under hydrogen embrittlement dictates that lower stress conditions be used. Two under-speed conditions were also investigated, denoted as “95% of Full” and “90% of Full”. The results show that the Full Speed condition would require seven stages to achieve the desired discharge pressure, while the under-speed conditions would require eight and nine stages, respectively. Previous preliminary analysis had indicated that a maximum of three frames (i.e., nine stages) should be used. Therefore, using a lower speed and nine stages would be convenient because it allows a system to be designed with three identical compressor frames. The use of lower speed also provides increased stress and fatigue safety margins.

Further analysis was performed to evaluate if other designs could achieve the desired discharge pressure in two identical frames (i.e., six stages) without exceeding the selected maximum allowable tip speed. The two most common approaches used in compressor design to increase discharge pressure are employing forward-swept blade angle and vaned diffusers. A single compression stage was analyzed to determine the performance gain of forward-sweep and vaned diffusing. As expected, the discharge pressure increased in both cases. The costs of these approaches, however, are increased power requirement, increased manufacturing costs and decreased surge-choke margin. In the multi-stage analysis, both a vaned diffuser and a forward-swept blade resulted in about 8% differential pressure improvements. The power penalty was much greater with the forward-swept blade (15%) compared to only 2% from the vaned diffuser. However, the vaned diffuser and forward-swept blade approaches greatly increase the likelihood of system instability. Since the operating conditions could vary greatly, the most versatile, stable and cost-effective design is a three-frame design (i.e., nine stages) with vaneless diffuser and back-swept impeller blades.

Rather than using three identical stages, frames 2 and 3 were modified with alternate shroud contours through a technique known as reprofiling, which dramatically improves stability and surge margin without the added cost of designing and manufacturing unique compressor stages. The additional pressure margin achieved in the reprofiled design is due, primarily, to the addition of the vaned diffuser. The use of a vaned diffuser in the identical stage design was not practical because it would only add instability to the compressor system.

A detailed blade design was conducted using a quasi-three dimensional inviscid internal flow analysis with well-known, commercially available compressor design software. The flow field was analyzed for areas of excessive diffusion, sudden velocity gradients and flow separation. The design was optimized through minor changes in impeller blade geometry. Once a design was found to have satisfactory flow field characteristics,
structural and rotordynamic evaluation was performed. Four key design iterations were conducted between aerodynamics, structural and rotordynamics in order to arrive at the final compressor concept. This was followed by computational fluid dynamics (CFD) analysis of a single stage to validate the aerodynamic performance predictions.

Compressor designs created from aerodynamic analysis were verified for structural integrity using FEA. Structural analysis was focused on the rotor, impeller hub and impeller blades. Three high strength materials were evaluated: an aluminum alloy; a titanium alloy and a high-strength steel. The results confirmed low stresses in the impeller blades. Peak stress in the impeller was on the backface of the hub; however, stress magnitudes were well below the yield strength of the material. The results indicated significant safety margin with respect to strength for all three selected materials. However, the low fatigue limit of the aluminum alloy is of major concern. In fact, the blade stress is three times larger than the fatigue limit of this material. Since the steel and titanium alloy provide sufficient safety margins based on strength and low cycle fatigue, and aluminum does not, aluminum was dropped from further consideration.

The MiTi® 9-stage hydrogen compressor design consists of three double entry systems, each with three back-to-back compression stages (Figure 2). Two MiTi® foil journal bearings are located towards either end of the shaft. Two foil thrust bearings are located at the center of the shaft. Coupled finite difference and finite element methods were used to analyze the foil thrust bearing. The pressure profile was predicted through elastohydrodynamic analysis using the finite difference method and applied to the structural finite element model of the foil thrust bearing. Four MiTi® compliant radial foil seals, which are being characterized under a parallel effort, are used for inter-stage sealing. The predicted elastohydrodynamic plus hydrostatic pressure was applied to the finite element model of the radial foil seal.

Whirl speed and stability analysis were conducted using dynamic FEA. The speed-dependent stiffness coefficients were calculated and damping properties were estimated for the foil bearings and seals. Rotor dynamic analysis was conducted for one frame. Based on preliminary aerodynamic analysis, an optimized shaft diameter between the compressor wheels was selected. Rotordynamic analysis was performed with the three selected materials. It was determined that the material type had little impact on the rotordynamic behavior. The whirl speed map in Figure 3 shows the first four damped natural frequencies, including the cylindrical and conical rigid body modes, as well as the 1st and 2nd bending modes as a function of rotational speed. The logarithmic decrement values for these four modes indicated excellent stability for all four modes.

The configuration of the 9-stage hydrogen compressor has been finalized. The system consists of three frames operating at 56,000 rpm. Each frame is a double entry design consisting of three back-to-back compression stages. The design includes vaned diffusers and a return channel. The final stage of each frame discharges to a volute. A complete system layout was drawn (Figure 4).
15,128 hp for a specific energy metric of 0.439 kW-hr/kg of compressed H₂, which is less than the DOE’s target of 0.6 kW-hr/kg. The system contains three frames coupled to a single rotating shaft. The overall system footprint is estimated to be 160 ft², which includes intercoolers located beneath each compressor frame, the drive system and the transmission.

Conclusions and Future Directions

During this reporting period, the design of a 9-stage centrifugal hydrogen compressor was completed. The design process included detailed analysis of a single stage as well as overall system layout, bearing analysis, rotordynamics, and system costs and economics. Analysis methods employed included FEA modeling of stress and deflection of the impeller hub and blades, multi-stage system stability, rotordynamic analysis of the compressor rotor, CFD analysis, and full system layout, including drive components. The results of this analysis indicate that an oil-free centrifugal hydrogen compressor is capable of achieving the performance goals requested by the DOE.

In addition to further analysis of the design concept presented in this report, several other design concepts will be evaluated during the next reporting period. A high-performance and high-speed concept is being analyzed in which the maximum allowable impeller tip speed has been increased to 2,000 fps. While this design will allow for a reduction in the total number of stages, reduced input power and overall system size, such high tip speeds present several technical challenges that are being addressed. A trade-off study will be performed in which the costs and benefits of increased tip speed on system performance is assessed. The following tasks are planned for the remainder of Fiscal Years 2010 and 2011:

- System cost analysis
- Increased speed designs and trade-offs
- Development of a single stage simulation test rig
- Fabrication of components for testing
- Single stage performance testing

Subcontractors:
- Praxair Corporation, Tonawanda, NY
- Texas A&M University, College Station, Texas
- HyGen Industries, Eureka, CA

Project Start Date: June 1, 2008
Project End Date: July 30, 2011

Objectives

Develop and demonstrate an advanced centrifugal compressor system for high-pressure hydrogen pipeline transport to support DOE’s strategic hydrogen economy infrastructure plan.

- Delivering 100,000 to 1,000,000 kg/day of 99.99% hydrogen gas from generation site(s) to forecourt stations.
- Compressing from 350 psig to 1,000 psig or greater. Reduce initial installed system equipment cost to less than $9M (compressor package of $5.4M) for 240,000 kg/day system by FY 2017.
- Reduce package footprint and improve packaging design. Achieve transport delivery costs below $1/gasoline gallon equivalent, gge.
- Reduce maintenance cost to below 3% of total capital investment by Fiscal Year (FY) 2017.
- Increase system reliability to avoid purchasing redundant systems.
- Maintain hydrogen efficiency (as defined by DOE) to 98% or greater.
- Reduce H₂ leakage to less than 0.5% by FY 2017.

Technical Barriers

This project addresses the following technical barriers from the Delivery (Section 3) of the Fuel Cell Technologies Program Multi-Year Research, Development, and Demonstration Plan [1]:

(B) Reliability and Costs of Hydrogen Compression

Technical Targets

The project has met the following DOE Targets as presented in DOE’s 2007 Technical Plan for Hydrogen Delivery Projects[1] (Table 1 and Figure 1).

TABLE 1. Progress towards Meeting Technical Targets for Delivery of Hydrogen via Centrifugal Pipeline Compression

(Note: Letters correspond to DOE’s 2007 Technical Plan-Delivery Sec. 3.2 - page 16)
Accomplishments for Phase I (Completed) and Phase II (in Progress)

Developed computer models to aid in analysis of hydrogen compressor:

- **System Cost and Performance Model**
  - Suitable as a macro for DOE “HDSAM v2.0” economics model.
  - Identifies hydrogen compressor package performance and component cost with respect to a variety compressor–gearbox configurations.

- **System Reliability and Maintenance Cost Model**
  - Estimates comparative reliabilities for piston and centrifugal compressors for pipeline compressors developed.
  - Failure Mode and Effects Analysis (FMEA) for component risk and reliability assessment.
  - Estimates operation and maintenance costs for compressor system.
  - Uses Federal Energy Regulatory Commission operation and maintenance database as the basis for determining the maintenance costs for a centrifugal compressor.

- **Anti-surge algorithm developed to assist in controls analysis and component selection preliminary design (completed) and detailed design of pipeline compressor module (in progress) including:**
  - Compressor design conditions confirmed by project collaborators.
    - $P_{inlet} = 350$ psig, $P_{outlet} = 1,250$ psig; flow rate $= 240,000$ kg/day.

- A six-stage, 60,000 revolutions per minute (rpm), 3.6 (max) pressure ratio compressor with a mechanical assembly of integrally-geared, overhung compressor impellers.
- Stress analysis completed.
- Volute (compressor housing) design in progress for two-stage prototype.
- Rotordynamics completed to verify shaft-seal-bearing integrity at operating speeds.

- Design of compressor’s major mechanical elements completed and satisfied by two manufacturers per component:
  - Titling-pad radial and thrust bearings designs validated for use.
  - Two commercially available gas face seals have been validated for use.

- Interconnect pipe diameters selected to minimize pressure drop.
  - Including volute with low solidity airfoil as the flow guide vanes and diffusing and Bellmouth at the inlet of the volute.

- Heat exchanger specifications met by two manufacturers to cool hydrogen gas to 100°F between stages.
  - Tranter plate-type heat exchanger design.
  - Heatric heat exchanger (compact, plate-fin surface core).

- Piping and instrumentation diagram for module.
Introduction

The DOE has prepared a Multi-Year Research, Development, and Demonstration Plan to provide hydrogen as a viable fuel for transportation after 2020, in order to reduce the consumption of limited fossil fuels in the transportation industry. Hydrogen fuel can be derived from a variety of renewable energy sources and has a very high BTU energy content per kg, equivalent to the BTU content in a gallon of gasoline. The switch to hydrogen-based fuel requires the development of an infrastructure to produce, deliver, store, and refuel vehicles. This technology development is the responsibility of the Production and Delivery sub-programs within the DOE. The least expensive delivery option for hydrogen involves the pipeline transport of the hydrogen from the production sites to the population centers, where the vehicles will see the highest demand, and thus, have the greatest impact on reducing the U.S. dependency on fossil fuel. The cost to deliver the hydrogen resource to the refueling stations will add to the ultimate cost per kg or per gallon equivalent that needs to be charged for the hydrogen fuel. Therefore, it is necessary that the cost to deliver the hydrogen be as low as possible, which implies that the cost of the compressor stations, their installation costs, and their efficiency in pumping the hydrogen fuel to the refueling stations must be kept low. DOE has set a target of $1/gge.

The delivery cost target can be met if the compressor system can be made more reliable (to reduce maintenance costs), more efficient (to reduce operation costs), and be a smaller, more complete, modular package (to reduce the compressor system equipment, shipment, and its installation costs). To meet these goals, the DOE has commissioned Concepts NREC with the project entitled: The Development of a Centrifugal Hydrogen Pipeline Gas Compressor.

Approach

A three-phase approach has been programmed to implement the technical solutions required to complete a viable hydrogen compressor for pipeline delivery of hydrogen. This approach is summarized in Figure 2.

The technical approach used by Concepts NREC to accomplish these goals is to utilize state-of-the-art aerodynamic/structural analyses to develop a high-performance centrifugal compressor system for pipeline service. The centrifugal-type compressor is able to provide high pressure ratios under acceptable material stresses for relatively high capacities -- flow rates that are higher than what a piston compressor can provide. Concepts NREC’s technical approach also includes the decision to utilize commercially available, and thus, proven bearings and seal technology to reduce developmental risk and increase system reliability at a competitive cost. Using its expertise in turbomachinery analysis, design, machining, and testing, Concepts NREC is researching the use of a material that is compatible with hydrogen and that can enable the highest possible impeller tip speeds, reducing the number of required stages while meeting DOE’s goals for overall pressure ratio and efficiency. In order to minimize the development time and ensure industrial acceptance of the design for the new pipeline compressor system, Concepts NREC has assembled a project team that will assist in the advanced engineering of the compressor
while also preparing an implementation plan that can provide for near-term industrial pipeline applications.

The engineering challenge to implement this technical approach is to design a compressor stage that can achieve the highest acceptable pressure ratio and thermodynamic efficiency per stage, while also using as few stages as possible and employing the smallest diameter impeller. For centrifugal-type compressors, the pressure ratio is proportional to the square of the rotor speed \((\text{rpm}^2)\) and the square of the radius \((\text{radius}^2)\). Thus, even a small increase in tip speed or impeller radius results in significant increases in pressure. The aerodynamic design challenge in reducing the number of stages is to maximize tip speed of the centrifugal compressor impeller while staying within acceptable design safety levels of the strength limitations of the material, in addition to utilizing advanced diffuser systems to maximize recovery of dynamic head into static pressure. However, material stresses also increase proportionally to \(\text{rpm}^2\) and \(\text{radius}^2\), and also by material density. Ultimately, the major constraint is imposed by the limitations of the maximum stress capability of impeller material. This constraint is further aggravated by the need for the material selection to consider the effects of hydrogen embrittlement on the strength of the material. The selection of a rotor material that can enable the high tip speeds to be achieved while avoiding damage from hydrogen embrittlement was selected as the major technical challenge for the project.

To eliminate other more conventional challenges when developing a new compressor, the engineering directive was also to select only commercially available components that are operated within the manufacturer’s design guidelines for state-of-the-art materials, loads, stresses, operating speeds, and power ratings. Principal among these components is the choice of the bearings, shaft seals, gearing, and hydrogen controls and safety instrumentation.

Concepts NREC has met all of these engineering challenges in order to provide a pipeline compressor system that meets DOE’s specifications for near-term deployment.

**Results**

Concepts NREC has developed several computer design models that have helped to optimize the design choice for the pipeline compressor module that complies with DOE requirements. These models include:

1. Compressor Package Performance Model,
2. Cost Model using algorithms to determine the relative component cost and operational risks,
3. Engineering Reliability and Maintenance Cost Model [2,3],
4. Anti-surge Algorithm for providing anti-surge component specifications; and
5. Failure Mode and Effects Analysis (FMEA).

The engineering analysis, conducted in Phase I and continuing in Phase II, resulted in the design of the pipeline compressor package shown in Figure 3. The complete modular compressor package is 26 ft long x 10 ft tall x 6 ft wide at the base x 8 ft wide at the control panel, approximately one-half of the footprint of a piston-type, hydrogen compressor. The

![FIGURE 3. Engineering Analysis and Design Results: Pipeline Hydrogen Centrifugal Compressor 240,000 kg/day; 350 to 1,285 psig; 6,300 kWe](image)
packaged module can be transported to the installation site as a pre-assembled package with a minimum of final alignment, water piping and electrical power connections, and instrumentation and controls start-up.

The compressor selection uses six stages, each operating at 60,000 rpm with a tip speed of less than 2,100 ft/s. Each compressor, shown in Figure 4, is 8 inches in diameter and has an overall stage efficiency of between 79.5 and 80.5%, for an overall compressor efficiency of 80.3%. Each compressor impeller is a single, overhung (cantilevered) impeller attached to a drive shaft that includes a shaft seal, bearing, and drive pinion. The impeller rotor is designed without a bored-hub in order to reduce the hub “hoop” stresses. This requires the impeller to be mechanically attached to the high-strength steel alloy, a drive shaft with a patented design attachment system that enables the rotor to be removed from the gearbox without removing the drive shaft, and thus does not disturb the shaft seal and bearings. A gas face seal will provide the isolation of the hydrogen from the lubricating oil. The 1,400 hp per stage can be sustained by using two tilting-pad hydrodynamic bearings on either side of a 2.5 inch-long drive-pinion gear. The face seal and bearings are commercially available from Flowserve or Eagle-Burgmann and KMC or Waukesha, respectively. The pinion is part of a custom gearbox manufactured by Cotta Transmission Company and utilizes commercially available gear materials that are subjected to stresses and pitch line speeds that meet acceptable engineering practice.

The material chosen for the compressor is an aluminum alloy. The choice is based on its mechanical strength-to-density ratio or \( \frac{S_{\text{yield}}}{\rho} \) which can be shown to be a characteristic of the material’s ability to withstand centrifugal forces. Several grades of aluminum have a strength-to-density ratio that is similar to titanium and high-strength steels at the 140°F (max) operating temperatures that will be experienced by the hydrogen compressor. However, unlike titanium and most steels, aluminum is recognized by the industry as being very compatible with hydrogen.

Aluminum also helps to reduce the weight of the rotor, which leads to an improved rotodynamic stability at the 60,000 operating speed. A rotor stability and critical speed analysis has confirmed that the overhung design is viable.

The project team includes researchers at Texas A&M, led by Dr. Hong Liang, who are collaborating with Concepts NREC to confirm the viability of aluminum alloys for this compressor application. A test protocol has been established based on a series of discussions with notable researchers in several national laboratories, including:

1. Sandia National Laboratories (fracture mechanics testing; Dr. Chris San Marchi).
2. Savannah River National Laboratory (specimen “charging” with hydrogen plus tensile testing with \( \text{H}_2 \); Dr. Andrew Duncan).
3. Argonne National Laboratory (Dr. George Fenske).

The team determined that a small punch test (Figure 5) is appropriate for properly assessing the relative effects that hydrogen has on the strength of the material. A protocol for hydrogen charging of the 3 mm diameter x 0.5 mm thick specimens included prolonged exposure (4 months) in an atmosphere of hydrogen at 10,000 psig and 200°F.

The results of a preliminary test, also shown in Figure 5, indicate that the 2618-T61 and 3003-H14 aluminum alloys appeared to be minimally (if at all) affected by hydrogen, whereas the titanium Ti-6Al-4V was affected by the presence of hydrogen.

**Conclusions and Future Directions**

The preliminary engineering and design of an advanced pipeline compressor system has been completed and meets DOE’s performance goals for a reliable 98% hydrogen efficiency compressor system, with a footprint one-half the size of existing industrial systems and at a projected system cost of approximately 75% of DOE’s target, and a maintenance cost that is less than the $0.01/kWh. The detailed analysis of this pipeline compressor system is in progress in Phase II of the project. The advanced centrifugal compressor-based system can provide 240,000 kg/day of hydrogen from

III.5 Advanced Hydrogen Liquefaction Process

### Objectives

Develop low-cost hydrogen liquefaction systems to produce 30 and 300 tons/day:

- Improve liquefaction energy efficiency.
- Reduce liquefier capital cost.
- Integrate improved process equipment invented since last liquefier was designed.
- Continue ortho-para conversion process development.
- Integrate improved ortho-para conversion process.
- Develop optimized new liquefaction process based on new equipment and new ortho-para conversion process.

### Technical Barriers

This project addresses the following technical barrier from the Delivery section (3.2.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(C) High Cost and Low Energy Efficiency of Hydrogen Liquefaction

### Technical Targets

We are addressing the capital cost and energy efficiency targets.

- Capital Cost:
  - Improved process design.
  - Improved process equipment.

- Energy Efficiency:
  - Increased equipment efficiency.
  - Improved process efficiency.
  - Improved ortho-para conversion efficiency with a goal of reducing energy required for ortho-para conversion by at least 33%.

### Accomplishments

- Constructed improved test unit capable of operating over a temperature range from 77 K to about 150 K.
- Developed spreadsheet model to calculate energy requirements for hydrogen liquefaction.
- Identified problems with commercial process simulation software for modeling ortho and para hydrogen and worked with program supplier to solve the problems.
- Prepared and tested new materials for improved ortho-para conversion using recipes and equipment that produce materials similar to those that could be produced in commercial quantities.
- Developed process models for existing and proposed liquefier designs.
- Showed that overall power consumption can be reduced by about 2.5% if catalyst is used in the high-temperature heat exchanger.
- Identified a process where the performance of the improved ortho-para conversion process is sufficient to reduce total power consumption.
• Identified a process where the performance of the improved ortho-para conversion process, even when accounting for future improvement, is unlikely to be sufficient to reduce total power consumption.

Introduction

Hydrogen liquefiers are highly capital intensive and have a high operating cost because they consume a significant amount of electrical power for refrigeration. There are only a few hydrogen liquefiers in the world and only six currently operating in the U.S. These plants are not built frequently, so they have not been thoroughly optimized for today’s equipment. Furthermore, many of them were built when power was much less expensive than it is today, so those plants do not have optimized efficiency.

Approach

This project focuses on improving liquefier efficiency and reducing overall liquefaction cost, including reducing capital cost. The project is attempting to accomplish these goals using three different aspects of an integrated approach:

• Improved process design – Develop a more efficient refrigeration process including ortho-para conversion and refrigeration using available streams and equipment.

• Improved process equipment – Integrate improvements made in process equipment since the most recent liquefier design to take full advantage of the increased capabilities and improved efficiency. Project the impact of further improvements in process equipment, including novel devices currently being developed.

• Improved ortho-para conversion process – Ortho-para conversion consumes a significant amount of refrigeration energy because it requires cooling at low temperatures. Improvements in ortho-para conversion can lead to a significant reduction in power requirements.

This project builds on previous work done at Praxair, some of which was part of a project funded through Edison Materials Technology Center (EMTEC). The previous project demonstrated that the improvements in ortho-para conversion were possible, but developing the complete optimized process design was beyond the scope of the project.

Results

The material screening test system used during the EMTEC project has been recommissioned to perform additional material testing. We are developing new materials to test. This system can test materials at the boiling point of the cooling fluid, such as liquid nitrogen. The system can test ortho-para conversion at pressures up to 400 psig. This was a significant limitation in earlier testing because it did not allow for testing over a temperature range. The previous system has the advantage of being a simple system that is excellent for preliminary screening of materials. Figure 1 shows this system. New materials work has proceeded from the EMTEC project with new recipes and methods developed to provide samples with properties that more closely approximate those that would be obtained using commercial-scale materials manufacturing.

A pilot-scale system to conduct process testing on desired materials over a range of temperatures was built and testing has begun (Figure 2). This new test system is fully automated to allow for both remote control and eventual material life testing. The system consists primarily of a series of pressure vessels, each of which houses a material bed. The annular space between the inside of the pressure vessel and the outside of the material bed contains a liquid coolant that can be pressurized. The ortho-para conversion process is conducted at very low temperatures (<150 K) and therefore a liquid coolant such as liquid nitrogen or liquid argon is required to achieve temperatures in this range. Each pressure vessel contains a vent line equipped with a back pressure control valve to allow for control of the liquid boiling pressure. By controlling the liquid boiling pressure, temperature can be controlled indirectly over a range of 77 K to 126 K using liquid nitrogen as the coolant and temperatures up to about 150 K using liquid argon.

FIGURE 1. Material Screening Test System
This new test system has been used to determine performance characteristics of the ortho-para conversion system. These results have been used in the process model to determine the overall performance of a system using the improved ortho-para conversion process. These results are shown in Figures 3 and 4.

Modeling

Process simulations were developed for hydrogen liquefaction processes that used the improved ortho-para conversion process to compare those to processes that did not. Of the processes that did not use the improved ortho-para conversion process, it was found that adding ortho-para conversion catalyst to the high-temperature heat exchanger reduced overall energy consumption by about 2.5%.

Several different processes have been conceived that use the improved ortho-para conversion process. The modeling portion of the project will compare these processes to hydrogen liquefaction processes with standard ortho-para conversion. Concept α and Concept β have been evaluated to this point. Figures 3 and 4 show the results.

The point in the center is the target based on ortho-para performance meeting the base case power target. The y-axis represents the power required for hydrogen liquefaction as a percentage of the base case power target. The x-axis shows ortho-para performance as a percentage of demonstrated performance in the laboratory. The target is based on demonstrated performance (100% of current ortho-para performance) meeting the base case power target. In Figure 3, about 150% of the current demonstrated performance is required to meet the base case power target. Although there has been steady improvement in demonstrated performance throughout the project, marginal gains are lower than they were earlier in the project. It is unlikely that Concept α will meet the target required to be an economically viable process.

In Figure 4, 100% of the current demonstrated performance results in total power consumption below the base case power target. There has been steady improvement in demonstrated performance throughout the project and some future advancement is expected. Concept β has already met the target required to be an economically viable process on an energy basis. The difference in capital cost will be evaluated later this year and compared to the power cost savings possible through Concept β.

Conclusions and Future Directions

- Ortho-para conversion performance has been measured using laboratory and pilot reactors.
- The demonstrated performance is sufficient for at least one identified process concept to show reduced power cost when compared to hydrogen liquefaction processes using conventional ortho-para conversion.

FIGURE 2. Pilot-Scale Test System

FIGURE 3. Ortho-Para Performance for Concept α

FIGURE 4. Ortho-Para Performance for Concept β
The impact of improved ortho-para conversion can be significant, but ortho-para conversion uses only about 20-25% of the total liquefaction power.

Most of the energy used in liquefaction is for gas compression. The focus of the project will now be to evaluate different compressors and compression schemes to find possible efficiency improvements.

Project Start Date:  June 1, 2008
Projected End Date:  December 31, 2011

Objectives

This project has several well-defined objectives intended to experimentally demonstrate highly efficient hydrogen liquefiers. These include:

- Develop validated engineering design data for active magnetic regenerative liquefiers (AMRLs) for liquefied hydrogen (LH₂) (or liquefied natural gas) to meet or exceed DOE’s liquefaction targets for both capital and energy efficiency.

- Analyze, design, fabricate, and test one or more liquefier prototypes to experimentally demonstrate this technology and answer numerous questions such as how to design optimized layered magnetic regenerators with bypass flow of the heat transfer fluid.

- Validate the high figure of merit (FOM) predicted by our unique numerical simulation model used to analyze and design AMRL prototypes.

- From June 2009 through May 2010 our focus has been to analyze, design, fabricate, and test our first AMRL prototype with a target of spanning from ~290 K to ~120 K with a high FOM.

Technical Barriers

This project addresses the following Delivery barrier from the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan:

(C) High Cost and Low Energy Efficiency of Hydrogen Liquefaction

Technical Targets

Conventional hydrogen liquefiers at any scale have a maximum FOM of ~0.35 due primarily to the intrinsic difficulty of rapid, efficient compression of either hydrogen or helium working gases (depending on the liquefier design). This novel AMRL project uses regenerative magnetic refrigeration with solid working refrigerants to execute an efficient thermodynamic liquefaction cycle that avoids the use of gas compressors. Detailed modeling of the AMRL technology indicates it has promise to simultaneously lower installed capital costs/unit capacity and to increase thermodynamic efficiency from a FOM of ~0.35 toward ~0.5 to ~0.6. Results from experimental prototypes should support the design and deployment of hydrogen liquefier plants that meet the DOE 2010 hydrogen production and delivery targets:

- Delivery cost of LH₂ at <$1.00/kg;
- $40 MM capital cost for a turn-key plant with a capacity of 30 te/day; and
- Operational efficiency of a complete liquefier plant of 75% as defined by DOE and commensurate with a liquefier FOM of ~0.6.

Accomplishments

- Finished design five subsystems of a 290 K to 120 K AMRL prototype including:
  - The 7-T solenoidal superconducting magnet subsystem;
  - Cold box including the annular access tube subsystem;
  - Gifford McMahon cryocooler subsystem;
  - Cryogenic structural subsystem; and
  - Cryogenic instrumentation and LabVIEW control subsystem.

- Procured all components and completed the assembly of the five subsystems above.

- Successfully tested the five subsystems after diagnosing/fixing several vacuum leaks, sensor electronic noise, and cryocooler performance to obtain ~1.5 W of cooling at 4 K.
• Began the design of remaining three subsystems for our first AMRL prototype:
  – Wrote Mathcad programs for design of efficient active magnetic regenerators by optimizing heat transfer, pressure drop, and longitudinal thermal conduction.
  – Began to design heat transfer fluid subsystem to match requirements of the AMRL prototype and keep pressure drop low for required flow rates.
  – Analyzed force imbalance due to dual magnetic regenerators reciprocating in/out of the 7-T s/c solenoidal magnet to design the mechanical drive subsystem.
  – Used our AMRL performance simulation code to calculate the impact of the thermal mass differences due to temperature and magnetic field dependence of ferromagnetic refrigerants using controllable bypass heat transfer fluid flow rates.

Introduction

AMRL technology promises cost-effective and efficient liquefaction of hydrogen because it eliminates the compressors, the largest source of inefficiency in Claude-cycle liquefiers. However, as with any innovative technique, many questions have to be investigated and understood before commercial applications happen. Since the mid 1970s, magnetic refrigeration technology has been investigated with increasing understanding of magnetic cycles and magnetic refrigeration prototype designs. The seminal patent on the ‘active magnetic regenerator’ was issued in 1982. Only in the last decade or so has there been significant engineering effort on two applications; non-chlorofluorocarbon refrigeration near room temperature using permanent magnets and cryogenic liquefiers for hydrogen and natural gas.

The AMRL project funded under this DOE contract is an extensive engineering effort to analyze, design, fabricate, and test several natural gas and hydrogen liquefer prototypes. Successful demonstration of AMRL prototypes will enable use of advanced liquefiers into various hydrogen infrastructure projects to cost-effectively provide LH₂ energy storage/delivery for gaseous hydrogen produced by electrolysis at renewable energy stations such as wind or solar. The AMRL technology readily scales up or down in capacity so it could be scaled to DOE’s target of 30 te/day to a vehicular refueling station size (~2-3 te/day) where gaseous hydrogen is produced via steam methane reformation, liquefied/stored and supplied as LH₂ and/or as compressed hydrogen produced from liquid hydrogen.

Approach

During the past year our approach was to analyze, design, build, and test our first AMRL prototype that will eventually span from ~290 K to ~120 K. The experimental data will validate our numerical simulation model. It will also guide the design of the second AMRL prototype.

Results

A block process flow diagram of a complete turn-key LH₂ facility was created and is illustrated in Figure 1. The function of various modules is shown. The AMRR is combined within a cold box with a process heat exchanger to produce LH₂ from a gaseous feedstock stream. Also shown are nominal compositions, flow rates, heat/work flows, and other features of a safe operational plant.

The mechanical design of a reciprocating design of a 290 K to 120 K AMRR prototype required numerous calculations of the thermodynamics, heat transfer, fluid dynamics, structural loads, and many related items. One of the more challenging design features was the support of the 4 K superconducting magnet that has to be structurally capable of withstanding large magnetic forces between the magnetic materials in the regenerators and the magnetic field of the magnet. The large magnetic forces impact the design of mechanical drive mechanism; i.e., an AMRR cycle takes ~0.1 seconds to magnetize/demagnetize by moving the dual regenerators ~26 cm along the vertical z axis of the solenoid. The regenerators stop for dwell periods of ~0.4 seconds while the heat transfer fluid flows from hot to cold or cold to hot through the regenerators. Figure 2 illustrates the calculated magnetic forces on a single gadolinium cylindrical regenerator with ~5” outer diameter and ~5” length at 7 Tesla. The same figure includes the force reduction that is possible when two identical magnetic regenerators are balanced as much as possible. This force imbalance is several times larger than the net magnetic force required to provide the work input for the thermodynamic cycle and suggests a future rotary AMRL choice.

Figure 3 shows a two-dimensional mechanical design of the prototype that includes the superconducting magnet, the Gifford McMahon (GM) cryocooler to conduction cool the magnet and thermal shield, the elaborate support structure, and the top plate to mount the prototype in the double-walled Dewar that serves as the cold box. The center access tube through the magnet is insulated from the magnet to enable the dual regenerators to operate between ~290 K and ~120 K.

Figure 4 presents a photograph of the partially assembled AMRR prototype with the bottom heat shield.

Barclay – Heracles Energy Corporation

ready to be raised and attached to the ~40 K thermal shield. The prototype has been instrumented with numerous sensors and connected to a LabVIEW-based data acquisition system. The cold box was evacuated to ~1 x 10^-7 torr for excellent thermal isolation from the surroundings. The GM cryocooler cooling power on the first and second stage was measured and found to be better than the manufacturer’s specifications. The GM cryocooler successfully cooled the magnet before it was charged with a proper power supply designed for high current, low voltage and operated in persistent mode. The magnetic field profile was measured as was the adiabatic temperature change in a sample of gadolinium. Both of these measurements gave results that agree very well with calculated values.

Conclusions and Future Directions

Heracles/Prometheus is making excellent progress toward completion of its first AMRL prototype spanning a large temperature span from near room temperature to the temperature of liquefied natural gas. Five subsystems of the first lab-scale prototype have been designed, built, and successfully tested. The designs of the remaining three subsystems of the prototype are in progress; when the resultant subsystems are completed and integrated with the first five subsystems, full prototype testing will be done. The results will experimentally answer key questions regarding the best design for layers of magnetic materials in regenerators with varying amounts of bypass flow of the heat transfer fluid. We expect that ~15% of bypass flow should significantly improve the thermodynamic performance. The measurements will include the temperature span, cold thermal cooling power, hot heat rejection power, and thermodynamic efficiency (as FOM) as a function frequency, heat transfer fluid flow rate, applied magnetic field, hot temperature, bypass flow, layering technique, etc. The experimental results will be analyzed and compared to performance simulations to further validate the numerical performance model. Assuming the progress on this project is sufficient for a “GO” decision for additional funding, we expect to use results from the first AMRL prototype to design a multi-stage, ~290 K to ~20 K AMRL to make ~10-15 kg/day of LH₂. Results from the second prototype will be used to establish an engineering database for larger AMRL designs. Such a prototype will be the world’s first AMRL to make LH₂. The report obligations for this project are completed when due.

Subcontractor:
Spencer Composites, Sacramento, CA

Project Start Date: April 30, 2005
Project End Date: September 30, 2012

Objectives
- Quantify economic performance advantages of cold glass composites.
- Develop delivery trailer capable of realizing most of those advantages.
- Demonstrate this delivery approach can surpass all significant technical risks.

Technical Barriers
This project addresses the following technical barriers from the Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:
(F) Gaseous Hydrogen Storage and Tube Trailer Delivery Costs
(G) Storage Tank Materials and Costs

Technical Targets
This project is expected to meet several of the 2012 DOE technical targets for hydrogen delivery. It addresses all the key targets relevant to a hydrogen infrastructure between centralized production and the filling station. Capacity targets it meets include a delivered hydrogen capacity over 1,000 kilograms, well above the 700 kilogram 2012 target, and delivered hydrogen pressure of 7,000 psi. The end-to-end cost of delivered hydrogen is minimized by a projected trailer capital cost below $140 per kilogram delivered. This detailed estimate for delivery trailer capital cost allows cold, compressed, glass composite pressure vessel delivery trailers to compete with and ultimately to beat the alternatives in minimizing delivery cost from identical hydrogen sources into identical vehicular hydrogen storage.

Table 1 shows that project’s estimated capital costs (on a per-kilogram delivered basis) exceed DOE’s Multi-Year Program Plan technical targets. Detailed capacity modeling shows both 200 K and 140 K designs can even surpass the 1,000 kg capacity target for 2017 while continuing to meet the capital cost target. Table 1 summarizes much more detailed costs from component-level modeling (based on DOE’s H2A Delivery model) of our project’s approach. The same detailed results show our approach’s superiority over other compressed hydrogen delivery alternatives. Colder designs can deliver far more hydrogen in a volume limited trailer envelope. (Our project presumes an International Organization for Standardization standard twenty-foot equivalent unit shipping container.)

Accomplishments
- Designed a pressure vessel suitable for affordable development at full-scale which enabled the reduction of all technical risks when incorporated into a trailer capable of delivering hydrogen at a cost below $1.00 per kilogram (not including forecourt expenses). This design is proceeding to prove this delivery concept will work both technically and economically. The effort is on schedule, and makes use of prior Spencer-proprietary materials testing efforts and licenses.
- Subscale S-Glass fiber wound pressure vessels were successfully built and burst at 500 and ~170 K, failing within 2% of design at 20,000 psi.
• The first batch of full-scale S-Glass fiber vessels were built, demonstrating the manufacturability of all high technical risk trailer components and processes.

• Several novel manufacturing problems were found and fixed to achieve these results. Along the way various materials properties were investigated, including tensile strength, toughness, and thermal shock tolerance, and some beneficial changes were made to proprietary formulations.

Introduction

We are currently conducting both research and development efforts aimed at delivering hydrogen by truck. Our system concept relies on composite pressure vessels to minimize delivery cost through an optimized combination of hydrogen properties and fiber characteristics. Preliminary H2A-based analysis indicated that our system concept has the potential to greatly reduce the cost of hydrogen delivery by taking advantage of increased strength in inexpensive glass fiber proven to be available at cold temperature.

LLNL embodied this concept to minimize the total cost of hydrogen delivery by reducing the cost of tube trailers. Information gained from ongoing experimental research is being applied to a full-scale hydrogen pressure vessel development program.

Approach

• Optimization of operating pressure and temperature: Today’s hydrogen delivery technologies (compressed and liquid) are restricted to single points at extremes of the hydrogen phase diagram. Minimum cost of delivering hydrogen from centralized production (or pipelines) to filling stations can be found by exploring the entire phase diagram. Pressures and temperatures that minimize cost attain high storage density without the heavy thermodynamic penalty of hydrogen liquefaction. Cold hydrogen at high pressure (between ~140 K and 200 K, at up to 10,000 psi) appears most promising.

• Use of inexpensive glass fiber: Glass fiber is typically considered an inexpensive low-performance alternative to carbon fiber. However, glass fiber achieves higher strength in low-temperature operation, strengthening as much as 80% as it is cooled down from 300 K to 70 K. Our project confirmed this effect on one of the least expensive glass fibers in 2008, and found legacy published data on an even less expensive glass where the effect was even stronger. Cold glass fiber should maximize delivered hydrogen per dollar of delivery cost, maximizing capacity of the truck’s trailer. The combination of higher density reducing trucking labor, fuel, and capital expense with direct reductions in trailer capital cost more than compensates for the increased capital and energy costs of refrigeration and compression (as demonstrated above in Table 1), keeping delivered cost projections well below $1/kg-hydrogen (excluding forecourt expenses).

Results

Experimental Program

LLNL is developing a hydrogen delivery solution that can function at various temperatures and pressures. However, design, manufacturing processes, and capital plus operating costs of this solution depend on currently unknown properties of fibers, plastics, and processed surfaces. The single most important unknown is the fiber strength versus temperature. Even if currently available glass fiber types show only half the cold strength gain LLNL has found in legacy data, the cold glass pressure vessel delivery option minimizes delivery cost per kilogram of hydrogen.

Last year we identified legacy data that shifted our projection of delivery-cost-optimal trailer storage temperature down to ~140 K. (At temperatures somewhat lower than this, the increasing costs of refrigeration would not be repaid.) Since 2006, LLNL has been experimentally pursuing the collection of new cold strength data for all the grades of commercially available glass fiber. In 2008, LLNL data confirmed experimentally that the cold strength effect was sufficient to give our concept the lowest projected hydrogen delivery cost. Since that time, it has become clear that neither proven plastic liners nor metal liners can serve as the vital hydrogen containing layer of a composite pressure vessel that would advantageously operate at cold enough temperatures.

Spencer Composites is collaborating with LLNL in pursuit of a fundamental advance in the manufacturing cost of large composite structures, including pressure vessels. That advance relies on the properties and manufacturing process savings implicit in a new category of plastics. This category will be termed “ROMP” catalyzed, which stands for Ring Opening Metathesis Polymerization. Spencer Composites intends to apply ROMP plastics in numerous aerospace and energy applications. Among the features of this advance are low thermal expansion and full properties retention at temperatures as low as 77 K. These plastics are expected to form both liner and matrix of a new generation of inexpensive pressure vessels. LLNL has sized vessels built with these advanced plastics for low temperature hydrogen delivery trailers.
Experimental research is underway to measure unknown properties of available cold glass composites. Additional experimental research centered on the toughness of high-performance ROMP plastics at low temperature is underway as a direct component of this project’s development effort.

Subscale Vessel Development

Figure 1 shows several of the 3” diameter experimental test articles prototyped to affordably determine unknown properties and improve formulations. Roughly 40 of these articles began prototyping, and roughly 25 survived enough of the ~18 steps in a minimal process sequence to become hydroburst test articles. Another three process steps were added to the most successful prototypes, while three articles received post-prototyping steps intended to improve permeation. All 18 were burst tested to gain feedback for manufacturing process improvement. One of these was burst at ~170 K in acetone cooled by dry ice, a process Spencer had used before, while LLNL is setting up to burst with liquid nitrogen fill.

The decision to proceed with subscale development was obvious given the development cost of full-scale tooling. Several iterations in 3” spin casting tools were conducted in Fiscal Year (FY) 2009. The small size proved convenient for storing and displaying the results of testing. However, the small size implied a factor of roughly 7 scale-up to transfer into a full-scale process. It also made it more difficult to observe defects, and imposed tolerances too tight to prototype Spencer’s full-scale pressure vessel seal design.

Spencer has a proven seal design of the right size to specify the 3” liner tooling for ROMP plastic liner molding. That design was known to seal to 18,000 psi, and relied on a spring-compressed Teflon® C-ring (similar in cross section to a square ‘O-ring’) whose excessive thermal coefficient of expansion and tendency to plastic deformation made it unlikely to survive thermal cycles below 200 K. Such a compromise turned out to be warranted because the full-scale seal design (which was computationally tested to withstand worst case thermal and pressure cycling to 77 K and 25,000 psi without exceeding 20% of the elastic limit of the advanced plastic) could not realistically be scaled down. Ultimately the expedient C-ring seal withstood 22,000 psi before leaking.

Three of the best 3” test articles survived hydroburst to greater than 20,000 psi, with one of these being nearly thermally equilibrated at ~170 K before its seal leaked. The winding design for the ambient test article that failed at slightly over 20,000 psi burst within 2% of its design value. The low temperature result did not fail structurally. Its leaking seal did not re-seat well enough to try a second cycle, but its strength exceeded 23,000 psi, at least 15% higher than the same design and fabrication process at ~300 K. In the course of the subscale test program, both graphite and S-glass fibers were wound with epoxy and ROMP catalyzed plastic matrixes. The two successful articles just mentioned were both made with epoxy matrix S-Glass.

Before achieving these successful subscale results, the development process had to go back to process development for ~4 months after the 2009 Annual Merit Review. An apparently well-formed ROMP liner that passed all visible and thickness inspections failed at unexpectedly low pressures in the earliest subscale burst tests. Cracks that were not apparent in the ROMP liners before they were wound were obvious in the end dome region. Some of these premature
failures occurred at pressures that could not have strained liners in the regions that cracked more than 0.5%. Yet the same ROMP material, processed into flat specimens and cut into “dog bone” tensile test articles was stretching ~18% before failure! Figure 2 shows some of the expedients it took to solve this problem.

Over 60 round plaques of a standardized shape were cast with different formulations of ROMP plastic and broken by dropping an impactor from an ASTM-specified toughness test apparatus built to debug this problem. A large number of hypotheses emerged for what our project called the “anomalous toughness” problem, and a full matrix of seven plaques times seven formulations would not suffice to sort these out. Tensile test “dog bone” specimens were broken at room temperature and roughly dry ice temperature for original and candidate fix formulations. Ultimately our team decided that a slight decrease in strength was a good tradeoff for significant improvement in toughness, and the improved formulation liners sailed through burst testing without cracks. Subsequent employment of the 3” subscale vessel test articles has been restricted to testing with less wound fiber in order to achieve strains anticipated in the full-scale design, since the materials we have developed withstood their worst case design stresses.

Full-Scale Development Program

A first generation of tooling for full-scale liner production was assembled in FY 2009. That tooling realized the liner and boss details that build a calibrated finite element design, which combines with already-measured ROMP plastic strengths to keep all structural components well within their elastic range during independent pressure cycles to 22,500 psi (maximum design burst pressure) and temperature cycles from 77 K to 365 K. LLNL enabled this design in 2007 by performing preliminary pressure optimization in order to size vessel diameter. This design resulted in an economic optimum of 8,000 psi maximum expected operating pressure (MEOP) for the delivery trailer at the time that tooling diameter was specified in May of...
2009. LLNL also made sure this full-scale design is robust enough to fit in our container when wound with sufficient fiber to preserve “Safety Factors” of 2.25 at any MEOP from 1,500 psi to 11,500 psi. This robustness allows the same tooling to minimize cost for stationary hydrogen storage applications (including filling station storage and renewable energy buffering).

The tooling for ROMP catalyzed spin casting is highly affordable compared to tooling for other plastic articles as big as our full-scale design. This affordability was put to the test through a series of mechanical redesigns. Conventional rotational molding tooling is very similar in degrees of freedom, but needs to operate inside an oven, which means every potential change must be designed to withstand thermal cycling. Several rounds of drive alignment changes were needed just to achieve sufficient rotational symmetry in molded liners, and those drive mechanism alterations could be bought out of catalogs because they need not run at high temperature. Other unexpected phenomena emerged at full-scale that could not have been noticed at the 3” subscale, and affirmed our strategic assertion that only full-scale development proves that a technology really works.

The most alarming encounter our development effort had on the way to achieving its Go/No-Go milestone of full-scale component production came the first time a full length liner emerged from the tooling. The surprise is shown in Figure 3 – the full length wasn’t full length even though two shorter length vessels had been built from liners made ‘successfully’ in the same tooling. Full diameter turned out not to be full-scale because of the effect of the greater mass of plastic resin that had to be introduced and spun up to mold the same diameter liner at full length. The part that emerged had an incomplete cylindrical section because most of the resin had solidified in a flat-topped lump at the bottom of the mold before it had a chance to spin up. Yet this same formulation had a 20 minute “pot life” in the 3” tooling, and it didn’t take even a minute to spin up the tool. The answer has to do with the rate of catalysis that solidifies the ROMP resin, and the reconfiguration of the tooling (to introduce the resin progressively after the tooling was already spun up) rendered subsequent liners acceptable.

**Trailer Integration Design and Field Test Program**

Figure 4 shows our first batch of full-scale pressure vessels. The first produced was a ‘shortie’ with a 5” cylindrical section of the liner and S-Glass epoxy overwrap. It was designed to burst at 18,000 psi,
Aceves – Lawrence Livermore National Laboratory

III. Hydrogen Delivery

molding was completed on a large lathe. Bubbles in that liner were ‘fixed’ by a subsequent spin in the lathe, but this part was not considered to have full quality, and was intended to be a permeation rig debug article and showpiece. Given these intended roles, it was wrapped with 700 ksi graphite fiber epoxy composite to illustrate the relevance of this technology for vehicular applications. The third article shown was full length, making use of the progressive resin introduction step described above, and was the first to have a full-scale S-glass fiber overwrap (with epoxy) matrix, thereby completing the promised milestone.

Building more of these full-scale test articles is only the beginning of a test program that is intended to remove all significant technical risks from this advanced, inexpensive pressure vessel technology. That test program has been planned to make the best use of the extended development timeline of 4 years, culminating with cycling of pressure and temperature as its final milestone. All of the risk reduction testing we have planned was presented in our FY 2009 progress report. In the last year, a test site has been selected for the dangerous permeation and cycle testing. We are in the process of designing and building a second generation transport case capable of carrying full-scale

and was produced before slight eccentricities in the tooling spin axis drive were corrected. It therefore had asymmetric liner thicknesses, which were not noticed in the customary inspection (with bright internal lamination) before wrapping. This unit was intended to survive as a souvenir small enough to keep after being exercised as a seal test unit through pressure cycling and then subsequent thermal cycling. Its relatively small size makes it less expensive in time and refrigerant to cycle. In hindsight, it was too short to be a fully representative example of the stresses in a wound high-pressure vessel of this diameter because the spreading out of the transition between cylinder and dome that accompanies the fiber trajectories of an 18,000 psi burst design built from S-Glass meant that it has no truly cylindrical section far enough from the domes to obtain the most accurate strain gage readings.

The other short pressure vessel that appears in Figure 4 was almost 48” from boss to boss, and proved that finished liners could be extracted from the mold. Even though drive eccentricity had been fixed, there were still many pounds of liquid resin inside the mold before it spun up, and this eccentric mass was enough to cause one spin axis bearing to seize. In order to prevent this partially solidified liner from slumping, its

FIGURE 4. Full-Scale Test Articles: The photograph at top shows the first completed full-scale, full-length pressure vessel developed by this project, wrapped with S-Glass fiber in an epoxy matrix, over a ROMP catalyzed plastic liner sealed into 316L stainless steel bosses at either end. The photograph at lower left shows that vessel’s liner dome with thickness markings reflecting quality control of its molding, mounted on one end boss and bolted to a removable winding spindle. Middle and right photographs in the lower row show the first (short white) and second (48” long, graphite composite wound) test articles produced on the same tooling.
and full-length test vessels weighing up to 900 pounds. (Our current heaviest design weighs 650 pounds, but it is conceivably that more fiber can be wound on linings from this tooling to burst over 36,000 psi.) This next generation of case will be gas tight to sense hydrogen permeation and ventilate with chilled nitrogen.

Complete plans for addressing the remaining significant technical risks in our vessel technology will be complete by mid-FY 2011 with the exercise of full-scale vessels in the new transportable case. This case raises the issue of shifting vessel mass during transport, which is already undergoing preliminary design to handle atypical mounting requirement of these vessels inside our delivery container design. The cold strength effect enables vessels that use it to stretch perhaps twice as much as conventional plastic lined (Type IV) composite pressure vessels, and as much as 8 times more than metal or Type III pressure vessels. The accommodation of this stretching must be accompanied by the ability with withstand significant vehicle acceleration loads in a design that favors spreading these external loads over several bands around each delivery vessel.

LLNL’s diameter specification and length margin budgets provide sufficient room for this design to expand in routine service without its vessels touching, even assuming the most extreme likely cold strength effect. One other unavailable component is necessary to make these geometric budgets feasible, and its technical risks are moderate. Our team has begun designing and prototyping a hollow tile (made from cast plastic and metal foil) to provide planar vacuum insulation in a thin form inside the delivery container’s walls. A second generation of trailer thermal management design indicates that two layers of such tiles could provide more than seven days of durability for a stranded delivery trailer before hydrogen would need to be vented to avoid any safety decrease due to diminished cold strength. Variants of this design have been modeled for three layers with nearly three weeks durability, and for single cylindrical tank delivery configurations. A development pathway that can affordably prove single tank configurations is also being considered for a follow on development effort that can make best use of the next generation of (larger) full-scale tooling.

**Conclusions and Future Directions**

- Subscale S-Glass fiber wound pressure vessels were successfully built and burst at 500 and ~170 K, bursting within 2% of design at 20,000 psi.
- The first batch of full-scale S-Glass fiber vessels were built, demonstrating the manufacturability of all high technical risk trailer components and processes.
- Several novel manufacturing problems were found and fixed to achieve these results. Along the way various materials properties were investigated, including tensile strength, toughness, and thermal shock tolerance, and some beneficial changes were made to proprietary formulations.
- Designed a thermal management system for containerized and single cylinder delivery trailer that preserves trailered hydrogen for more than a week before needing to vent. This effort included planning an affordable development pathway for single large pressure vessel delivery.
- Future work culminates development of full-scale pressure vessels with a test program that eliminates all unique risks of this technology. Planned proof-of-concept tests include hydrostatic burst of a statistically significant number of full-scale vessels, pressure and temperature cycling of one such article before bursting it, and hydrogen permeation testing. A site has been selected for these dangerous tests, and will be prepared to safely mitigate the explosion risks of testing experimental vessels filled with hydrogen.
- Materials research and further development efforts are planned to extend our improved understanding of toughness to lower temperature, and to improve permeation of hydrogen through ROMP materials with mitigation layers.
- Design and modeling efforts planned for our future trailer integration efforts include the full specification for insulating tiles containing thin vacuum layers, suspension for vessels that isolates them from worst case trailer acceleration loads, and suspension design that also isolates the container and its insulation from the significant length and diameter expansion under pressure expected due to the cold strength effect on glass composites.
- Spencer Composites and other industrial partners will assist LLNL’s formulation of realistic production cost models. In future years we anticipate adding a tube-trailer-integration-capable subcontractor to form a team of industrial partners with the capability and incentive to prototype advanced hydrogen delivery trailers.
- Future work includes initiatives to prepare federal regulators in other agencies to consider cold hydrogen systems pressure safety, funding initiatives with potential Department of Transportation collaboration to demonstrate a full hydrogen delivery container in the field, and initiatives to partner with gas vendors.

Contract Number: DE-FG36-08GO18062
Project Start Date: July 1, 2008
Project End Date: June 1, 2011

Objectives

The objective of this project is to design and develop the most effective bulk hauling and storage solution for hydrogen in terms of:

- Cost
- Safety
- Weight
- Volumetric Efficiency

Technical Barriers

This project addresses the following technical barriers from the Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(G) Storage Tank Materials and Costs

Technical Targets

This project has focused primarily on the design and qualification of a 3,600 psi pressure vessel and International Organization for Standardization (ISO) frame system to yield a storage capacity solution of approximately 8,500 liters of water. Second phase is to perform and qualify same size container at higher pressures.

Accomplishments

- Successful completion of design and qualification of a 3,600 psi pressure vessel.
  - Qualification testing included:
    - Hydrostatic Burst
    - Ambient Pressure Cycle Test
    - Leak Before Burst Test
    - Penetration Test
    - Environmental Test
    - Flaw Tolerance Test
    - High Temperature Creep Test
    - Accelerated Stress Rupture Test
    - Extreme Temperature Cycle Test
    - Natural Gas Cycle Test with Blow-down

- Successful completion of design and qualification of an ISO frame capable of holding four 3,600 psi pressure vessels with a combined capacity of 600 kg of hydrogen. In addition to the structure, a system for loading, unloading, and pressure relief have been designed and implemented.
  - Qualification testing included:
    - Stress Analysis
    - Dimensional Analysis
    - Stacking
    - Lifting – Top and Bottom
    - Inertia Testing

Introduction

Hydrogen holds the long-term potential to solve two critical problems related to energy use: energy security and climate control. The U.S. transportation sector is almost completely reliant on petroleum, over half of which is currently imported, and tailpipe emissions remain one of the country’s key air quality concerns. Fuel cell vehicles operating on hydrogen produced from domestically available resources would dramatically decrease greenhouse gases and other emissions, while also reducing our dependence on oil from politically volatile regions of the world.

Successful commercialization of hydrogen fuel cell vehicles will depend upon the creation of a hydrogen delivery infrastructure that provides the same level of safety, ease, and functionality as the existing gasoline delivery infrastructure. Today, compressed hydrogen is shipped in tube trailers at pressures up to 3,000 psi (about 200 bar). However, the low hydrogen-carrying capacity of these tube trailers results in high delivery costs.

Hydrogen rail delivery is currently economically feasible only for cryogenic liquid hydrogen; however, almost no hydrogen is transported by rail. Reasons include the lack of timely scheduling and transport to avoid excessive hydrogen boil-off and the lack of rail cars capable of handling cryogenic liquid hydrogen. Hydrogen transport by barge faces similar issues in that few vessels are designed to handle the transport of hydrogen over inland waterways. Lincoln Composites’ ISO Tank Assembly will not only provide a technically feasible method to transport compressed hydrogen over rail and water, but a more cost and weight efficient means as well.

Approach

In Phase 1 of this project, Lincoln Composites will design and qualify a large composite pressure vessel and ISO frame that can be used for storage and transport of compressed hydrogen over road, rail or water.

The baseline composite vessel will have a 3,600 psi service pressure, an outer diameter of 42.8 inches and a length of 38.3 feet. The weight of this tank will be approximately 2,485 kg. The internal volume is equal to 8,500 liters water capacity and will contain 150 kg of compressed hydrogen gas. The contained hydrogen will be approximately 6.0% of the tank weight (5.7% of the combined weight).

Four of these tanks will be mounted in a custom-designed ISO frame, resulting in an assembly with a combined capacity of 600 kg of hydrogen (Figure 1). Installing the compressed hydrogen vessels into an ISO frame offers a benefit of having one solution for both transportable and stationary storage. This decreases research and development costs as well as the amount of infrastructure and equipment needed for both applications.

The large size of the vessel also offers benefits. A limited number of large tanks is easier to package into the container and requires fewer valves and fittings. This results in higher system reliability and lower system cost. The larger diameter also means thicker tank walls, which will make the vessel more robust and damage tolerant.

Phase 2 of the project will be to evaluate using the same approximate sized vessel(s) and ISO frame at elevated pressures. The pressures that are targeted for scope are 5,000 psi and 8,300 psi. Basic design of the individual vessels will remain approximately the same size at the 5,000 psi pressure and minor changes may be needed for the higher pressure. Higher pressures are needed to accommodate goals of the project.

Results

Design and Manufacture of a 3,600 psi Pressure Vessel

The design of the 3,600 psi pressure vessel architecture has been completed using finite element analysis to find a composite solution that resolves the internal pressure requirements and expected external loads. This design was translated into a manufacturing process that addresses the feasibility of vessel production. Several development units were fabricated and pressurized until burst to validate the proposed manufacturing process and design.

With the completed design and working manufacturing process, several additional vessels were fabricated and tested to address optimizing manufacturing issues and minimize production expenses.
One of the units was fabricated and tested to ensure the highest risk associated with material availability could be addressed. By ensuring multiple sources of supplied materials, more leverage is available during procurement and lower production costs can be realized. Another vessel was fabricated to help establish confidence with migrating to a design having a higher margin of safety. Both of these vessels were subjected to a proof cycle and hydraulic burst test. The result of the testing met the expectations predicted by the design.

Qualification of 3,600 psi Vessel

Due to the tanks geometry and construction, there are no published standards that can be used to directly qualify the product. There do exist, however, standards to qualify small pressure vessels of similar construction. These standards were reviewed for input to determine the appropriate requirements that would apply to a vessel of this geometry and construction and include:

- ISO 11439, gas cylinders – High Pressure Cylinders for the On-board Storage of Natural Gas as a Fuel for Automotive Vehicles
- ISO 11119-3, Gas Cylinders of Composite Construction (fully wrapped non-metallic liners)
- ASME Code Case in Work/ASME BPV Project Team on Hydrogen Tanks and Section X

All qualification vessels have successfully been fabricated and completed through the following tests:

- Hydrostatic Burst
- Ambient Pressure Cycle Test
- Leak Before Burst Test
- Penetration Test
- Environmental Test
- Flaw Tolerance Test
- High Temperature Creep Test
- Accelerated Stress Rupture Test
- Extreme Temperature Cycle Test
- Natural Gas Cycle Test with Blow-down

Qualification of the ISO Frame

A complete assembly was constructed including ISO frame, four pressure vessels, and all relevant plumbing including pressure relief system. The following tests were performed on the entire assembly:

- Stress Analysis
- Dimensional Analysis
- Stacking
- Lifting – Top and Bottom
- Inertia Testing
- Impact Testing
- Bonfire Testing

American Bureau of Shipping has successfully approved the entire ISO assembly for production including, pressure vessels, ISO frame and subsequent valves, fittings and pressure relief system.

Conclusions and Future Directions

Proposed objectives for Phase 1 of this project were completed in the fourth quarter of 2009. This includes successful completion of a large 3,600 psi pressure vessel able to contain 8,500 liter water capacity. The successful qualification of an entire assembly into an ISO container was also completed. Lincoln Composites will continue to evaluate cost reductions in design of the vessel as well as in the manufacturing processes. Pursuant of a higher pressure vessel is underway and will continue. Trade studies will be completed followed by fabrication and testing of the higher pressure vessels. Pressure targets are set at 5,000 and 8,300 psi. This will show results more closely to the targets for Hydrogen Storage.

Project Start Date: October 1, 2006  
Project End Date: October 1, 2012

Objectives

Fiber Reinforced Composite (FRC) Pipeline

- Focused evaluation of FRC piping for hydrogen service applications.
- Development of structural integrity life management methodology.
- Evaluation of structural integrity – environmental effects and flaw tolerance.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(D) High Capital Cost and Hydrogen Embrittlement of Pipelines

(I) Hydrogen Leakage and Sensors

(K) Safety, Codes and Standards, Permitting

Technical Targets

This project is focused on the evaluation of FRC piping for hydrogen service applications. Assessment of the structural integrity of the FRC piping and the individual manufacturing components in hydrogen will be performed. Insights gained will support qualifications of these materials for hydrogen service including the DOE 2012 delivery targets:

- Pipeline Transmission and Distribution Cost: $0.6M/mile and $0.27M/mile, respectively.
- Hydrogen Leakage: to be determined, <0.5% by 2017

Accomplishments

- Completed plan for life management methodology of FRC.
- Completed review of existing FRC design specifications/standards.
- Initiated FRC environmental effects testing.
- Initiated FRC flaw tolerance testing.

Introduction

The use of FRC piping materials for hydrogen service will rely on the demonstrated compatibility of these materials for pipeline service environments and operating conditions. The ability of the polymer piping to withstand degradation while in service, the fiber strength wrapping to resist hydrogen attack, and the fiber-resin interface to remain intact are all critical to the successful implementation of these materials for hydrogen pipeline. The goal of the overall project is to successfully adapt spoolable FRC from oil and natural gas use to high-pressure hydrogen use. In Fiscal Year (FY) 2010 an FRC life management plan was developed by SRNL and ASME to focus the direction for the research and testing needed to have FRC codified in the ASME B31.12 Hydrogen Piping Code. The plan also provided the tasks needed for the post construction management of FRC to insure structural integrity through end of life. The plan calls for detailed investigation of the following areas:

- System design and applicable codes and standards
- Service degradation of FRC
- Flaw tolerance and flaw detection
- Integrity management plan
- Leak detection and operational controls evaluation
- Repair evaluation

Approach

SRNL has begun investigation into the first three areas of the Life Management Plan. Codes and standards for the high-pressure FRC and process and transport pressure vessels were reviewed. Creep data on glass fiber was also reviewed to evaluate the effect of creep life on the glass fiber. The results indicate that a design margin of at least 3.5 is required to address long-term creep effects.

The effect of flaw tolerance has also been evaluated in the current FY 2010 funding. Samples for FRC design to a recognized national consensus standard were
III. Hydrogen Delivery

Additional test have been performed to evaluate the effect of chemical environment on the FRC. The purpose of the chemical exposure tests are used to determine a measure of soil pH on the FRC materials. The first series of tests measured the chemical resistance of S- and E-type fiberglass strands typical of those which are used to fabricate the load-bearing overwrap used for the composite pipeline segments.

Results

S and E glass fiberglass strands were exposed to aggressive chemical environments in order to determine reasonable bounds on the base mechanical properties of tensile strength and chemical resistance. These bounds were adopted by consultation with technical literature on the subject [1] as representative of the range where reasonable differences might be observed relative to samples which have not seen chemical exposure. These samples were subjected to solutions of pH 2.4, 7 and 10.6 for periods of either 24 hours or 120 hours (5 days). These samples were then subjected to tensile strength testing using an Istron 4507 Electromechanical System with a strain rate of 200 μm/sec per ASTM 1557-03.

Results typical of these tests are shown in Figures 1 and 2. These tests were performed using thread grips and the samples were inspected after testing to ensure that failure occurred in a position not associated with applied stress or pinching at the grip surfaces. As can be seen, mechanical failure typically occurred for the untreated samples below the 3% strain threshold, with the both samples showing impressive reproducibility in the strain point of the initial point of failure.

A series of tests have been performed to evaluate the burst capacity for FRC containing flaws.

Samples were taken from the same lot of fiberglass and were subjected to the chemical environments described above. These results are summarized in Table 1. S-Glass samples are, in most cases, the stronger of the two fiberglass make-ups, which is consistent with technical literature available on the subject. It can be seen that the aggressive chemical environments that the samples are subjected to have a deleterious effect on their mechanical properties, as is expected. These results confirm that preconditioning of the component fiberglass materials in harsh chemical environments can have an effect on the overall mechanical durability of the composite pipeline materials, and thus is an area that warrants continued scrutiny in the development of the

high-density polyethylene pipelines for hydrogen service. It should also be noted, however, that the test conditions to which these glass samples were exposed are very aggressive and do not necessarily represent actual field conditions; these test conditions were selected to demonstrate the potential for an environmental effect and to highlight the need for further work and consideration of this potential effect.

To address third party damage issues the sensitivity of FRP to flaws must be established. The flaw testing was performed over a range of flaw sizes to determine the flaw tolerance of the FRC piping. FRC piping with single-layer reinforcement and multi-layer reinforcement was evaluated. The results of the single-layer tests are shown in Figure 3. A reduction in burst pressure from unflawed condition to a 2 inch long flaw cutting the reinforcing layer of 75% was observed. With the 2 inch long flaw cutting the reinforcing layer the burst pressure drops below the rated pressure for the single-layer product. The single-layer reinforced piping does not provide sufficient redundancy to tolerate third party damage. The results of the multi-layer tests are provided in Figure 4; reduction in burst pressure from the unflawed condition to a 40% through wall flaw of 28% were observed. With the 40% through wall flaw there is still a margin of 3 above the rated pressure of the FRC multi-layered piping product. Larger flaws and creep effects still need to be reviewed for the multi-layered FRC product.

Conclusions and Future Directions

Conclusions

- FRC Pipe Fabricated API 15HR is the most relevant standard reviewed to date for the fabrication of FRC line pipe for hydrogen service. This standard can be tailored to address the need for hydrogen pipelines.
- Scoping tests show that the burst pressure obtained using the ASTM D2992 (Hydrostatic Design Basis) provides additional design margin above what is needed for stress rupture when compared to the Lawrence Livermore National Laboratory long-term tests. This additional margin provides needed excess capacity to address third party damage and environmental effects.
- The initial environmental test indicate that a service factor for will need to be evaluated for all installations. Acceptable performance tests need to be developed to address the field environmental effects and flaw tolerance.

Future Work

- Initiate FRC life management methodology development.
- Initiate flaw tolerance/third party damage testing for FRC piping.
- Evaluation of environmental degradation of FRC piping.

DOE Project Officer: Paul Bakke
Phone: (303) 275-4916
E-mail: Paul.Bakke@go.doe.gov

Contract Number: GO15045
Start Date: May 1, 2005
Projected End Date: December 31, 2011

Objectives

• Mechanistic understanding of hydrogen embrittlement in pipeline steels in order to devise fracture criteria for safe and reliable pipeline operation under hydrogen pressures of at least 15 MPa and loading conditions both static and cyclic.

• Explore methods of mitigation of hydrogen-induced failures through inhibiting species (e.g., water vapor) or regenerative coatings (e.g., surface oxidation).

• Explore suitable steel microstructures to provide safe and reliable hydrogen transport at reduced capital cost.

• Assess hydrogen compatibility of the existing natural gas pipeline system for transporting hydrogen.

Technical Targets

This project is conducting fundamental studies of hydrogen embrittlement of materials using both numerical simulations and experimental observations of the degradation mechanisms. Based on the understanding of the degradation mechanisms the project’s goal is to assess the reliability of the existing natural gas pipeline infrastructure when used for hydrogen transport, suggest possible new hydrogen-compatible material microstructures for hydrogen delivery, and propose technologies (e.g. regenerative coatings) to remediate hydrogen-induced degradation. These studies meet the following DOE technical targets for Hydrogen Delivery as mentioned in Table 3.2.2 of the FCT Multi-Year RD&D Plan:

• Pipelines: Transmission—Total capital investment will be optimized through pipeline engineering design that avoids conservatism. This requires the development of failure criteria to address the hydrogen effect on material degradation (2012 target).

• Pipelines: Distribution—Same cost optimization as above (2012 target).

• Pipelines: Transmission and Distribution—Reliability relative to H2 embrittlement concerns and integrity, third party damage, or other issues causing cracks or failures. The project’s goal is to develop fracture criteria with predictive capabilities against hydrogen-induced degradation (2017 target). It is emphasized that hydrogen pipelines currently in service operate in the absence of design criteria against hydrogen-induced failure.

• Off-Board Gaseous Hydrogen Storage Tanks (Tank cost and volumetric capacity)—Same cost optimization as in Pipelines. Transmission above. Current pressure vessel design criteria are overly conservative by applying conservative safety factors on the applied stress to address subcritical cracking. Design criteria addressing the hydrogen effect on material safety and reliability will allow for higher storage pressures to be considered (2015 target).

Accomplishments

• Discovered the nature and characteristics of the hydrogen degradation mechanisms of two promising microalloyed, low-carbon steel microstructures
designated as B\textsuperscript{1} and D\textsuperscript{2} hereafter. The samples were provided by the DGS Metallurgical Solutions, Inc. The mechanisms of fracture were identified by using focused ion beam (FIB) machining to lift-out sections from fracture surfaces along with transmission electron microscopy (TEM) analysis of the extracted thin foils.

- Characterized the microstructure of pipelines steels through optical analysis, scanning electron microscopy (SEM), and TEM, and identified particle composition through energy dispersive spectroscopy for: a) laboratory specimens from Air Liquide, Air Products, and Kinder-Morgan industrial pipelines; b) new microalloyed, low-carbon steels from Oregon Steel Mills provided by DGS Metallurgical Solutions, Inc.
- Developed a thermodynamic theory of hydrogen-induced decohesion that was used to model and simulate hydrogen-induced subcritical cracking in high strength steels.
- Augmented our modeling and simulation capabilities of transient hydrogen transport to account for the mechanical deformation and hydrogen-induced grain boundary decohesion in high strength steels. Predictions have been made of threshold stress intensities associated with subcritical crack growth.
- Demonstrated environmental similitude between the single edge notch specimen (SENT) and a pipeline with an axial crack on the inner diameter surface. Hence, the SENT specimen can be used as a laboratory specimen to reliably estimate the fracture resistance of a pipeline steel in the presence of hydrogen.

Introduction

Hydrogen is a ubiquitous element that enters materials from many different sources. It almost always has a deleterious effect on material properties. The goal of the project is to develop and verify a lifetime prediction methodology for failure of materials used in pipeline systems and welds exposed to high-pressure gaseous environments. Development and validation of such predictive capability and strategies to avoid material degradation is of paramount importance to the rapid assessment of the suitability of using the current pipeline distribution system for hydrogen transport and of the susceptibility of new alloys tailored for use in hydrogen related applications.

Last year we focused our attention on identifying and characterizing the mechanisms by which hydrogen induces fracture in microalloy steels B and D. We used FIB machining to lift out sections underneath the fracture surfaces in order to examine whether hydrogen-induced fracture follows a crystallographic cleavage plane or a slip plane. We carried out finite element calculations of transient hydrogen transport simulating hydrogen uptake and transport through an axial crack on the inner diameter surface of a pipeline, and determined through constraint fracture mechanics that the SENT specimen is the appropriate laboratory specimen for the study of the fracture resistance of a pipeline.

Approach

Our approach integrates mechanical property testing at the microscale, microstructural analyses and TEM observations of the deformation processes of materials at the micro- and nano-scale, first principle calculations of interfacial cohesion at the atomic scale, and finite element modeling and simulation at the micro- and macro-level.

To understate the hydrogen-induced fracture processes, we use high resolution SEM with three-dimensional (3-D) visualization and TEM studies of samples taken from just below the fracture surface by the lift-out technique using FIB machining. In order to come up with fracture criteria for safe pipeline operation under hydrogen pressures of at least 15.0 MPa, we investigate the interaction of hydrogen transient transport kinetics with material elastoplastic deformation ahead of an axial crack either on the inside diameter or the outer diameter surface of a pipeline. Using finite element simulations of the hydrogen transport in the neighborhood of the crack tip, we explore the transient and steady-state hydrogen population profiles and how their development influences the fracture processes/events.

To quantitatively describe the hydrogen effect on internal material cohesion as a function of the hydrogen concentration under transient hydrogen conditions, we devised a thermodynamic theory of decohesion at internal material interfaces such as grain boundaries, precipitate/matrix, and second-phase/matrix interfaces. We used first-principles calculations of the hydrogen effect on these interfaces, which constitute potential fracture initiation sites, to calibrate the parameters of the thermodynamic theory such as the ratio of the reversible work of separation in the presence of hydrogen to that in the absence of hydrogen. The information for the fracture mechanisms from the experiments and the hydrogen concentration profiles from the
III. Hydrogen Delivery

Simulations help to establish the regime of critical hydrogen concentrations and critical elapsed time for a crack to remain stable under high hydrogen pressure. Quantitatively this is assessed through the development of engineering fracture criteria in terms of macroscopic parameters.

Results

Identification and Characterization of the Fracture Mechanisms

The study of the fractured surfaces of our compact tension specimens using optical and SEM analyses revealed that hydrogen-induced fractures are distinctly different from the overload fractures in the absence of hydrogen. Figure 1 shows the SEM images of B and D type steels where the direction of the cracks was from bottom to top. In the fracture of these materials, the ductile fracture features such as microvoid nucleation, growth, and coalescence process expected for low and medium strength pipeline steels are not clearly identifiable.

In order to understand the fracture processes, we use high resolution SEM with 3-D visualization and TEM studies of samples taken from just below the fracture surface by the lift-out technique using FIB machining (see 2009 annual progress report). This technique can identify microstructural features such as grain boundaries and secondary phases such as carbides immediately below the fracture surface.

Examination of the fracture surfaces reveals several distinct morphologies such as precipitate nucleated failure, feathery region, ductile ridges, and flat fracture features. It is concluded that except for the precipitate nucleated failure, these features are not due to any compositional variation. The high-resolution SEM image (Figure 2b) of the feathery morphology (Figure 2a) reveals the presence of “saw-teeth” on top of the ridges and no evidence of precipitates at the ridges. These ridges are reminiscent of “saw-teeth” formed on final separation of thin sections as can be seen in Figure 2c for Cu-3%Co alloy deformed in situ in TEM. The presence of such ridges (Figure 2b) suggests plastic processes [1].

Certainly, our research so far points away from the traditional and vague designation of the fracture processes as quasi-cleavage – this is the designation frequently used when the fracture surface appearance is neither clearly ductile nor clearly cleavage and the underlying fracture mechanism is not understood. In fact, the 3-D visualization of the fracture topography (January-March 2010 trimester report) demonstrates clearly the absence of cleavage characteristics and confirms the ridge formation. Feature height

---

**FIGURE 1.** Wide-view SEM of compact tension specimens made from B and D type steel samples and fractured in 3 ksi hydrogen gas.
measurement shows that ridges are protrusions of approximately 400 nm. In particular, TEM analysis of the lift-out section beneath the fracture surface (Figure 3) shows slip bands parallel to ridge edges, suggesting a fracture mechanism completely governed by dislocation slip. In fact, enhanced and confined slip activity is consistent with the hydrogen enhanced local plasticity mechanism [2]. This year’s discovery requires the development and introduction of a new component in our model of the hydrogen-deformation interaction which is the subject of ongoing work.

The identification and characterization of the precise mechanism of hydrogen-induced fracture in pipeline steel materials serves all objectives of the project.

Micro- and Macro-Modeling and Simulation

We used our hydrogen-transport/material-deformation simulation tool (see 2009 annual progress report) to investigate for the first time issues of environmental similitude which is a key requirement for the transferability of fracture toughness results from laboratory specimens to a real-life pipeline.

We solved the initial/boundary-value problem for transient hydrogen diffusion coupled with material elastoplasticity in an SENT specimen embedded in a hydrogen atmosphere with a shallow crack under tension load. The dimensions of the specimen and the applied tension load were chosen such that the cracks in the SENT specimen and pipeline were subjected to the same stress intensity factor $K_I$ and $T$-stress for a given hydrogen pressure which is the hydrogen transport pressure.

The stress and deformation fields close to the crack tip for the SENT specimen and the pipeline structure are shown in Figure 4. In view of the fact that the stress intensity factor and $T$-stress for the SENT specimen and the pipeline are the same, the associated stress and deformation fields near the crack tips are almost identical. This ensures mechanical transferability of the fracture resistance results obtained from the SENT specimen. Superposed on Figure 4 are the normalized normal interstitial lattice sites (NILS) hydrogen concentrations $C_I/C_0$ ahead of the crack tip from the

FIGURE 3. Electron micrograph showing the microstructure immediately beneath the ridges on the fracture surface. Two ridges on the fracture surface are evident. Image shows slip bands parallel to ridge edges, suggesting that quasi-cleavage is not a cleavage like process but is related to dislocation slip.
hydrogen transport solutions for the SENT specimen and pipeline for two different boundary conditions respectively on the remote boundaries and outer diameter surface: zero flux and zero NILS hydrogen concentration. One can clearly see that the hydrogen concentration profiles for the two solutions (SENT specimen and pipeline) are extremely close with a deviation of only about 2% between the two solutions at the location of the peak NILS hydrogen concentration. Hence, one can state that environmental transferability is also warranted [3].

We are continuing on with the modeling and simulation of the rising load fracture toughness tests performed at the Sandia National Laboratories on steel types B and D. In this test, the load on the fracture specimen which is embedded in a hydrogen environment is increased at a constant stress intensity factor rate. The test is used to determine the “initiation threshold”, a very important parameter which denotes the critical stress intensity factor for the onset of crack propagation in hydrogen containing vessel.

The simulations described in this section are meeting all objectives of our project.

Conclusions and Future Directions

- In collaboration with Sandia National Laboratories, we carried out fracture testing of promising microalloyed, low-carbon steel microstructures. Using FIB machining, high-resolution SEM, and TEM studies, we discovered that the hydrogen-induced failure mechanism in these steels is hydrogen induced localized plasticity. In particular, we found that the fracture process is governed by intense slip activity despite the fact that the fracture surfaces have the appearance of what is known to be quasi-cleavage type of fracture. In fact, our research establishes that quasi-cleavage is a mode of fracture fully controlled by ductile processes.

- We will model the discovered mechanism of failure and implement the result in our finite element codes to simulate and predict onset of crack propagation under gaseous hydrogen transport at fixed pressure (static conditions). The predictions will be compared with results from rising load fracture toughness testing. This will lead to the development of a fracture criterion for pipeline safe operation in terms of the hydrogen pressure, geometric, and material characteristics of the pipeline. Next, we will carry out fatigue fracture testing and modeling for damage tolerance assessment under cyclic pressure conditions.

- Carrying out hydrogen transport simulations coupled with material deformation, we demonstrated that the fields in the SENT specimen exhibit mechanical and environmental similitude to those ahead of an axial crack in a pipeline. Therefore the SENT specimen can be used to reliably assess the fracture resistance of pipeline steels.

- We continue our collaboration with the Hydrogen National Institute for Use and Storage (HYDROGENIUS) of Japan. We participate in the annual meetings of automobile Industry of Japan (Toyota, Honda, Nissan) on Hydrogen Technology Standards.

Special Recognitions & Awards/Patents Issued

1. P. Sofronis visited Japan from June 9 to June 25, 2006 as a fellow of the Japan Society for the Promotion of Science (JSPS) to collaborate on research related to hydrogen/material compatibility.

2. P. Sofronis and I. Robertson were invited speakers at the International Hydrogen Energy Development Fora organized by HYDROGENIUS at Fukuoka, Japan on January 31 - February 1, 2007, February 4-8, 2008, February 4-6, 2009, and February 3-4, 2010.

3. Sofronis was elected a fellow of the American Society of Mechanical Engineers (ASME) for his contributions to the field of hydrogen embrittlement.

Start Date: January 2005
Projected End Date: Project continuation and direction determined annually by DOE

Objectives

- Investigate the use of composite pipeline technology (i.e., fiber-reinforced polymer [FRP] pipelines) for transmission and distribution of hydrogen, to achieve reduced installation costs, improved reliability and safer operation of hydrogen pipelines.
- Evaluate current composite pipeline liner materials with respect to their performance as a hydrogen barrier; consider the hydrogen permeabilities of the materials to determine the degree of improvement (if any) that is necessary, and propose a path forward based on the available liner materials and modifications or treatments.
- Assess joining methods for composite pipelines.
- Determine integrated sensing and data transmission needs pipelines to provide health monitoring and operational parameters; report on state-of-the-art in structurally integrated sensing and data transmission.

Technical Barriers

The project addresses the following technical barriers from the Hydrogen Delivery section (3.2.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(D) High Capital Cost and Hydrogen Embrittlement of Pipelines

Technical Targets

The long-term project objective is to achieve commercialization and regulatory acceptance of FRP pipeline technology for hydrogen transmission and distribution. Accordingly, the project tasks address the challenges associated with meeting the DOE Hydrogen Delivery performance and cost targets for 2017 [1]:

- Transmission pipeline total capital cost: $490K per mile
- Distribution pipeline total capital cost: $190K per mile
- Hydrogen delivery cost: <$1.00/gasoline gallon equivalent (gge)
- Transmission and delivery reliability: Acceptable for H₂ as a major energy carrier
- Hydrogen pipeline leakage: <0.5% (leakage target is currently under review by Delivery Tech Team)

Accomplishments

- Completed evaluation of Polyflow braided aramid fiber reinforced pipeline:
  - Hydrogen leakage is below nominal target for pipeline delivery.
  - Co-extruded polyphenylene sulfide-polyamid (PPS-PA) liner has lower permeation than a comparable high-density polyethylene (HDPE) liner.
  - Hydrogen blowdown test produced delamination of layer in co-extruded liner.
- Hydrogen compatibility measurements for glass fiber used as FRP underway with preliminary results showing no deleterious effects of hydrogen on fiber tensile strength.
- New and improved polymer diffusion and permeation measurement apparatus now in operation.

Introduction

Pipelines could be a feasible long-term solution for delivering large quantities of gaseous hydrogen over long distances and distributing it in urban and rural settings. However, there are hydrogen compatibility issues in steel pipelines, and the capital costs for pipeline installation must be dramatically reduced. Composite pipeline technology is a promising alternative to low-alloy high-strength steel pipelines from both performance and cost considerations. For instance, FRP pipelines are engineered composite pipelines that are widely used in upstream oil and gas operations and in well interventions. FRP pipelines typically consist of
an inner non-permeable liner that transports the fluid (pressurized gas or liquid), a protective layer applied to the liner, an interface layer between the protective layer and the reinforcement layers, multiple glass or carbon fiber reinforcement layers, an outer pressure barrier layer, and an outer protective layer. The pipeline has large burst and collapse pressure ratings, high tensile and compression strengths, and tolerates large longitudinal and hoop strains. Thousands of feet of continuous pipe can be unspooled and trenched as a seamless entity, and adjoining segments of pipeline can be joined in the trench without welding using simple connection techniques. The emplacement requirements for FRP pipelines are dramatically less than those for metal pipe; installation can be done in a narrower trenches using light-duty, earth-moving equipment. This enables the pipe to be installed in areas where right-of-way restrictions are severe. In addition, FRP pipe can be manufactured with fiber optics, electrical signal wires, power cables or capillary tubes integrated within its layered construction. Sensors embedded in the pipeline can be powered from remote locations and real-time data from the sensors can be returned through fiber optics or wires. This allows the pipeline to be operated as a smart structure, providing the unique advantage of lifetime performance and health monitoring.

Approach

The challenges for adapting FRP pipeline technology to hydrogen service consist of evaluating the constituent materials and composite construction for hydrogen compatibility, identifying the advantages and challenges of the various manufacturing methods, identifying polymeric liners with acceptably low hydrogen permeability, critiquing options for pipeline joining technologies, ascertaining the necessary modifications to existing codes and standards to validate the safe and reliable implementation of the pipeline, and determining requirements for structural health monitoring and embedded real-time measurements of gas temperature, pressure, flow rate, and pipeline permeation.

These challenges are being addressed by performing bench-scale tests of FRP pipelines and constituent materials to determine their long-time compatibility with hydrogen, identifying pipeline liner materials that exhibit good performance in hydrogen environments, evaluating current methods for pipeline joining with consideration of the unique requirements for hydrogen service, and assessing the state-of-the-art in integrated sensing technologies for composite structures.

Results

We completed hydrogen leak rate measurements in Polyflow Thermoflex® FRP pipeline. These measurements were designed to assess how well this particular pipeline contains high-pressure hydrogen gas. The specimen was a 4.8-cm inside diameter, 6.1 cm outside diameter, 77-cm-long specimen of Thermoflex®, which had a liner of coextruded PPS (inner layer) and nylon PA-6 (outer layer), with each layer ~1.7 mm thick. The fiber reinforcement architecture was aramid fiber rovings helically braided on top of the liner and laid over four longitudinal rovings. The pipeline had an exterior jacket of 2-mm-thick polypropylene with damage indicating colorant. The pipeline ends were terminated with swaged steel couplings and sealed with threaded steel caps. The specimen was pressurized to ~100 bar (1,500 psia), which is the maximum allowable operating pressure, and leak rate measurements were made at 30 and 60°C. The leak rate determinations were based on our typical temperature-corrected pressure-decay measurement technique. The hydrogen decay curves are shown in Figure 1. The leak rates associated with the two temperatures are shown with the curves. These rates are approximately 50% less than those measured in similar lengths of glass fiber reinforced pipeline with a 5-mm-thick HDPE liner. For both pipelines – PPS-PA6 lined, aramid-reinforced and HDPE lined, glass-fiber-reinforced – the leak rates are significantly below the nominal 0.5% leakage target.

Following the completion of the leak rate measurements we performed a hydrogen blowdown test on the Thermoflex® specimen. We used the procedure in Appendix D of American Petroleum Institute (API) standard 15S to perform the test [2]. We pressurized the specimen with hydrogen to its 1,500-psi maximum pressure rating, heated the specimen to its 60°C temperature rating, and held it at these conditions until the pipeline liner was saturated with hydrogen gas. Following this hold period, we depressurized the specimen at -3,800 psi/min, which was almost four times greater than the prescribed rate of 1,000 psi/min. (We used a simple ball valve to

![FIGURE 1. Hydrogen leakage curves dn/dt, where n is the number of moles of hydrogen in the pipeline, for a 77-cm-long Polyflow Thermoflex® pipeline specimen.](image-url)
we observed a small decrease in the tensile strengths of fibers that were aged for eight months in hydrogen compared to those that were aged in air. Although statistically significant, we could not rule out the possibility that the reduction in tensile strength was due to improper post-conditioning handling. Thus we are in the process of repeating the hydrogen conditioning and accelerated aging on a larger number of glass fibers with better controls, performing more tensile tests at shorter intervals, and using statistical analysis that reduces the large error bars due to extreme values in the data sets. Table 1 displays selected measurement results obtained on fibers tested weekly through 11 weeks (2.5 months) of exposure. These fibers have not exhibited any significant degradation in tensile strength. The tests will continue through a minimum of 35 weeks (eight months) of exposure.

TABLE 1. Results of tensile tests performed on glass filaments subjected to accelerated aging in air and high-pressure hydrogen environments.

**Conclusions and Future Directions**

Conclusions from this year’s work:

- Hydrogen leakage rates in off-the-shelf FRP pipelines with different liner materials, liner constructions and reinforcement architectures are comparable in magnitude, are lower than predicted using a simple analytical model, and a strong argument can be made that they are significantly lower than the leakage target.

- Liners constructed from co-extruded polymers could have reliability and longevity problems in instances where rapid pipeline depressurization occurs.

During the remainder of this project year and the entirety of the next we plan to:

- Begin the next phase of hydrogen compatibility testing by evaluating composite pipelines for environment- and strain-induced hydrogen deterioration.
  - Objective: Verify that the combinations of hydrogen environment and stress do not
adversely affect composite pipeline integrity and service life.

- Update our economic feasibility analysis to determine if additional pipeline cost reductions can be realized from recent advancements in composite pipeline technology.
- Perform long-term stress rupture tests and high-pressure cyclic fatigue tests:
  - Stress rupture testing is the API prescription for qualifying the pressure rating of the pipeline.
  - High-pressure cyclic fatigue tests provide information on pipeline integrity after repeated hydrogen gas pressurization-depressurization cycles.
  - Fatigue tests provide information that can’t be derived from constant pressure testing, including liner collapse resistance (similar to blowdown testing), resistance to microcracking, crazing, crack propagation, fiber-resin interface failure of composite reinforcement layer, resistance to environmental stress-corrosion phenomena.
- Subject pipeline specimens to 4-pt flexural bending to produce microcracks before leak rate measurements to reveal the extent that microcracking increases permeation and leakage.
- Measure hydrogen pressure inside pipeline wall as a function of depth in wall and within composite layers to determine hydrogen concentration gradient in the wall.
- Assess the integrity of joint attachment/joint sealing under cyclic loading.

Our out-year plans are to:
- Evaluate feasibility of large-scale manufacturing operations, plan prototype manufacturing for a demonstration project, manufacture prototype FRP pipeline for hydrogen service, coordinate commercial demonstration of pipeline technology.

Objectives

(1) Demonstrate reliability/integrity of steel hydrogen pipelines under cyclic pressure conditions:
   - Measure fatigue crack growth rates and fracture thresholds of line pipe steels in high-pressure hydrogen gas.
   - Evaluate performance of steel pipelines by applying a code-based structural integrity model coupled with steel properties measured in hydrogen gas.
   - Optimize materials test methods in hydrogen pipeline design codes.

(2) Enable development of micromechanics models of hydrogen embrittlement in pipeline steels:
   - Establish physical models of hydrogen embrittlement in line pipe steels using evidence from analytical techniques such as electron microscopy.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section (3.2.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(D) High Capital Cost and Hydrogen Embrittlement of Pipelines

Introduction

Carbon-manganese steels are candidates for the structural materials in hydrogen gas pipelines, however it is well known that these steels are susceptible to hydrogen embrittlement. Decades of research and industrial experience have established that hydrogen embrittlement compromises the structural integrity of steel components. This experience has also helped identify the failure modes that can operate in hydrogen containment structures. As a result, there are tangible ideas for managing hydrogen embrittlement in steels and quantifying safety margins for steel hydrogen...
containment structures. For example, fatigue crack growth aided by hydrogen embrittlement is a well-established failure mode for steel hydrogen containment structures subjected to pressure cycling. This pressure cycling represents one of the key differences in operating conditions between current hydrogen pipelines and those anticipated in a hydrogen fuel distribution infrastructure. Applying code-based structural integrity models coupled with measurement of relevant material properties allows quantification of the reliability/integrity of steel hydrogen pipelines subjected to pressure cycling. Furthermore, application of these structural integrity models is aided by the development of micromechanics models, which provide important insights such as the hydrogen distribution near defects in steel structures.

**Approach**

The principal objective of this project is to enable the application and optimization of structural integrity codes for steel hydrogen pipelines. The new ASME B31.12 design code for hydrogen pipelines includes a fracture mechanics-based design option, which requires material property inputs such as the fracture threshold and fatigue crack growth rate under cyclic loading. Thus, one focus of this project is to measure the fracture thresholds and fatigue crack growth rates of technologically relevant line pipe steels in high-pressure hydrogen gas. These properties must be measured for the base materials but more importantly for the welds, which are likely to be most vulnerable to hydrogen embrittlement. These data can be used to evaluate the reliability/integrity of steel hydrogen pipelines and to establish pathways for optimizing materials test methods in the design code.

A second objective of this project is to enable development of micromechanics models of hydrogen embrittlement in pipeline steels. The focus of this effort is to establish physical models of hydrogen embrittlement in line pipe steels using evidence from analytical techniques such as electron microscopy. These physical models then serve as the framework for developing sophisticated finite-element models, which can provide quantitative insight into the micromechanical state near defects. Understanding the micromechanics of defects can ensure that structural integrity models are applied accurately and conservatively.

**Results**

Efforts during Fiscal Year (FY) 2010 focused on measuring fatigue crack growth rates and fracture thresholds of X52 line pipe steel in hydrogen gas. The fatigue crack growth rate (da/dN) vs. stress-intensity factor range (∆K) relationship and the fracture threshold are necessary material-property inputs into code-based structural models that allow the reliability/integrity of steel hydrogen pipelines to be quantified. One such reliability/integrity methodology was recently published in the ASME B31.12 code.

The X52 line pipe steel was selected for this activity because of its recognized technological relevance for hydrogen pipelines. We decided to test the X52 steel from the round-robin tensile property study (FY 2008) for the following reasons: 1) some characterization of the material was already provided from the round-robin study, 2) ample quantities of material were still available from Concurrent Technologies Corporation, one of the participants in the Pipeline Working Group, and 3) the X52 steel was in the form of finished pipe, which is the most relevant product form and also allows samples to be extracted from the seam weld.

The hydrogen-affected fatigue crack growth law (da/dN vs. ∆K) for the structural steel is the basic element in pipeline reliability/integrity models. Results from the technical literature indicate that the da/dN vs. ∆K trends for steels in hydrogen gas exhibit several transitions, and these transitions can depend on variables such as the R ratio (i.e., ratio of minimum applied load to maximum applied load). Consequently, it is important to measure the da/dN vs. ∆K relationship over a wide enough range in ∆K to capture the transitions. The da/dN vs. ∆K relationships were measured for the X52 steel at two R ratios (0.1 and 0.5) to establish baseline trends. These tests were conducted in 21 MPa (3,000 psi) hydrogen gas and a load-cycle frequency of 1 Hz. The pressure represents the upper limit specified for hydrogen pipelines in the ASME B31.12 code. The load-cycle frequency was selected to balance test effectiveness and test efficiency, since fatigue crack growth rates are enhanced at lower test frequency but the test duration can become prohibitively protracted. The measured da/dN vs. ∆K data are plotted in Figure 1.

The data in Figure 1 illustrate the expected transitions in the da/dN vs. ∆K trend measured in hydrogen gas. In particular, data for the test conducted at R=0.1 show that crack growth rates are similar to those measured in air until a critical K level is reached. At this point, the crack growth rates accelerate and the da/dN vs. ∆K relationship has a characteristic slope in the log-log plot. As ∆K continues to increase, another transition is observed in which the slope of the da/dN vs. ∆K trend abruptly decreases.

The da/dN vs. ∆K relationships in Figure 1 were measured at a load-cycle frequency of 1 Hz. This frequency was selected to enhance the efficiency of measuring the baseline da/dN vs. ∆K relationships. However, fatigue crack growth rates are known to depend on the load-cycle frequency, and it is important to ensure that the da/dN vs. ∆K relationships represent.
conservative data for reliability/integrity calculations. This dependence of crack growth rate on frequency is related to the kinetic steps necessary for hydrogen transport from the gas into the steel. To address the limiting test frequency for producing conservative da/dN vs. ∆K data, the fatigue crack growth rates for X52 steel were measured at a fixed ∆K and R ratio (0.5) over a range of frequencies. The fixed ∆K levels were selected as 10.0 and 17.5 MPa m^{1/2}, since the crack growth rates at these ∆K levels are high (Figure 1). Establishing the limiting test frequency at high fatigue crack growth rates ensures that this test frequency will yield reliable data at lower crack growth rates as well, since the limiting test frequency for conservative crack growth rates increases as the growth rate decreases. The da/dN vs. load-cycle frequency data measured for X52 in 21 MPa hydrogen gas are summarized in Figure 2.

Several features are notable in the da/dN vs. load-cycle frequency plots in Figure 2. First, the fatigue crack growth rates are consistent with the growth rates in the da/dN vs. ∆K plot from Figure 1 at ∆K levels equal to 10.0 and 17.5 MPa m^{1/2}, respectively. Second, the growth rates appear to be essentially constant below a limiting frequency, i.e., 1 Hz and 0.1 Hz for ∆K equal to 10.0 and 17.5 MPa m^{1/2}, respectively. These trends suggest that the da/dN vs. ∆K results in Figure 1 do not represent conservative data in the higher range of crack growth rates. In addition, the limiting test frequency for conservative crack growth rates depends on the absolute crack growth rate. Further testing is planned to determine limiting test frequencies for lower crack growth rates.

It must be noted that the results in both Figures 1 and 2 represent tests that have rather extended durations. For example, the test in Figure 1 at R=0.5 required almost 6 days to complete. In addition, the data point at f=10^{-3} Hz in Figure 2 represents 5 days of testing time. These results demonstrate that reducing test duration by developing more efficient test methods is one pathway for optimizing pipeline structural integrity codes.

Fracture threshold measurements were conducted on the X52 steel under rising-displacement conditions in hydrogen gas. Recent results from the Materials Compatibility task in the Safety, Codes and Standards project at Sandia indicate that fracture threshold measurements under rising-displacement loading may yield more conservative values compared to measurements under static-displacement loading. As such, the fracture thresholds for X52 were measured under rising-displacement loading at rates of approximately 0.0051 and 0.051 mm/min. Similar to the issue with load-cycle frequency in fatigue crack growth rate testing in hydrogen gas, the limiting displacement rate for measuring lower-bound fracture thresholds must be established. The crack growth resistance curves in Figure 3 indicate that the fracture thresholds (indicated by the intersection of the dashed “blunting line” with the resistance curve) for X52 steel are not sensitive to loading rate over the range explored.

**Conclusions and Future Directions**

- Measured fatigue crack growth laws allow evaluation of reliability/integrity of steel hydrogen pipelines under cyclic pressure conditions. Hydrogen embrittlement can be accommodated by measuring fracture properties in hydrogen following ASME B31.12 pipeline design standard.
- Measurements show that fatigue crack growth rates in hydrogen depend on load-cycle frequency. These results can help optimize test methods in pipeline codes, i.e., enhancing test efficiency without compromising data reliability.
III. Hydrogen Delivery

- (future work) Complete measurements of da/dN vs. frequency for X52 steel in hydrogen at lower fatigue crack growth rates.
- (future work) Complete fracture threshold measurements for X52 steel in hydrogen as a function of displacement rate.
- (future work) Measure fatigue crack growth laws for X52 steel seam welds and girth welds in hydrogen.

Contract Number: DE-FG36-05GO15021

Subcontractors:
• R&D Dynamics, Bloomfield, CT
• Massachusetts Institute of Technology (MIT), Cambridge, MA

Project Start Date: August 1, 2005  
Project End Date: August 1, 2011

Objectives

Reduce the cost and improve the efficiency of hydrogen liquefaction:

• Develop and model a large capacity (50,000 kg/day or greater) hydrogen liquefaction cycle that:
  – Attain efficiencies which are a 33% improvement over present state-of-the-art systems.
  – Significantly reduce the capital expense relative to similar capacity systems.

• Identify and develop the key components needed for the hydrogen liquefaction cycle that are not commercially available.

Technical Barriers

This project addresses the following technical barriers from the Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(C) High Costs of Hydrogen Liquefaction

Technical Targets

This project is designing an innovative hydrogen liquefaction cycle. The resulting design will meet the DOE Fiscal Year (FY) 2012 technical targets (nearest term target) for small-scale liquefaction (30,000 kg/day) of:

• Installed Capital Cost: $40 million for a 30,000 kg/day system or $1,333/kg of daily output
• Energy Efficiency: 75%

The results of the first year work have shown that the GEECO innovative hydrogen liquefaction cycle design results in both significantly increased efficiency (50% better) and significantly lower capital cost.

Accomplishments

• Designed a practical hydrogen liquefaction cycle that significantly increases efficiencies over existing technologies.
• Identified and designed the key component – the continuous catalytic heat exchanger (CHEX).
• Began fabrication of testing apparatus.
• Designed a 50,000 kg/day plant using low/no risk development components.
• Documented a significant reduction in the total cost of hydrogen liquefaction at the complete 50,000 kg/day production level.

Introduction

The purpose of this project is to produce a pilot-scale liquefaction plant that demonstrates GEECO’s ability to meet or exceed the efficiency targets set by the DOE. This plant will be used as a model to commercialize this technology for use in the distribution infrastructure of hydrogen fuel. It could also be applied to markets distributing hydrogen for industrial gas applications. Extensive modeling of plant performance will be used in the early part of the project to identify the liquefaction cycle architecture that optimizes the twin goals of increased efficiency and reduced cost. The major challenge of the project is to optimize/balance the performance (efficiency) of the plant against the cost of the plant so that the fully amortized cost of liquefying hydrogen meets the aggressive goals set by DOE.

This project will design and build a small-scale pilot plant (several hundred kg/day) that will be both a hardware demonstration and a model for scaling to larger plant sizes (>50,000 kg/day). Though
an effort will be made to use commercial or near-commercial components, key components that will need development for either a pilot- or full-scale plant will be identified. Prior to starting pilot plant fabrication, these components will be demonstrated at the appropriate scale to demonstrate sufficient performance for use in the pilot plant and the potential to achieve the performance used in modeling the full-scale plant.

**Approach**

The simplest liquefaction process is the Joule-Thomson expansion cycle. The gas to be liquefied is compressed, cooled in an after-cooler, and then undergoes isenthalpic expansion across a throttle valve. If the gas is cooled below its inversion temperature in a heat exchanger, then this expansion results in further cooling – and may result in liquid formation at the valve outlet. For hydrogen, this temperature is -95ºF. The Joule-Thomson cycle alone cannot be used for liquefaction of hydrogen without any pre-cooling of hydrogen below its inversion temperature. A modification of this cycle is sometimes used in which liquid nitrogen is used to cool the gaseous hydrogen below its inversion temperature and then Joule-Thomson expansion is used to liquify hydrogen.

Joule-Thomson expansion is inherently inefficient as there is no work done during expansion. The industrial gas industry departed from using Joule-Thomson as a primary process used in liquefaction of atmospheric gases in the 1960s. Turbo-expanders or expansion engines are now used at most industrial gas plants to provide the necessary refrigeration for liquefaction. The expansion across a turbo-expander is ideally isentropic, or in other words, some useful work is done in expansion.

The project as originally proposed was intended to use an optimized combination of the Reverse-Brayton expansion cycle (or a modified Claude cycle) with the Joule-Thomson expansion cycle. At the beginning of the project, the scope was expanded to look at a broader range of alternate cycles. The resulting innovative cycle is shown in Figure 1. It is a once-through cycle that uses a helium-based refrigeration cycle employing Reverse-Brayton turbo-machinery. The heat removal from the hydrogen stream is performed by standard two- and three-channel heat exchangers. The baseline modeling assumes that the catalytic heat exchangers are isothermal, though additional modeling showed the added efficiency gain by using continuous catalytic heat exchangers throughout the cycle.

**Results**

The following is a summary of the major work efforts and accomplishments to date.

- Completed development and validated accuracy of CHEX numerical model.
- Through modeling, demonstrated that typical heat exchanger channel dimensions are satisfactory for pressure drop, heat exchange, and catalyst reaction rate criteria.
- Completed design of CHEX article test apparatus.
- Fabricated sensor for measuring para/ortho make-up and verified sensor performance.
- Verified through testing that the selected hydrogen and helium compressor will support the planned testing of the CHEX.
- Designed auxiliary heat exchangers.
- Designed test article “cold box.”

The results of the first year work showed that the innovative liquefier cycle design results in both significantly increased efficiency (30% better) and significantly lower capital cost. During the second year, a numerical model was developed for the catalytic heat exchanger and validated against previous testing performed on simplified catalytic heat exchangers. The continuous catalyst numeric model was created and successfully tested against known data. The model uses MATLAB for controlling inputs, outputs, and referencing thermo-physical properties, and COMSOL Multiphysics for the finite element computations. The model breaks the heat exchanger into alternating lengths of adiabatic catalytic conversion and “normal” heat exchange. This numerical model was then applied to a physical configuration that uses “typical” shell and tube heat exchanger dimensions (1/8 inch inside diameter, 5 inch length). The heat exchanger tube design is similar to the existing adiabatic catalytic heat exchanger test data examining the para to ortho transition (cold to warm). A satisfactory step size was determined so that the model acceptably simulates a continuous and simultaneous catalytic and heat exchange process. The model was then exercised by comparing it to known data and test conditions. The model results were in good agreement with the results from existing data. In addition, several parametric runs using the model confirmed the very weak pressure dependence expected for the process.

During the second year, the basic design of the test facility was completed. This is shown in Figure 1. Figure 1 also indicates the detailed design and fabrication responsibility for the test article system split between GEECO and MIT. Work has been started on the fabrication of the test apparatus to test scaled-down versions of the heat exchangers. The test apparatus para to ortho measurement devices were built and successfully tested, catalytic material acquired, and compressors to run the helium and hydrogen flow loops were identified and tested (Figure 2). In addition, sizing the auxiliary heat exchangers (recuperators for the independent hydrogen and He loops) has been
completed (Figure 3). The CHEX test article cold box has been designed to use an existing cryostat. The cold box has been sized to accept cryogenic recuperators and heat exchangers. The tubing and instrumentation will pass through the cryostat upper lid (Figure 4).
Conclusions and Future Directions

Based on simulations run using the model it was found that several configurations of “practical, buildable” heat exchangers can be loaded with catalytic material and effectively used in the liquefaction cycle developed during the first year. GEECO is proceeding with the 2010 work plan outlined as follows:

- Finish design and build of test apparatus
- Build adiabatic catalyst bed
- Test adiabatic catalyst bed
- Build CHEX
- Identify full-scale compressor
- Test CHEX
- Assess and report
Objectives

The primary objective of this project is to design and fabricate optimized dehydrogenation reactor/heat exchange systems to deliver hydrogen using liquid organic hydrogen carriers. Specifically, the project comprises the following tasks:

- Liquid organic hydrogen carrier sourcing and processing (Task 1).
- Dehydrogenation reactor development. Iterative design and fabrication of 0.1 to 1 kW prototypes of dehydrogenation reactor/heat exchange systems to deliver H₂ (Task 2).
- Conduct an economic evaluation of the delivery and storage system for the liquid carrier H₂ delivery concept (Task 3).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section (3.2.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) Lack of Hydrogen/Carrier and Infrastructure Options Analysis
- (E) Low Cost, High Capacity Solid and Liquid Hydrogen Carrier Systems
- (G) Storage Tank Materials and Costs

Technical Targets

Discovery of hydrogen carriers that maximize the carrier H₂ content was the subject of a separate project for H₂ storage (“Design and Development of New Carbon-Based Sorbent Systems for an Effective Containment of Hydrogen”, DE-FC36-04GO14006) that was completed in FY 2009. The objectives of the current project address the carrier system energy efficiency (through activities in Tasks 1 and 2) and total system cost contribution evaluation (Task 3).

Accomplishments

- A microchannel dehydrogenation reactor prototype developed by PNNL has successfully achieved a 7X improvement over packed-bed reactor performance; the reactor demonstrated 1.5 g H₂/g Pt/minute catalyst productivity in initial proof-of-principle testing.
- BMW has successfully performed dehydrogenation tests at conversion rates above 90% with packed-bed and annular tube reactors, provided by Air Products.
- BMW has established a direct in situ gas analysis of the produced hydrogen during dehydrogenation.
- BMW completed the construction of a (re)hydrogenation unit (5 liter inner volume, 100 bar and 250°C max working pressure and temperature).
specially designed to handle the exothermic hydrogenation reaction. Testing the newly built facility demonstrated complete hydrogenation (up to >99% conversion).

- BMW performed a comparative theoretical parameter study for the two different catalysts, palladium and platinum, during system evaluation.

**Introduction**

An alternative approach for the large-scale delivery of hydrogen from large central production facilities to forecourt users (e.g. customers at fueling stations) is the use of reversible carrier media that liberate hydrogen at the point of use. The hydrogen can be obtained from the carriers at the fueling station for subsequent dispensing to vehicles. Ideally, the carrier can be used for hydrogen storage onboard the vehicle and hydrogen can be released on demand for vehicle propulsion. Primary advantages of carrier-based distribution of hydrogen potentially include lower capital and operating costs, higher efficiency, and enhanced safety.

This project is directed at providing the reactor technology, integration of reactor designs with vehicle and stationary power sources, and economic analysis for a liquid phase carrier that will enable an integrated delivery and storage of hydrogen, while meeting the DOE targets for hydrogen storage density and delivery efficiency. Due to decreased FY 2010 funding (vs. FY 2009) and delays in receiving obligated funds, work towards FY 2010 objectives was delayed until the third quarter of FY 2010. The decreased funding level has resulted in the performance of no experimental work by Air Products or UTRC. Therefore, the reported results represent less than one year of effort.

**Approach**

Efficient dehydrogenation of the liquid carrier is integral to the viability of this concept for hydrogen storage and delivery. Microchannel reactor technology was identified at an early stage as one promising reactor architecture for carrier dehydrogenation. The technical approach is to develop catalyst substrates that are able to effectively segregate liquid from gas and release the hydrogen as it is generated from the catalyst structure. PNNL is a leader in the development of microchannel reactors and in collaboration with Air Products and BMW, several generations of “proof-of-principle” reactors are under development at PNNL. After initial testing at PNNL, the reactors will be used for integration studies at BMW. BMW’s objective is to evaluate the integration of liquid carrier storage systems with hydrogen internal combustion engines. This will define certain configurations of integrated systems, determine the preliminary requirements to guide reactor development and allow modeling of more complex scenarios to show overall system performance needs. Additional reactor testing will occur at BMW. Data from the reactor testing will be used by UTRC for the modeling of stationary and mobile fuel cells. UTRC’s objective is to evaluate the integration of liquid carrier storage systems with fuel cell systems. This will define certain configurations of integrated systems, determine the preliminary requirements to guide reactor development and allow modeling of more complex scenarios including transient operation. Air Products is supplying the necessary liquid carrier and conducting an economic evaluation of the use of liquid carriers for hydrogen distribution.

**Results**

**Task 1. Liquid Phase Hydrogen Carrier Raw Materials Sourcing and Processing**

Air Products is responsible for providing perhydro-N-ethylcarbazole and perhydrofluorene for reactor testing at PNNL and BMW. A suitable inventory of the two hydrogenated liquid carriers exists to supply all of the carrier needs for reactor testing anticipated during FY 2010. The successful completion and testing of a hydrogenation reactor at BMW adds additional flexibility for sourcing liquid carrier under this task.

**Task 2. Dehydrogenation Reactor Development and Systems Integration Modeling**

**PNNL:** The microchannel reactor concept originally pursued in FY 2009 focused on segregating the liquid carrier from the H₂ being produced to prevent the catalyst from drying out as the 2-phase flow transitioned from exclusively liquid to up to 98% H₂ gas by volume. Catalyst was coated onto thin porous substrates that wetted the liquid carrier and behaved as wicks. When placed in a microchannel with a vapor plenum adjacent to the wick, the H₂ was separated from the liquid as it was generated to keep the catalyst from drying out. Proper balancing of the liquid and vapor pressures keeps the liquid in the wick by capillarity and causes the liquid to flow through the wick. Experimental results from microwick reactors showed significantly lower catalyst productivity in comparison to a packed bed of 210-420 micron particles. The two principal causes were volatilization of the liquid carrier and diffusion limitations.

N-ethylcarbazole has a small but significant vapor pressure at the operating temperatures of 200-230°C that allowed the liquid carrier to volatilize into the vapor plenum and bypass the catalyst, which limited conversion and suppressed catalyst productivity. In addition, an analysis of diffusion limitations in the packed-bed revealed that the reaction kinetics are an
order of magnitude faster than the H\textsubscript{2} diffusion rate within the pores of the liquid-filled catalyst particles and is of the same order of magnitude as the H\textsubscript{2} diffusion rate through the liquid boundary layer surrounding the particles. Furthermore, the wick reactor concept exacerbates the mass transfer resistance by slowing the liquid space velocity and increasing the mass transfer boundary layer thickness. The project team concluded that although the wick reactor effectively accomplished its intended purpose of segregating gas and liquid and keeping the catalyst wetted, mass transfer limitations is the more important technical issue to address.

The effort shifted toward brainstorming ideas that would enhance mass transfer. A reactor concept emerged that enabled using smaller catalyst particles to enhance internal and external mass transfer without introducing untenable pressure drop through the reactor. Proof-of-concept results from this new ‘suspended slurry’ concept are shown in Figure 1 for three different versions. The data showing conversion as a function of catalyst loading divided by liquid feed rate are compared to results from a packed bed of 210-420 micron catalyst particles. Quantitative comparison is facilitated by fitting to first-order reaction rate kinetics. The best results obtained show a 7X increase from packed bed productivity of 0.2 g H\textsubscript{2}/g Pt/minute to 1.5 g H\textsubscript{2}/g Pt/minute at 90% conversion for the suspended slurry reactor.

At the outset of the project, a catalyst productivity target was set at 2 g H\textsubscript{2}/g Pt/min to enable microchannel reactor technology that could be installed on a vehicle to support H\textsubscript{2} production for primary power. The project has now achieved 75% of this initial target at 90% conversion with significant gains remaining as this novel technology matures.

**BMW:** The planned upgrade of the dehydrogenation reactor testing apparatus with additional test equipment (e.g. flow meter, temperature controller and pressure gauges) was successfully completed. With the new equipment, a quantified validation of prototype reactors developed during the project during FY 2010 will be possible. To establish the reactor test protocols, dehydrogenation measurements with a packed-bed reactor using a 5% Pd on alumina catalyst were completed. Following this, the reactor testing progressed to a microchannel annular tube reactor with a platinum catalyst (Figure 2), originally constructed by Air Products. For all experiments, an excellent repeatability of the test results could be demonstrated.

The dehydrogenation reactor testing apparatus capability has been extended by an in situ direct gas analysis of the produced hydrogen. The extension of the test rig is shown on the right hand side (“H\textsubscript{2} quality testing”) of Figure 3. Routine analysis of the hydrogen produced from the dehydrogenation reactor confirmed the high purity of the hydrogen product.

In support of system design activities in Task 2, the necessary reactor residence time for 95% conversion of the fully hydrogenated N-ethylcarbazole have been calculated for reactors containing platinum (Figure 4). Similar modeling clearly shows much faster reaction kinetics of platinum in comparison to palladium at a given temperature. The comparison of platinum-catalyzed dehydrogenation at different temperatures shows an increase of reaction speed by a factor of approximately 10, if temperature is increased by 100 K. Very short residence times can be achieved at temperatures suitable for heat integration with hydrogen internal combustion engines.
III. Hydrogen Delivery

Cooper – Air Products and Chemicals, Inc.

For the (re)hydrogenation of liquid organic hydrogen carrier, an apparatus has been constructed at BMW. The apparatus can process several liters of liquid organic hydrogen carrier during the exothermic hydrogenation reaction. It consists of a commercially available autoclave from Swiss company Buechi (5 liter inner volume, 100 bar and 250°C max working pressure and temperature) with a magnetically coupled turbo stirrer. The autoclave is oil heated by using a Julabo Forte HT60-C.U. system with a max working temperature of 400°C, in combination with a water cooling system (max cooling power 15 kW). Based on designs of similar autoclaves in use for liquid organic hydrogen carrier hydrogenation at Air Products, process diagrams have been drawn and a worst case overtemperature/overpressure scenario analysis has been performed. Based on the derived results, during the risk assessment, we decided to operate the autoclave unit in a separate, remote controlled autoclave room.

The autoclave was tested by performing several test hydrogenations and it was possible to easily handle the exothermic reaction and to finally achieve reaction conversions of up to 99%.

Task 3. Hydrogen Delivery Economics

A detailed economic analysis was completed in FY 2009 and is in preparation as a report to DOE. Based upon our analysis, we consider the H₂ liquid carrier economics to be favorable, in the range of $0.85–$4.50/kg H₂ delivery cost with respect to current DOE targets, provided that certain performance and cost targets can be achieved for the liquid carrier, hydrogenation catalyst productivity, liquid carrier loss rate and dehydrogenation efficiency.

Conclusions and Future Directions

- A viable microchannel dehydrogenation reactor concept has been invented that is capable of achieving catalyst productivity to support H₂ delivery on board vehicles. Further development of this new, novel technology promises additional improvements. Proof-of-concept reactors that are heated with hot gas and scalable to larger reactors will be first demonstrated at 0.1 g H₂/min (nominally equivalent to 100 W e proton exchange membrane fuel cell output) and subsequently scaled to 1 g H₂/min.
- A fully tested and capable dehydrogenation reactor testing apparatus is ready for the testing of the third-generation dehydrogenation reactor prototype (scheduled for the fourth quarter of FY 2010) and the final proof-of-concept reactor (FY 2011, pending funding).
- Extension and modification of existing dehydrogenation testing apparatus from electric heating to gas heating of the reactor.

FY 2010 Publications/Presentations

III.15 Materials Solutions for Hydrogen Delivery in Pipelines

Objectives

Overall goal of the project is to develop materials technologies that would enable minimizing the problem of hydrogen embrittlement associated with the high-pressure transport of hydrogen:

• The most important aspect of the project is to identify base steel compositions/microstructures and processes suitable for construction of a new pipeline infrastructure or potential use of the existing steel pipeline infrastructure.
• Develop barrier coatings for minimizing hydrogen permeation in pipelines and associated processes.
• Understand the economics of implementing new technologies.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(D) High Capital Cost and Hydrogen Embrittlement of Pipelines
(K) Safety, Codes and Standards, Permitting

Technical Targets

The objective of the project is to develop materials technologies that would enable minimizing the problem of hydrogen embrittlement associated with the high-pressure transport of hydrogen through pipelines. Such materials technologies in combination with cost-effective excavation and fabrication technologies will facilitate reducing the capital cost of pipelines. Insights gained from these studies will be applied toward the design and construction of hydrogen delivery systems that meet the following DOE 2017 hydrogen delivery pipeline transmission targets:

• Reliability (relative to hydrogen embrittlement concerns and integrity; the first two bullet points are of main importance to the project):
  – Evaluate hydrogen embrittlement characteristics of existing commercial pipeline steels under high-pressure hydrogen. Based on results to date, there appears to be commercially available pipeline microstructures that perform better than others in the presence of gaseous hydrogen.
  – Evaluate hydrogen embrittlement characteristics of existing alternative commercially available steels under high-pressure hydrogen.
  – Develop alternate alloys and evaluate hydrogen embrittlement.
  – Develop coatings to minimize dissolution and penetration of hydrogen and evaluate hydrogen embrittlement in coated alloys.
• Pipeline Transmission Total Capital Cost ($M/Mile): $0.49 for 16” outside diameter transmission pipeline
• Financial analysis and incorporation into codes and standards.

Accomplishments

Accomplishments to date are as follows:

• Four commercially-available pipeline steels along with two commercially-available alternative steels
have been down-selected for initial study of their hydrogen embrittlement characteristics under high pressure hydrogen.

- The four commercially-available pipeline steel microstructures and mechanical property data have been characterized.
- Commercial X70 pipeline welds available.
- Two traditional screening tests have been explored.
- In situ Automated Ball Indentation (ABI) test has been developed.
- Processing techniques developed for glassy coatings, down-selected composition has been coated for properties and microstructural analyses.
- In situ tensile testing at Oak Ridge National Laboratory (ORNL) complete on the four pipeline steels
  - Two strain rates - $1 \times 10^{-4}$, $1 \times 10^{-5}$, hydrogen vs. helium, three pressures – 800 psi, 1,600 psi, 3,000 psi, total initial tests = 48, additional validation testing = 10, additional statistical testing of alloy A and B.
- The in situ tensile testing was evaluated and used to screen the four pipeline steels for further fracture and fatigue testing. From this evaluation, two of the pipeline steels were selected for further testing.
- Fracture and fatigue testing have been completed in hydrogen for the two selected pipeline steels. Gaseous hydrogen test pressures for fracture and fatigue testing were bracketed between 800 and 3,000 psi to represent potential transmission pressures. Fatigue testing utilizing two R-ratio values has been explored along with testing in air for comparison purposes.
- Actual construction costs of a pipeline project supplied by Columbia Gas of Kentucky reviewed by the project team.

Note that all work related to coatings has been placed on hold per DOE.

\[ \Diamond \Diamond \Diamond \Diamond \Diamond \Diamond \]

**Introduction**

Pipeline transmission is the most economical method for hydrogen delivery in large quantities from the point of generation to point of use. As transmission pressures are increased, steel pipelines that could be used for the transport of hydrogen at low pressures are prone to hydrogen embrittlement at the welds, the heat-affected-zone and/or the base metal regions in the pipeline. Over the past few years, significant advances have been made in understanding the mechanisms of hydrogen embrittlement in a wide variety of materials and in materials technologies. The increasing integration of computational techniques with experimental methods has resulted in the development of “designer” materials along with the scientific methodologies for developing customized materials better suited for any given application. New coating materials and coating technologies hold promise in developing barrier coatings to minimize the dissolution and permeation of hydrogen through steels.

The work on this project represents an integrated approach to developing and testing new materials solutions to enable pipeline delivery of hydrogen at high pressures. The scope of the project includes: (1) identification of steel compositions and associated welding filler wires and processes that would be suitable for new pipeline infrastructure or indicate use of existing pipeline infrastructure for transport of hydrogen at requisite high pressures; (2) development of barrier thin film coatings that would minimize the hydrogen permeation in the current natural gas pipelines; and (3) understanding the cost factors related to the construction of new pipelines and modification of existing pipelines and to identify the path to cost reduction. The team participating in this proposal is lead by SECAT Inc. and includes ORNL, DGS Metallurgical Solutions, Inc., ASME Standards and Technologies, University of Illinois, Schott North America-Regional R&D, Columbia Gas, Chemical Composite Coatings International LLC, Advanced Technology Corporation, EVRAZ North America (formerly Oregon Steel Mills), Reference Metals Company and Hatch Moss MacDonald.

**Approach**

Achievement of an understanding to the mechanisms of hydrogen embrittlement of commercially-available transmission pipeline steels and welding consumables will involve characterization of the mechanical properties and microstructures in both the absence and presence of high-pressure hydrogen gas. The study of vintage pipeline steels along with current pipeline steel technology and potential alternative alloy designs will help determine the optimum mechanical properties and microstructure required to operate in a high pressure hydrogen gas environment. Both in situ and ex situ methods will be used to study the effect of hydrogen gas under pressure on microstructural and mechanical properties. Thermokinetic modeling and microstructural characterizations will be used in the analysis.

In addition, glass and oxide coatings to impede the permeation of hydrogen gas to the steel will be explored, developed and tested in the presence of high-pressure hydrogen gas. Coated steel mechanical properties in the presence of high-pressure hydrogen gas will be tested and compared to uncoated specimens. Successful coatings will be tested for resistance to damage related
III. Hydrogen Delivery

Factors related to materials and construction costs are incorporated into the project. This understanding will allow for recommendations for optimum material selections and fabrication of transmission pipeline systems suitable for high pressure hydrogen gas transport.

Results

Four commercially-available pipeline steels and two commercially-available alternative steels have been down-selected for initial study of their hydrogen embrittlement under high-pressure hydrogen. The compositions of these steels are shown in Table 1. It is anticipated that a study of these steels would be representative of advanced steels and would point to additional compositions that need to be studied in order to develop an appropriate relationship between compositions, structure, and hydrogen embrittlement characteristics.

Mechanical properties, microstructural characterizations, thermokinetic modeling, ex situ high-pressure hydrogen testing, 2,000 psi testing at ATC, corrosive National Association of Corrosion Engineers (NACE) testing and in situ of the four pipeline alloys have been completed. All of these results have been reported prior. All of this testing has shown that microstructural differences cause different behaviors in the presence of hydrogen. Some of the behaviors appear to be positive while others may appear negative.

Glass coating development has been progressing and has been reported in previous reports. In addition, actual costs to construct a natural gas pipeline were supplied by Columbia Gas of Kentucky. These costs were reviewed, discussed and reported in previous reports. Changing economic conditions will affect the cost of steel and will require review of these construction costs in the future.

ORNL has completed the tensile testing matrix at three different pressures (800, 1,600, 3,000 psi) and two different strain rates ($10^{-4}$, $10^{-5}$) for the four commercially selected pipeline steels (Alloys A-D) in Table 1 (grade, base chemistry, microstructural characterization comparisons) [1]. The results were reported in previous reports; however Figure 1 shows results from $10^{-5}$ strain rate for review. From this work, Alloys B and D were chosen for additional fracture and fatigue testing for full mechanical property characterization at 800 and 3,000 psi.

Fracture toughness testing measuring ($K_{IC}$) was completed on Alloys B and D at 800 and 3,000 psi (5.5 and 21 MPa) [2]. Both alloys performed well however, Alloy B with the ferrite/coarse acicular ferrite microstructure performed better at each pressure.

TBD - to be determined
Figure 2. In addition, opposite to what others have reported, increasing strength did not degrade fracture toughness which demonstrates the importance of microstructures in this pressure range, Figure 3.

Fatigue testing utilizing two R-ratio values (0.5 and 0.1, R is the ratio of the minimum to maximum load applied to the specimen) was completed on Alloys B and D at 800 and 3,000 psi (5.5 and 21 MPa). In addition, testing was completed in air for both alloys for comparison. There was no significant difference in fatigue results by R-ratio values or microstructures. However, both microstructures showed tendencies of convergence with those values generated in air at lower stress intensity factor range values (stress state near the tip of the crack caused by remote loading) during fatigue, (ΔK expressed in MPa m1/2), Figures 4 and 5.

Remaining work for Fiscal Year (FY) 2010 and FY 2011 includes:

Steels
- Optical, scanning electron microscope (SEM) and transmission electron microscope (TEM) microstructural characterization of alternative Alloys E and F.
- Fracture and fatigue testing of alternative Alloys E and F at 3,000 psi.
- Publish final report of microstructure vs. mechanical property performance in gaseous hydrogen under pressure for the alloys selected.
Conclusions and Future Directions

Preliminary testing in FY 2006, FY 2007 and FY 2008 showed that high-pressure hydrogen may have an effect on mechanical properties depending on microstructure design. Additional limited testing at ATC showed that mechanical properties, especially fracture toughness can be affected in the presence of high-pressure hydrogen. NACE testing demonstrated that microstructures, especially those containing pearlite/upper bainite, are susceptible to cracking in the presence of hydrogen. FY 2009 testing at ORNL utilizing high pressure in situ tensile testing confirmed that microstructure does appear to play a role in resistance to the effects of hydrogen, especially with increasing pressure. In FY 2010 testing, fracture toughness testing of the polygonal ferrite microstructure (Alloy D) vs. a polygonal ferrite/10% coarse acicular ferrite microstructure (Alloy B) showed that the acicular ferrite microstructure performed better at both lower and higher hydrogen pressures. There was no significant difference between the Alloy B and Alloy D in fatigue testing, even under two different R-ratio values. There does appear to be a convergence of performance of the two alloys with that tested in air at lower ∆K values. This may be a positive in fatigue performance in relationship to gaseous hydrogen transmission as lower ∆K values may be more realistic in actual operation.

Based on current available funding, the following represents additional work in FY 2010 and FY 2011:

Steels

- Fracture and fatigue testing of Alloys E and F at 3,000 psi gaseous hydrogen.
- Complete microstructural characterization of Alloys E and F by optical microscopy, SEM and TEM evaluation.
- Additional information gathered will be shared with the ASME B31.12 Hydrogen Piping and Pipelines codes and standard committee for review and consideration for incorporation. This will be done through partners ASME and DGS Metallurgical Solutions.

Economic Analysis

- Recommend steel for implementation.
- Evaluate economic impact of suggested materials systems.

Results from the testing will be used to help identify optimum alloy/microstructure design required to safely transport high-pressure hydrogen gas through steel pipelines. Some of these alloy/microstructure designs may already exist in the existing pipeline infrastructure. This work has generated ASME Codes and Standards interest along with private industry that has resulted in additional fracture and fatigue testing to take place of additional alloys/microstructures in a Phase 2 project.

FY 2010 Publications/Presentations

1. An oral presentation regarding the overall project status was given at the DOE Pipeline Working Group Meeting – NIST Boulder, CO (August 2009).
2. Poster presentation regarding the overall project status was given at the DOE Annual Merit Review Meeting (June 2010).

Contract Number: DE-FG02-07ER84772  
Subcontractor:  
Sustainable Innovations, LLC, Glastonbury, CT  
Start Date: June 20, 2007  
End Date: August 14, 2010

Objectives

- Demonstrate feasibility of a solid-state electrochemical hydrogen compressor (EHC) cell capable of compressing hydrogen from near-atmospheric pressure to up to 6,000 psi.  
- Increase the cell performance (reduce power consumption, improve compression efficiency) while lowering the cost compared to previous designs.  
- Study thermal and water management to increase system reliability and life.  
- Scale up EHC to a short stack.

Technical Barriers

This project addresses the following technical barrier from the Hydrogen Delivery section (3.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(B) Reliability and Costs of Hydrogen Compression

Technical Targets

This project is directed at demonstrating the feasibility of solid-state electrochemical hydrogen compression. The EHC is an enabling device for low-cost hydrogen delivery. Phase II goals include the following:

- Compress hydrogen from 300 psi to up to 6,000 psi.
- Develop multi-cell stack design and validate in a short stack.  
- Demonstrate compression ratio up to 300:1.  
- Achieve stack performance stability at 3,000 psi for 500 hours.  
- Increase hydrogen recovery efficiency to 98%.

The ultimate goal of the project is to meet the DOE targets for forecourt compressors [1].

Accomplishments

- Hydrogen Pressure: Reached 6,000 psi hydrogen pressure (single cell).  
- Compression Efficiency: Reduced specific energy consumption by >80% compared to the best Phase I result (Figure 1).  
- EHC Scale Up: Cell technology scaled up from 3-cell to 10-cell stack.  
- Compression Mode Operation: Demonstrated compression ratio of over 500:1 in a single step.  
- Operation Hours: 3,000 hr operating time at up to 3,000 psi in single cell, and >500 hr at 3,000 psi in 3-cell stack.  
- Hydrogen Recovery: Achieved >98% hydrogen recovery rate in single cells, and 95% in a 10-cell stack.

Introduction

With the depletion of fossil fuel reserves and a global requirement for the development of a sustainable economy, hydrogen-based energy is becoming increasingly important. Production, purification and compression of hydrogen represent key technical challenges for the implementation of a hydrogen economy, especially in the transportation sector where on-board storage of pure hydrogen may be required at pressures up to 10,000 psi and compression of the hydrogen fuel up to 12,000 psi.

The level of maturity of current hydrogen compressor technology is not adequate to meet projected infrastructure demands. Existing compressors are inefficient and have many moving parts, resulting in significant component wear and therefore excessive maintenance. New technologies that achieve higher operational efficiencies, are low in cost, safe and easy to operate are therefore required. This project addresses
III. Hydrogen Delivery

high-pressure hydrogen needs by developing an efficient, low-cost, solid-state EHC.

Approach

The approach to address the Phase II goals consists of the following major elements:

- Build on Phase I experience to develop high-pressure stack design.
- Flow field design to increase hydrogen recovery efficiency.
- Reduce capital cost by reducing catalyst loading and simplifying system design.
- Reduce operating cost by improving membrane and electrode design.

To this end, the approach includes the construction and evaluation of advanced stack architecture, and the development and demonstration of critical sealing technology to contain the high-pressure hydrogen within the cathode compartment of the stack.

Results

The EHC cell architecture has been improved to reduce energy consumption. The specific energy consumption to compress hydrogen from atmospheric pressure to 2,000 psig is 3.8 kWh/kg, as shown in Figure 1. This is a >80% reduction compared to the best Phase I result. The goal of demonstrating a compression ratio of 300:1 has been met. Moreover, in the past year the EHC has been scaled up from a 3-cell stack to a 10-cell stack. It was designed, fabricated and tested at pressures up to 3,000 psi. Hydrogen recovery rates of >98% and 95% have been demonstrated in single cells and a 10-cell stack, respectively.

Conclusions and Future Directions

This project has successfully demonstrated the feasibility of the EHC technology. All major technical targets of this project have been met. They include:

- Compressed hydrogen from near-atmospheric pressure to up to 6,000 psi in a single step without any moving parts.
- Developed multi-cell stack design and validated in a 10-cell stack.
- Demonstrated compression ratio of 300:1.
- Achieved stack performance stability at 3,000 psi for more than 500 hours.
- Demonstrated hydrogen recovery efficiency of >98% in EHC single cells.

This project is ending in Fiscal Year (FY) 2010. Additional work required to further advance the EHC technology includes:

- Improve stack performance to reach 98% hydrogen recovery efficiency.
- Further scale up EHC to increase its capacity to meet demands of near-term applications.
- Further reduce power consumption to approach Nernst equation.
III. Hydrogen Delivery

Special Recognitions & Awards

1. This work was awarded the 2009 DOE Hydrogen Program R&D Award during the DOE Hydrogen Program Merit Review and Peer Evaluation Meeting in Washington, D.C.

Project Start Date: May 1, 2004
Project End Date: September 30, 2012

Objectives

- Develop welding/joining technology that greatly reduces the capital cost and eliminates hydrogen embrittlement (HE) concerns in constructing new pipelines and converting existing pipelines for high-pressure hydrogen delivery.
- Quantify the effects of welding and joining on the resistance to HE of high-strength pipeline and other structural steels under high-pressure hydrogen.
- Develop the technical basis and guidelines to manage hydrogen, stress and microstructure in the weld region to ensure structural integrity and safety of hydrogen delivery systems.
- Develop risk assessment-based approach to manage the integrity and safety of hydrogen pipelines including weld joints.
- Determine the hydrogen transport behavior (absorption, diffusion, trapping, etc.) in steels.

Technical Barriers

This project addresses the following technical barriers from the Delivery section of the Fuel Cell Technologies Program’s Multi-Year Research, Development and Demonstration Plan:

- (D) High Capital Cost and Hydrogen Embrittlement of Pipelines
- (F) Gaseous Hydrogen Storage and Tube Trailer Delivery Costs
- (G) Storage Tank Materials and Costs
- (K) Safety, Codes and Standards, Permitting

Technical Targets

This project is to develop the scientific understanding, technical basis and cost-effective engineering solutions to control and mitigate hydrogen embrittlement in the steel weld region of pipelines and other high-pressure hydrogen delivery infrastructure systems. Insights gained from this project will be applied toward the hydrogen delivery infrastructure that meets the following DOE 2017 hydrogen pipeline delivery targets:

- Capital cost: $490K/mile for transmission pipeline and $190K/mile for distribution pipeline.
- Cost of delivery of hydrogen <$1.00/gasoline gallon equivalent, gge
- Reliability/Integrity: Acceptable for H₂ as a major energy carrier

Accomplishments

- Baseline high-pressure hydrogen permeation measurements established the effects of weld microstructure, surface conditions, temperature and hydrogen pressure on hydrogen permeation, diffusion and trapping of selected pipeline steels.
- Initial studies on friction stir welding of pipeline steels indicated considerable improvement of weld toughness and strength over the conventional arc welds.
- Testing with recently developed spiral notch torsion test (SNTT) and multi-notch tensile testing was able to quantify and rank the sensitivity of different microstructures in the weld region to hydrogen embrittlement.
- A general approach based on the finite element model has been developed to determine the fracture toughness of materials tested by SNTT.

Introduction

The hydrogen energy delivery infrastructure will require extensive use of steels and other cost-effective structural and functional materials under high-pressure gaseous hydrogen (H₂) exposure. For example, high pressure (up to 3,000 psi) hydrogen pipelines are presently considered to be one of the most cost-effective and energy-efficient means to transport very large amounts of hydrogen to much of the market as is done currently for natural gas [1]. Under high hydrogen pressures, there are concerns about HE of steel...
pipelines and its potential catastrophic consequences [2]. Concerns regarding hydrogen embrittlement are not limited to steel pipelines; according to a recent DOE Basic Energy Science Office report [3], hydrogen embrittlement needs to be addressed for a variety of hydrogen storage and delivery system parts made of metallic materials that are exposed to hydrogen.

As in the case of natural gas and other energy carrier transmission pipelines, welding will be used to construct steel pipelines for high-pressure hydrogen delivery. Welding will be also widely used in fabrication of other system components for hydrogen production, storage, and delivery. However, welds in pipeline steels and other engineering materials are often the most susceptible regions to HE due to the formation of unfavorable microstructures and high tensile residual stresses. Indeed, recent studies [4] on pipeline steels have shown that the weld region exhibits delayed cracking (signature of hydrogen embrittlement) when exposed to high-pressure hydrogen gas. Furthermore, the weld region typically has substantially lower resistance to hydrogen crack initiation and higher crack growth rates, when compared to the baseline pipeline steel (base metal). In this regard, the weld region can be the weakest link for the structural integrity and safety of hydrogen pipelines and hydrogen delivery infrastructure. A systematic approach to deal with weld property degradation under high-pressure hydrogen gas is critical to ensure the safe, cost-effective operation and long-term reliability of the hydrogen delivery infrastructure.

**Approach**

While there have been extensive studies in the past on hydrogen embrittlement and hydrogen induced material property degradation of pipeline steels, the high-pressure hydrogen delivery pipeline presents some unique issues that are seldom addressed in the past. At the center of these issues is the hydrogen transport behavior in metal – the absorption, diffusion, and trapping of hydrogen in metal. At the present time, very limited knowledge is available about the rate of diffusion and amount of hydrogen in steel under high-pressure gaseous environment relevant to the hydrogen delivery infrastructure. Therefore, the first major effort in this project is directed toward high-pressure H₂ permeation and mechanical performance tests to systematically study the hydrogen permeation behavior and to evaluate the tolerance level to hydrogen of different steels before considerable mechanical property degradation would occur.

The weld joint in steel pipeline is expected to be a critical region mostly susceptible to hydrogen embrittlement due to the formation of unfavorable microstructure and the high residual stresses. The second major activity of this project focuses on developing new welding technology and/or improving existing welding technology to optimize weld microstructure and proactively control the weld residual stress for H₂ pipeline construction and repair. In addition, special testing methods need to be developed to quantify the degradation of mechanical properties in the weld region with complex microstructure and HE resistance gradients. Finally, a risk assessment-based approach will be developed to manage the integrity and safety of hydrogen pipelines including the weld joints.

**Results**

The Fiscal Year (FY) 2010 activities focused on the development of the SNTT method and associated finite element analysis for measuring the fracture toughness degradation of steel welds and base metals under high-pressure hydrogen.

Current standard methods for testing hydrogen-induced mechanical property degradation of base metal have shown to be inadequate when applied for the weld metal region due to the highly inhomogeneous microstructure and property gradients of the weld region [4]. In this project, we designed and fabricated miniaturized and self-loading testing devices for in situ measurement of mechanical property degradation of weld metal in high-pressure gaseous hydrogen environment. The compact size and self-loading mechanisms employed in the testing devices make it possible that the entire loading assembly and the test specimen be placed inside a relatively small high-pressure chamber. This minimizes the capital cost of the testing system and allows for multiple testing devices to be operated in a single high-pressure vessel to cost-effectively study and quantify the effects of the weld microstructure on HE resistance of different steels. The effects of high-pressure hydrogen on the stability of load sensors immersed in hydrogen have been solved with a novel sensor design.

In FY 2010, we focused on the further development of the SNTT method to test the fracture toughness of weld metal consisting of highly inhomogeneous microstructure. AISI 4340 high-strength steel samples with different level of microstructure inhomogeneity were studied. One sample was prepared by heat treatment at 850°C for one hour followed by oil quenching. The microstructure distribution was relatively uniform in this quenched sample. The other sample was prepared with simulated weld heating and cooling curves using the Gleeble system, a dynamic thermo-mechanical simulator. Highly non-uniform microstructure distribution was obtained resembling that encountered in the heat-affected zone of a weld.

Optical microscopy images of microstructure for the quenched sample at two transverse cross-sections are shown in Figure 1. The microstructure appears...
to be predominantly martensite. The average prior austenite grain size is estimated to be roughly 250 μm. The average Vickers harness is about 650. The Gleeble sample exhibited very different microstructure than the quenched sample, as shown in Figure 2. Preliminary analysis indicates that the microstructure at the center appears to be a mixture of bainite and martensite, whereas that at 12 mm away from center is mostly bainite. It is noted that the martensite in the quenched sample is different from that in the Gleeble sample in terms of the chemical homogeneity. The rapid heating and cooling in Gleeble sample provides little time for the alloy elements to redistribute themselves in the microstructure. On the other hand, the microstructure in quenched sample is expected to be much more homogenous since the high-temperature holding permits the homogenization of alloying elements.

Fracture Toughness Analysis for SNTT

A full three-dimensional (3-D) finite element analysis (FEA) model was developed to calculate the
stress intensity factor and the fracture toughness of SNTT sample as a function of the fracture load recorded in the SNTT experiment. The model was used to study the effect of microstructure inhomogeneity on fracture toughness. Figure 3 displays the 3-D finite element model mesh of the SNTT specimen. In the analysis, one end of the sample is fully constrained, while the other end is rotated to provide the torsional load to the SNTT specimen.

For the quenched sample, the fracture torque during testing is 1,100 in·lbf. Using the 3-D model, the critical fracture energy ($J_{lc}$) is found to be 33 kJ/m². For simplicity, it is assumed that the plastic component of $J$-integral is much smaller than the elastic component. Therefore, the fracture toughness $K_{lc}$ can be converted from $J_{lc}$ by

$$J_{lc} = \frac{K_{lc}^2}{E(1-\nu^2)},$$

and is found to be 84.1 MPa·√m (76.5 ksi·√in). This value is in good agreement with the reported fracture toughness ranging from 67 to 86 ksi·√in based on the compact tension test of 4340 base steel available in the

![FIGURE 2. Distribution of Microstructure and Hardness in the Gleeble Sample](image)
literature [5]. On the other hand, the Gleeble sample failed at a lower fracture torque of 77 kN·m (680 in·lbf). The post-test examination reveals that the fracture initiates from the central region of the sample where the hardness is highest and the microstructure consists of a mixture of bainite and martensite. The fracture toughness is calculated to be 51.8 MPa·\(\sqrt{\text{m}}\) (471 ksi·\(\sqrt{\text{in}}\)), i.e., 62% of that of quenched sample. The difference in fracture toughness between the Gleeble and quenched samples is largely due to the local microstructure. The microstructure in the quenched sample consists of mostly fine martensite, whereas the microstructure in the fractured region of Gleeble sample consists of a mixture of bainite and martensite. Furthermore, as discussed previously, the microstructure in the quenched sample is expected to be more chemically homogenous than that in the Gleeble sample.

The significance of the above results is the following. Firstly, the SNTT tested fracture toughness of quenched sample is very consistent with that based on the standard ASTM compact tension test. This demonstrates that SNTT is a sound and accurate technique for measuring fracture toughness. Secondly, the miniature specimen design and high constraint in SNTT offers potential advantages over the standard compact tension test when testing mechanical property degradation due to HE in high-pressure hydrogen. As reported in the literature, it is difficult to test weld fracture toughness in hydrogen using the compact tension test due to the irregular crack growth in non-uniform microstructure [4]. As demonstrated in the Gleeble sample, the ability to test fracture toughness in the sample with a highly non-uniformed microstructure provides a solid basis for testing the weld in high-pressure hydrogen using SNTT.

Further Enhancements to SNTT

The SNTT testing technique was further improved in the following two areas. First, an extensometer was installed to accurately measure the local rotational displacement during testing. Figure 4(a) shows the in-house biaxial extensometer with a gage length of 0.5 inch. The relationship between the applied torque and rotation angle measured from the rotary variable differential transformer and the extensometer is shown in Figure 4(b). It can be seen that under the same applied torque, the angle of twist per unit length measured by the extensometer was larger than that from the rotary variable differential transformer. This indicates that the middle section of the SNTT specimen underwent a larger twist deformation than the average of the whole sample. The deformation measured from the extensometer, a more realistic representation of the actual deformation in the notched section, will be used to further validate the 3-D model.

FIGURE 3. Mesh used in the Full 3-D Finite Element Model

FIGURE 4. (a) SNTT testing utilizing a biaxial extensometer; and (b) applied torque versus rotation angle per unit length measured from rotary variable differential transformer and extensometer.
Another improvement to SNTT is that sharp pre-cracks at the groove roots were induced using cyclic fatigue. Two samples were studied: One sample was machined in the as-received annealed condition; while the other was first annealed at 850°C for 1 hour and then oil-quenched to room temperature. Fatigue cycling was performed at room temperature for 10,000 cycles at 1 Hz frequency. The maximum and minimum torques applied during fatigue pre-cracking were 300 and 30 in-lbf, respectively. The pre-fatigued samples were then tested at an applied loading rate of 20 in-lbf/s.

Postmortem surface examination was performed on the fracture surfaces of the two samples using a stereo optical microscope and a scanning electron microscope (SEM). The photographs of the fracture surface of the samples are shown in Figure 5. As shown in the figure, for the as-received material, the fracture surface contains three regions. Region A appears to be smooth from a macroscopic point of view, while region B and region C appears to be rough. For the quenched material, the fracture surface contains only two regions, in which region A appears to be smooth and region B appears to be rough. Region A in both samples were suggested to be precracks introduced by fatigue loading, and region B in both samples were suggested to be the fast growth region of crack during final fracture. A possible cause for the occurrence of region C in the as-received material is that during the torsion test, the as-received sample was loaded and unloaded twice prior to the final fracture. So region C was probably introduced during the first two loading cycles. Region B exhibited a cleavage fracture feature, which is typical for the rapid growth region of cracks. The shape of region A is well-defined, and the crack length is similar measured from different parts of region A. This verifies the strong material constraint at the crack front in SNTT specimen.

Detailed FEA of a model with fatigue precrack is ongoing to calculate the fracture toughness from the fracture load. The above enhancements are expected to further improve the consistence and accuracy of the tested fracture toughness using SNTT. This is especially important for testing fracture toughness in high-pressure hydrogen.

Conclusions and Future Directions

This project focuses on the resistance of HE in the weld region of steels. Such region is regarded as the weakest link for the structural integrity and safety of hydrogen pipeline and hydrogen delivery infrastructure. In FY 2010, we have successfully demonstrated the SNTT method for testing fracture toughness of non-uniform microstructures in the heat-affected zone and weld region.
The project plan for the remaining of FY 2010 includes: (1) completing the development of SNTT method for fracture toughness testing in high-pressure hydrogen, and (2) performing tests on different arc welds and friction stir welds of pipeline grade steels and establishing a database of material performance in high-pressure hydrogen.

III.18 Hydrogen Pipeline Compressors

Objectives

- Develop advanced materials and coatings for hydrogen pipeline compressors.
- Achieve greater reliability, increased efficiency, and lower capital investment and maintenance costs in hydrogen pipeline compressors.
- Research existing and novel hydrogen compression technologies that can improve reliability, eliminate contamination, and reduce cost.

Technical Barriers

The project addresses the following technical barrier from the Hydrogen Delivery section (3.2.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(B) Reliability and Costs of Hydrogen Compression

Technical Targets

This project is directed toward the study of fundamental mechanisms associated with the tribology of hydrogen pipeline compressors (friction, wear, and degradation). The goal of the research is to identify materials and engineered surface treatments that provide low friction and wear resistance required to achieve the energy efficiency and reliability targets for pipeline compressors. Accordingly, the project tasks address the challenges associated with meeting the DOE hydrogen delivery performance and cost targets for 2017:

FY – Fiscal Year

Accomplishments

- Completion of installation and initial acceptance tests of new high-temperature hydrogen tribometer.
- Identification of new coating material (NFC7) that shows no measurable wear in two-hour test.
- Completion of tests that assessed friction and durability of proprietary diamond-like carbon (DLC) coating.

Introduction

Compressors are critical components used in the production and delivery of hydrogen. Current reciprocating compressors are costly, are subject to excessive wear, have poor reliability, and often require the use of lubricants that can contaminate the hydrogen (used in fuel cells).

The primary objective of this project is to identify – and develop as required – advanced materials and coatings that can achieve the friction, wear, and reliability requirements for dynamically loaded components (seal and bearings) in high-temperature, high-pressure hydrogen environments prototypical of pipeline and forecourt compressor systems.

The DOE Strategic Directions for Hydrogen Delivery Workshop identified critical needs in the development of advanced hydrogen compressors – notably, the need to minimize moving parts and to address wear through new designs (centrifugal, linear, guided rotor, and electrochemical) and improved compressor materials. The DOE is supporting several compressor design studies on hydrogen pipeline compression, specifically addressing oil-free designs that demonstrate compression in the 0-500 psig to 800-1,200 psig range with significant improvements in efficiency, contamination, and reliability/durability.
One of the designs by Mohawk Innovative Technology, Inc. (MiTi®) involves using oil-free foil bearings and seals in a centrifugal compressor, and MiTi® identified the development of bearings, seals, and oil-free tribological coatings as crucial to the successful development of an advanced compressor. MiTi® and Argonne have developed potential coatings for these rigorous applications; however, the performance of these coatings (as well as the nickel-alloy substrates) in high-temperature, high-speed hydrogen environments is unknown at this point.

**Approach**

The approach that is being undertaken is to evaluate the tribological performance of candidate seal and bearing materials under consideration by compressor manufacturers and provide data required to select the optimum seal and bearing material/coating configuration for a 300-kg/min centrifugal compressor and high-pressure, low-flow positive displacement compressor. This effort will include:

- Evaluating the effects of a hydrogen environment on the mechanical properties of Ni alloys,
- Evaluating the feasibility of coating suitable substrates with Argonne’s near frictionless coating (NFC) and outside vendor coatings,
- Establishing the requirements and testing needs for NFC and a series of foil seal coatings, and
- Evaluating foil seal and bearings under conditions prototypic of the proposed MiTi® hydrogen compressor.

The research uses facilities and expertise at Argonne – notably the ability to deposit advanced high-performance coatings (e.g., NFC), to test and evaluate coatings under extreme conditions, and to characterize and understand friction, wear, and surface degradation phenomena that determine component lifetime and reliability.

Different contact stress/sliding speed regimes were identified, depending on compressor design:

- Positive displacement – high contact stress, low sliding speed
- Axial flow compressors – high speed, low contact stresses
- Centrifugal compressors – intermediate speeds and contact stresses

Based on the range of contact stresses and sliding speeds anticipated for these compressors, we will replicate lab conditions to encompass nominal contact stresses between 2 and 1,500 psi, with sliding speeds from 0.1 to 10 m/s. Operating temperatures up to 500°C due to working-gas adiabatic heating and flash/asperity heating can add an additional 500 to 750°C (depending on load, speed, thermal properties, and friction) to the temperature of near-surface asperities. The coating deposition is focused on NFC and commercial coatings based on conventional solid lubricants. The substrates chosen are stainless steels, nickel alloys, and Cr-Mo steels.

**Results**

**New Test Machine**

In the past year, the main focus was the receipt and installation of a new high-temperature test rig, as shown in Figure 1. The machine exhibited deficiencies in performance acceptance tests. The operation requirements (speed of 2,000 rpm, test period of 1 hour, pressure of 0.9 bar, temperature of 800°C) with continuous measurement of friction, wear, temperature, and sliding distance were attained in N₂ gas but not in H₂. Safety interlock switches were installed to limit the maximum pressure to approximately half the specified pressure. The pressure issue is being addressed by using dual redundant differential pressure switches. The specified temperature could not be attained due to excessive convective cooling of the specimen holder as a result of the high heat conductivity of H₂, which is approximately seven times that of air. The convection issue is being addressed by the installation of quartz heat shields. During acceptance tests, the H₂ pressure regulation was lost because a pirani pressure gauge did not operate correctly in H₂ at pressures above 1 mbar. The regulation issue was solved by substituting a capacitance diaphragm gauge, which reads correctly over the complete pressure range, independent of gas species. The reducing nature of H₂ on uncoated nickel alloys was dramatized when the new machine jammed and galled during maintenance – necessitating factory repair.

**FIGURE 1. Photograph of New High-Temperature Hydrogen Test Machine**
Continuing Tests

Additional tribological data were obtained in FY 2010, particularly focusing on extended duration tests (2 hours). Summary results are shown in Table 1. At nominal room temperature, the new Argonne NFC7 carbon performs better than the former best-performing material, NFC6. As shown in Figure 2, the coefficient of friction of NFC7 is substantially less than that of NFC6, and yet the NFC7 shows no measurable wear. Tests were harsher with the NFC7: 2-hr duration at either 2,000 rpm or 6,000 rpm, 50% duty cycle, up to 15 N load. A proprietary DLC coating did not perform as well. A Ni/polytetrafluoroethylene (PTFE) coating was obtained on test coupons, but testing was delayed. A nondisclosure agreement is being negotiated with a company that offers a low-temperature diamond coating process.

New Characterization Methods

A newly installed Hysitron nanoindenter was used to probe the mechanical properties of unworn and worn surfaces (Table 2). Transfer films, as expected, are quite soft, but the new NFC7 is surprisingly hard with high elastic modulus when compared to the other leading candidate material NFC6, or the lesser-performing N3FC. The NFC7 exhibits surprising constancy in hardness and elastic modulus for various loadings (1-5 mN).

Conclusions and Future Directions

Longer-duration room-temperature testing was performed on existing (NFC6) and new (proprietary DLC and Argonne NFC7) materials, with excellent results for the latter. Installation of the new elevated-temperature tribometer is 80% complete, with shakedown tests performed in N₂ but not meeting specifications in H₂. Pending successful modifications and acceptance tests, we will finish up testing of promising materials at typical in-service temperatures. A series of tests of newly received Ni/PTFE test specimens will be performed.

TABLE 1. Friction Coefficients of Materials in Ambient-Pressure Hydrogen
The original goal of “Large Compressors: Transmission, Terminals, Geological Storage” is being broadened to include the section “Forecourt Compressors: Forecourt,” and discussions have been started with two suppliers of non-centrifugal hydrogen compressors who have products in the field that are exhibiting the need for frequent scheduled and unscheduled maintenance. This revised goal will involve conducting longer-term sliding tests on materials used in forecourt compressors for “bone dry” use (e.g., polyether-ether-ketone and carbon-tetrafluoroethylene instead of nickel alloys, as has been done so far). We will continue nanoindentation studies to elucidate the possible relationship of surface mechanical properties to tribology friction and wear, and will apply the focused-ion-beam method to understand how H₂ can affect near-surface and subsurface failure.

Accomplishments

- Several seal designs were evaluated in static and dynamic tests. The variations included the radial clearance, presence or absence of face bumps, preload level, and the axial length.
- Tests were conducted both with air and helium as the substitute gas for hydrogen. The effect of inlet pressure and speed were evaluated. The gas temperature was varied from the ambient to 500°F. The results confirmed that the flow factor, or seal leakage, decreased as the inlet pressure was reduced or the speed was increased.
- Presence of the face bumps decreased leakage, while preload had only a minor effect. Longer seals did not necessarily improve the seal performance. Seal leakage was significantly reduced at higher temperatures. A smaller leakage was obtained with helium as compared with air. The seal performance and durability improved when all surfaces that would come into contact were also coated with the Korolon® 7 coating.
- A continuous 3.5-hour test confirmed excellent durability for the seals as no wear or erosion were observed on the seal components after the test and the flow factors remained constant throughout the testing period.

Introduction

The objective of this project is to develop and demonstrate feasibility of using a close clearance, non-contacting, and dynamic compliant foil seal in hydrogen and/or natural gas pipeline compressors. The goal of this seal is to enhance the economic viability of hydrogen as an energy carrier and to substantially improve the efficiency of centrifugal compressors so
that they become feasible for use in transportation and delivery of hydrogen. Under Phase I, MiTi® completed the design of a compliant foil seal suitable for the previously sized hydrogen transportation and delivery compressors and fabricated the designed seal and tested it statically to assess the leakage flow as a function of differential pressure. Results showed considerably reduced leakage with the foil seal over other technologies and previous versions of the compliant foil seal. Under Phase II, the foil seal design is to be refined based upon lessons learned from Phase I: additional static testing is to be conducted to validate the design; and finally, dynamic testing of the final full-scale design will be completed to demonstrate that performance capabilities meet the specified needs of a hydrogen transportation and delivery compressor.

**Approach**

Additional testing will be performed using the seal design and hardware developed under Phase I to further characterize the secondary/tertiary losses and to assess approaches to reduce the secondary losses. The design will be revised to mitigate secondary leakage losses. Full-scale compliant foil seals will be tested under dynamic rotating shaft conditions. The critical foil seal dimensions and operating clearances will be selected to minimize leakage between stages of a hydrogen transportation centrifugal compressor capable of delivering up to 1,000,000 kg/day. Ambient hydrogen gas pressures, pressure rise per stage, shaft surface speed and expected rotor motions will be included in the analysis and seal design. A new test rig (or modifications to an existing test rig) will be developed to evaluate and characterize the seals under realistic operating conditions of speed, rotor radial displacements and differential pressures. The full-scale seals will be evaluated with the dynamic test rig to determine leakage and differential pressures representative of that expected in an operating hydrogen centrifugal compressor. During testing key parameters, such as upstream and downstream pressure, leakage flow, shaft speed, rotor radial motions and seal foil, temperatures will be measured. Based upon test data, the compliant foil seal design will be revised to address identified areas for improvement. A final report documenting the key seal design parameters and component sizing, the test results and an assessment of the benefits of the seal to the performance of hydrogen compressor will be prepared.

**Results**

The initial dynamic testing was carried out with four seal configurations in progressive settings in order to safely run to full operating speed and high inlet pressures. The static and dynamic performance of each seal configuration was first evaluated with a loose radial clearance and no face bumps. The flow factor was reduced as the speed was increased from 0 to 60,000 rpm due to centrifugal growth of the rotor and the developed hydrodynamic pressure. The results also confirmed that the leakage was higher for the static seal as compared to the dynamic conditions. The seal leakage increased as the inlet pressure was increased from 20 to 100 psi (see Figure 1).

Since the first set of tests were successfully performed with loose radial clearance seals and no face bumps, the face bumps were then installed without preload, using the same radial clearance as before. Both the static and dynamic performance of this seal configuration was then evaluated. The seal leakage was reduced as the speed was increased and as the inlet pressure was reduced. In the next series of test, the face bumps were preloaded while the radial clearance remained the same as before. The results were similar to those for the other two seal configurations described above.

As the last configuration for this series of parametric study, the seal radial clearance was reduced while the face bumps were kept loose without preload. The
dynamic performance of the four seal configurations under the same testing conditions was further compared as a function of inlet pressure at a fixed operating speed of 60,000 rpm, and as a function of operating speed at a fixed inlet pressure of 100 psi. The seal leakage was reduced when the face bumps were installed in the seal assemblies, while preloading the face bumps had no effect on the seal performance. The most significant contribution to the seal performance was from the radial clearance between the sealing surface and the test journal - the smaller the radial clearance the less seal leakage. The seal configuration with loose radial clearance and loose face bumps was selected for further testing to evaluate the seal performance under various conditions.

**Elevated Temperature:** To characterize the seal performance at elevated gas temperatures, four heat torches were installed at the air inlet of the high-speed test rig. The static and dynamic performance was evaluated first when the heaters were off. The heaters were then turned on and the temperature was set at 500°F. After the temperature reached the steady-state value, the seal performance was evaluated under static conditions and then under dynamic conditions at various speeds. The seal leakage was significantly reduced at the higher temperature.

To protect the seals from being damaged, the testing procedure was revised and the inlet pressure was kept above 70 psi during dynamic testing. Figure 2 compares the dynamic performance of the seals under ambient, 250°F, and 500°F temperatures. The leakage was reduced as the speed and temperature were increased and as the inlet pressure was reduced.

**Testing with Helium:** The seal performance was evaluated under ambient and elevated temperatures with helium as a substitute gas for hydrogen. While it was desired to test with helium subjected to higher inlet pressures up to 250 psi, the pressure was limited to about 120 psi due to heating by the heat torches used. The leakage was reduced as the temperature increased. The flow factor with helium was smaller than that with air under the same conditions at 500°F.

Dynamic tests with helium were conducted next at various temperatures; however, significant buzzing came from the inside of the test rig at ambient temperature. The seals were removed and examined after the test was completed. Significant erosion had occurred at the overlapped trailing and leading edges of both inner and outer smooth foils of the outboard mounted seal. However, the inboard mounted seal showed no visible damage. Therefore, it was decided to coat not only the sealing surface of the smooth top foils, but also the two touching surfaces of the inner and outer smooth foils with thinner Korolon® coating. The new seals were also tested at 250°F and 500°F. The additional coating reduced buzzing during testing and prolonged the seal life. Figure 3 shows the dynamic test results with and without the additional coating and compares the dynamic performance of the seals with helium at different temperatures. Similar to air, both temperature and speed help reduce the seal leakage.

**Different Coatings:** The smooth foils in the tests described above were coated with Korolon® 900. To compare the seal performances with different coatings, new seals were made and coated with Emralon® and Teflon®. The dynamic performance of the three coatings at operating speeds of 50,000 and 60,000 rpm at 70 psi were compared. For each coating, the leakage increased as the inlet pressure increased, and decreased as the operating speed increased. The leakage of the Korolon® coated seals was slightly larger than that from the other two coatings. However, these tests were conducted at ambient temperature only; the Korolon® coating has been designed for and has demonstrated excellent performance at elevated temperatures.

**Longer Axial Length Seals:** In order to further improve the seal performance, the seal design was modified. The axial length of the smooth foils was...
III. Hydrogen Delivery

Durability Testing: Long-term durability testing was conducted to verify seal life. Two standard axial length seals with Korolon® 900 coating were tested with air under ambient temperature at an operating speed of around 40,000 rpm and an inlet pressure of about 50 psi. The flow factor as a function of time during the 3.5-hour test was constant. The seal foil temperatures remained low and the flow factor stayed steadily below 0.007. The seals were checked after the test and showed no wear marks; therefore, the seals were capable of running continuously for an extended period of time.

Conclusions and Future Directions

Several seal designs were evaluated in static and dynamic tests. The variations included the radial clearance, presence or absence of face bumps, preload level, and the axial length. Tests were conducted both with air and helium as the substitute gas for hydrogen. The effect of inlet pressure and speed were evaluated. The gas temperature was varied from the ambient to 500°F. The results confirmed that the flow factor, or seal leakage, decreased as the inlet pressure was reduced or the speed was increased. Smaller clearance values decreased the leakage through the seals. Presence of the face bumps decreased leakage, while preload had only a minor effect. Longer seals did not necessarily improve the seal performance. Seal leakage was significantly reduced at higher temperatures. A smaller leakage was obtained with helium as compared with air. The seal performance and durability improved when all surfaces that would come into contact were also coated with the Korolon® 7 coating. A continuous 3.5-hour test confirmed excellent durability for the seals as no wear or erosion were observed on the seal components after the test and the flow factors remained constant throughout the testing period. The following tasks are planned for next year:

- Prepare the final report

FY 2010 Publications/Presentations

III.20 Rapid Low-Loss Cryogenic Hydrogen Refueling

Objectives

- Demonstrate rapid refueling of cryogenic vessels.
- Refuel cryogenic vessels even when warm and/or pressurized.
- Refuel at high density (>80 kg/m³).

Technical Barriers

This project addresses the following technical barriers from the Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

Accomplishments

- Identified pressurized liquefied hydrogen (LH₂) as a viable solution for cryogenic vessel refueling.
- Acquired LLNL institutional approvals for pump purchase and installation.
- Identified commercial LH₂ pump that will deliver required performance.

Introduction

Cryogenic pressure vessels have demonstrated highest performance for automotive hydrogen storage, with considerable advantages in terms of weight, volume, and cost [1,2]. One of the outstanding challenges for cryogenic pressure vessels is refueling. Today’s hydrogen storage technologies (compressed and liquid hydrogen) operate at fixed temperature. Cryogenic pressure vessels, however, drift across the phase diagram depending on the level of use. The challenge is demonstrating rapid, inexpensive refueling that minimizes evaporative losses regardless of the initial thermodynamic state of the vessel.

Approach

We have identified a promising technology for cryogenic pressure vessel refueling: a liquid hydrogen pump. This pump takes liquid hydrogen at low pressure (near atmospheric) and delivers it as high-pressure (3,000-12,000 psi) low temperature (30-50 K) high-density (>80 kg/m³) hydrogen that can be directly dispensed into a cryogenic pressure vessel, even when warm and/or pressurized. In this project we plan to purchase a LH₂ pump, install it in the LLNL campus, and demonstrate its virtues for rapid and efficient cryogenic vessel refueling.

Results

Cryogenic vessel temperature and pressure are strong functions of use patterns. After a cryogenic hydrogen fill, pressure vessels will remain cold and unpressurized if frequently driven due to (nearly) isentropic hydrogen expansion during gas extraction, thereby enabling efficient refueling from conventional low pressure (~100 psi) LH₂ Dewars. Extended periods of parking, however, will warm up and pressurize the vessel due to heat transfer from the environment. Refueling warm vessels with low pressure LH₂ is slow and produces considerable evaporative losses. A better solution is needed for practical cryogenic pressure vessel refueling.

Liquid hydrogen pressurization appears a viable solution. A pump may take LH₂ from a low pressure...
Dewar and deliver it at 30-50 K and 3,000-10,000 psi, enabling direct dispensing into even warm and/or pressurized vessels while minimizing evaporative losses.

A potential issue with direct dispensing from a LH$_2$ pump is the variability in the amount of hydrogen in a “full” tank as a function of initial conditions. While a cold tank can be filled to full capacity, a warm vessel can only be refueled to lower capacity to avoid evaporative losses when thermal equilibrium between the hydrogen and the vessel is reached. Fill variability may be acceptable to consumers because it is self-regulating: an infrequently driven vehicle is filled partially, but also requires less fuel because it is typically unused. A frequently driven vehicle has a cold vessel that can be filled to capacity, enabling long driving range.

Pressurized cryogenic refueling may also reduce station capital cost and hydrogen delivery cost. Unlike compressed gas dispensing, pressurized cryogenic dispensing does not require a cascade or refrigeration (Figure 1). The simpler station configuration reduces capital cost and makes the overall cost of liquid hydrogen dispensing comparable to the cost of compressed gas dispensing, even after considering liquefaction cost [3].

We have now identified a pump that satisfies the requirements for rapid cryogenic pressure vessel refueling. The pump takes advantage of LH$_2$ compressibility to deliver high density H$_2$ (over 80 kg/m$^3$, Figure 2) at rapid refuel rates (100 kg/hr) and with low evaporative rates (<3%). Evaporated hydrogen is not vented. Instead, it is recirculated into the station LH$_2$ Dewar, helping maintain its pressure.

LLNL is currently negotiating a contract with the manufacturer. Current plans call for pump installation (along with a large 3,000 gallon Dewar) at LLNL by early 2012.

**Conclusions and Future Directions**

- Rapid, low-loss refueling of cryogenic vessels is possible through pressurized LH$_2$ dispensing.
- Pressurized LH$_2$ dispensing reduces station cost by avoiding compressor, cascade, and refrigerator.
- Overall delivery cost of pressurized LH$_2$ is comparable to compressed gas, even after including the cost of liquefaction.
- Future work includes important tasks:

Aceves – Lawrence Livermore National Laboratory

III. Hydrogen Delivery

- Purchase and install a pressurized cryogenic pump.
- Demonstrate rapid refueling of (even warm or pressurized) cryogenic pressure vessels with low evaporative losses.
- Explore effect of higher pressure on evaporative losses, refueling speed and maximum vessel capacity.

Project Start Date: October 1, 2009
Project End Date: September 30, 2010

Objectives

- Develop the fuel cell vehicle (FCV) range optimization model.
- Compare onboard storage technologies.
- Support the DOE integrated analysis on storage and range issues.

Technical Barriers

This project addresses the following three barriers from the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

(A) System Weight and Volume from the Storage section
(B) System Cost from the Storage section
(B) Stove-piped/Siloed Analytical Capability from the System Analysis section

Technical Targets

This project optimizes the driving range for FCVs. Insights gained from the study can be applied toward assessment and planning of research and development (R&D) activities on onboard hydrogen storage in meeting the following DOE 2010 hydrogen storage targets [1]:

- Cost: $4/kWh net
- Specific energy: 1.5 kWh/kg
- Energy density: 0.9 kWh/L

Accomplishments

- Baseline analysis suggests that the optimal FCV range for the very near term is estimated to be 297-544 miles, depending on up to 10% variation on key parameters.
- Sensitivity analysis demonstrates the robustness of the optimization. A 10% variation on each of 16 key parameters results in -5.7% to +6.2% of change in the optimal range and the optimal onboard usable fuel capacity.
- Quantified the functional relationship between optimal range, storage cost, storage density, and fuel availability. In general, the optimal range is found to increase with lower storage cost or higher storage density, but decrease with better fuel availability.
- Based on the range optimization model, several storage technologies are compared in the transitional market context based on an integrated consumer value metric.
- Demonstrated the benefit of range optimization in informing policy making. Compared to the optimal range, the standard range assumption leads to an overestimate of FCV commercialization barrier by over $8,000 per vehicle. Such a significant overestimate of this transition barrier can seriously mislead policy making but can be corrected by range optimization.

Introduction

The driving range of FCVs needs to be properly determined for accurately assessing the market barriers and cost-effectiveness of this vehicle technology [2-5]. While an overestimated range means an overestimated cost of onboard storage, an underestimated range leads to exaggeration of refueling hassle especially in the early transition period when fuel availability is very limited. Either overestimation or underestimation of the driving range leads to exaggeration of commercialization barrier for FCVs and could mislead policies.

If FCVs become commercialized, it is logical and likely that the private sector will design the range to maximize the value for FCV customers. This suggests optimization of FCV range for proper representation of FCVs in analyses where various vehicle technologies are compared and the future vehicle market is projected. Currently, the FCV range commonly assumed in many analyses is based on engineering constraints and simple analogy to conventional vehicles [6], but not on optimization that reflects the storage technology status.
and fuel availability for FCVs. It is unclear to what extent the ongoing non-optimal range assumptions affect the FCV barrier assessment. It is necessary to revisit the issue by optimizing the FCV range in the context of transitional markets.

### Approach

The FCV range is optimized from the perspective of maximizing consumer value or minimizing total vehicle ownership cost. As a benefit to consumers, increasing the FCV range reduces the stress and time of accessing hydrogen stations, the wasted fuel in searching for stations and the time at the station. On the cost side, a longer FCV range results in loss of legroom or cargo space and higher storage system cost and vehicle price. The optimal range is defined as one where the marginal benefit equals the marginal cost. In preparation for the optimization, the stress and time of refueling are estimated based on calibration to 5,850 light-duty vehicles and appear to be more consistent with survey estimates than conventional analytical methods that consider only travel time cost [7]. Refueling travel time is calculated by assuming optimal station locations [8,9]. Onboard storage technologies are characterized based on published information from the hydrogen storage projects funded by U.S. DOE [1,10]. Value of vehicle interior space is currently based on published estimate that is based on statistical analysis of vehicle design and pricing data [11].

### Results

- The baseline analysis shows the optimal FCV range for the very near term ranging from 297 to 544 miles, depending on up to 10% variation on key parameters. The baseline case is intended to represent the near term characterized by very limited hydrogen station deployment and current technology status for onboard storage. For hydrogen availability, the percentage of stations providing hydrogen is assumed to grow from 1% at the present to 10% in 10 years. Onboard storage technology is assumed to be available at $15.6/kWh and 0.6 kWh/L.

- The barrier of limited range and fuel availability is described by the extra range cost relative to conventional gasoline vehicles, including storage hardware cost, loss of interior space, refueling travel stress and time, wasted fuel, dispensing time and station time overhead. The baseline case results show the extra range cost for a near-term FCV owner is more than $20k (Figure 1). Storage system cost, loss of interior space and refueling travel stress and time contribute to most of the extra range cost.

- Sensitivity analysis demonstrates the robustness of the optimization. A 10% variation on each of 16 key parameters results in -5.7% - +6.2% change in the optimal range and the optimal onboard usable fuel capacity (Figure 2).

- The relationship between optimal range, storage cost, storage density, and fuel availability is quantified. In general, the optimal range is found to increase with lower storage cost or higher storage density, but decrease with better fuel availability.

- Different storage technologies are compared based on range cost and infrastructure cost (Figure 3)
for the near-term scenario. Based on current technology status and near-term infrastructure deployment, cryo-compressed appears to be overall the most cost-competitive, even though its infrastructure cost is higher than compressed gaseous technologies. The chemical hydride technology based on liquid hydrogen carrier (LCH$_2$) is slightly more cost-competitive than compressed gaseous hydrogen. The two compression technologies, with pressures of 350 bar and 700 bar, do not differ substantially from each other in terms of total range and infrastructure costs. The chemical hydride technology based on sodium borohydride (SBH) has a good balance of storage system cost and density, resulting in a relatively low range cost, but its high infrastructure cost makes it the least cost-competitive among the five technologies. It should be noted that these comparisons reflect the near-term technology and infrastructure status and do not reflect the improvement potential of the technologies.

- The barrier overestimation by non-optimal range design can be significant. Compared to the optimal range, the standard range assumption leads to an overestimate of range cost by over $8,000 per vehicle. Such a significant overestimate of barrier can seriously mislead policy making and should be corrected by range optimization (Figure 4).
- The scenario analysis based on the DOE Scenario 3 shows that the FCV range does not necessarily exhibit a monotonic increase or decrease over time. It decreases initially and grows later in response to the relative development pace of storage technology and infrastructure (Figure 4). In reality, product design constraints and consumer expectation set by previous products may prevent the designed range from significantly decreasing. However, what is important is that by reaching the initial critical level of fuel availability, FCV range can be reduced to save costs if little progress is made on onboard storage. It also suggests that after the critical fuel availability level, a higher FCV range is realistic if onboard storage is significantly improved.

### Conclusions and Future Directions
- It is very likely that the non-optimal FCV range currently assumed in analyses has led to exaggeration of this market barrier. Compared to the estimated optimal range, the currently assumed FCV range is found to be too low, which reduces the cost of onboard storage hardware but will require early FCV owners to make more frequent trips to the very few stations that provide hydrogen. The collective effect is a range cost overestimation by over $8,000 per each early FCV owner. In integrated market analyses, such an overestimation would put FCVs into biased disadvantage. It should and can be corrected with range optimization that trades off onboard storage cost with refueling inconvenience.
- The optimal FCV range is found to be a function of fuel availability, onboard hydrogen storage cost and density. The optimal range increases with technological progress of onboard storage, because lower storage cost or higher storage density makes it cost-effective to have additional range in order to reduce refueling frequency. The optimal range decrease with refueling infrastructure deployment, because better fuel availability makes it worthwhile to reduce the range in order to save upfront storage cost.
- The FCV range should be adaptive to the developments of onboard storage technology and refueling infrastructure, for two reasons. First, as we have shown, the optimal FCV range is a function of storage cost, storage density and fuel availability. Second, all these three factors will likely change significantly during the transition period.
• High cost and low density onboard storage and limited fuel availability cause a serious market barrier for FCVs, even if the FCV range is optimized. To eliminate such a barrier, both improving onboard storage and deploying refueling infrastructure will help, but given the uncertainty of technology development and the diminishing contribution to fuel availability of more stations, building up the initial small-scale refueling network should be of higher priority.

• On future study, the methods or observations from this study should be utilized for integrated models. The optimization model can be used to track the progress of onboard storage R&D activities. More research is recommended to better understand the value of vehicle interior space. The optimization model can be expanded to other vehicle technologies, including electric vehicles and plug-in hybrid vehicles. Other factors may also need to be included in optimizing the range, such as weight, efficiency and leakage.

IV. HYDROGEN STORAGE
IV.0 Hydrogen Storage Sub-Program Overview

Introduction

Hydrogen Storage activities in Fiscal Year (FY) 2010 continued to focus on research and development (R&D) of low-pressure, materials-based technologies applicable to both stationary and transportation applications. For transportation, the key objective is to allow for a driving range of more than 300 miles (500 km) while meeting packaging, cost, safety, and performance requirements to be competitive with current vehicles. Materials projects are focused in three main areas: metal hydrides, chemical hydrogen storage materials, and hydrogen sorbents.

FY 2010 saw continued close coordination between the Office of Science’s basic research activities and Energy Efficiency and Renewable Energy’s (EERE’s) applied R&D portfolio. Twenty-five fundamental studies on hydrogen storage materials are being supported by the Office of Science. Within EERE, several projects were completed this past year and no new projects have been initiated. In summary, the storage portfolio currently comprises projects involving 39 universities, 13 companies, and 14 federal laboratories (Figure 1).

Goal

The sub-program’s primary goal is to develop and demonstrate viable hydrogen storage technologies for transportation and stationary fuel cell applications.

Objectives

The sub-program’s ultimate targets for transportation applications are intended to facilitate the introduction of hydrogen-fueled propulsion systems across the majority of vehicle classes and models, whereas the 2010 and 2015 intermediate targets will allow some hydrogen-fueled vehicle platforms to meet customer performance expectations. In pursuit of high-level goals and targets for hydrogen storage, there are many requirements to achieve technical success, including improvements in volume, weight, cost, durability, cycle life, and transient performance. The full set of hydrogen storage targets for light-duty vehicles can be found at: http://www1.eere.energy.gov/hydrogenandfuelcells/storage/pdfs/targets_on-board_hydro_storage.pdf. These targets are based on the requirements of the application—not the current status of the technologies—and they account for differences in vehicle architecture between conventional vehicles and fuel cell vehicles.

Although automakers have recently demonstrated progress with some vehicles that can travel more than 300 miles on a single fill, this driving range must be achievable across different vehicle models without compromising space, performance, or cost. Advanced storage materials and concepts are needed to meet the 2015 and ultimate targets to enable market penetration of hydrogen-fueled vehicles that can achieve greater than a 300-mile driving range without compromising packaging, cost, safety, and performance.

In FY 2010, the sub-program began to address storage options for stationary, portable, and backup power systems—to aid in the deployment of fuel cells in these early markets. A “hydrogen storage for early markets” topic was included in the FY 2010 Small Business Innovation Research solicitation, and a new project (at Hawaii Hydrogen Carriers LLC) on the use of low-cost metal hydrides in forklift applications was selected.

In October 2009, DOE issued a request for information to gather input from stakeholders on the requirements for fuel storage subsystems for early market fuel cell applications. In November 2009, DOE held a workshop on fuel storage requirements for early market applications. The input garnered from these activities will aid in identifying key challenges, priorities, and needs for fuel storage in early market, non-automotive applications and in development of future solicitations for research proposals in these areas.
Hydrogen storage for on-board transportation applications remains one of the most technically challenging barriers to the widespread commercialization of hydrogen vehicles. On-board hydrogen storage approaches under investigation include high-capacity metal hydrides, high-surface-area sorbents, chemical hydrogen storage carriers, low-cost and conformable tanks, compressed/cryogenic hydrogen tanks, and new materials or processes, such as conducting polymers, spillover materials, metal organic frameworks (MOFs), and other nanostructured materials. There are two principal classes of on-board storage systems. “On-board reversible” systems can be refueled on-board the vehicle from a hydrogen supply at the fueling station. These include physical storage systems, such as compressed/cryogenic tanks, as well as on-board reversible material systems such as metal hydrides and high-surface-area sorbents. “Regenerable off-board” systems involve materials that are not easily and quickly “refilled” or regenerated with hydrogen while on-board the vehicle. These include chemical hydrogen storage materials and certain metal hydrides where the temperature, pressure, kinetics, and/or energy requirements are such that the processes must be conducted off the vehicle.

The current projected storage system gravimetric and volumetric capacities are shown relative to the 2010 and 2015 targets in Figures 2 and 3. On a routine basis the sub-program has system capacity projections made for the various on-board hydrogen storage technologies under development. Analytical models use the best available data for the technologies to project the gravimetric and volumetric capacities of complete on-board hydrogen storage systems that meet the required operational specifications. The capacity projections are periodically revised as new and more complete data become available and when improvements to system models are developed. Confidence in the accuracy of the projection improves with the maturity of the technology; for instance, there is higher confidence in projections for relatively mature compressed gas systems than for much less mature complex hydride systems. The range bars shown in Figures 2 and 3 represent the ranges of volumetric and gravimetric capacity projections for all the on-board storage technologies made during the given year. The point within the bars is the average capacity (mean) for the technologies analyzed within the given year.
FIGURES 2 and 3. 2010 status of projected hydrogen storage system gravimetric and volumetric capacities versus 2010 and 2015 on-board system targets. Note that all systems were sized to provide 5.6 kg of useable hydrogen and that the plotted data points are the average value for all systems analyzed during each year while the bars correspond to the range of maximum and minimum values obtained for the year. Also note that systems with predicted capacities exceeding the gravimetric targets do not meet other targets.
IV. Hydrogen Storage / Overview

**FY 2010 Accomplishments**

During FY 2010, a number of new materials were developed and the performance of earlier materials improved through the three material Centers of Excellence (CoEs) and independent projects. Formal down-select reports were published for the Metal Hydride Center of Excellence (MHCoE)\(^1\) and Chemical Hydrogen Storage Center of Excellence (CHSCoE)\(^2\) in FY 2009. Through FY 2010, approximately 81 distinct materials have been considered experimentally within the MHCoE, and work on about 75% of those has been discontinued, based on criteria developed by the MHCoE—including material reversible capacity, sorption thermodynamics, and kinetics. Through FY 2010, the CHSCoE has evaluated a total of approximately 130 materials and combinations of materials; research on 95% of those has been discontinued, due to issues related to storage capacities, release temperature, kinetics, and spent-fuel regeneration. The Hydrogen Sorption Center of Excellence (HSCoE) has investigated 210 hydrogen sorbent materials through FY 2010; R&D continues on about 20% and has been discontinued on about 80% of these sorbent materials.

In FY 2010, the HSCoE published the Materials Go/No-Go Recommendation Document.\(^3\) The report gives an overview of the research strategies that the center has pursued in developing hydrogen sorbents to meet the DOE technical targets and makes recommendations on which strategies and sorbent material classes DOE should or should not continue to pursue in the future. The objective of the HSCoE has been to develop hydrogen sorbent materials that can store hydrogen at close to ambient temperature and at moderate pressure with the potential to meet the DOE system performance targets. The center’s strategy has included developing high-surface-area sorbents with high volumetric capacity and developing materials with high binding energy to allow closer to ambient temperature adsorption and moderate pressure. The report categorizes the sorbent materials and sorption mechanisms into four classes: physisorbents, substituted/heterogeneous materials, multiple dihydrogen adsorption, and weak chemisorption (spillover). For pure physisorption, the center recommends continued development only on materials exceeding 2,500 m\(^2\)/g with pore sizes between 0.7 and 1.2 nm. For substituted/ heterogeneous materials, they recommend continued development of materials with properly coordinated elements in high-surface-area structures (e.g., uncoordinated metal centers in a framework material). In the area of materials with multiple dihydrogen sorption sites, experimental work is needed to synthesize materials with appropriate structures to validate theoretical predictions. Finally, for weak chemisorption materials, further research is recommended to improve reproducibility of materials synthesis and measurements, hydrogen sorption kinetics, and catalyst integration.

CoE efforts will be completed by the end of FY 2010 as planned. During this last year, much of their efforts are devoted to optimizing key parameters for the promising storage systems as well as generating required data for use by the HSECoE and analysis efforts to develop complete system models for the more promising materials. To capture the research carried out by the three CoEs and independent projects, DOE is establishing a searchable materials database. The database will be populated with material compositions, synthesis methods, measured properties, spent fuel regeneration schemes, and references. Predicted materials and properties from theoretical computational modeling will also be included. The database is expected to be available on the DOE Web site by January 2011.

Three key material properties needed for system models are the materials’ capacity, thermodynamics (e.g., heat of ad/absorption and/or heat of reaction), and sorption kinetics under different temperature and pressure conditions. Significant R&D is needed to modify or “tune” the properties of high-hydrogen-capacity materials toward the required range of operating temperatures and pressures. The optimum scenario is to utilize the waste heat of the powerplant (i.e., fuel cell or internal combustion engine). For example, if hydrogen could be released at acceptable rates at less than 80°C,

---

the waste heat of the fuel cell could be utilized for endothermic desorption—avoiding the need to burn hydrogen to generate the needed temperature.

A useful alternative to depictions of gravimetric and volumetric capacity is to show capacity as a function of temperature. Figure 4 shows the current status of materials development in terms of material-based capacity on a weight basis as a function of release or uptake temperature. The system level requirements for weight and temperature are defined by the dashed lines (greater than 5.5 wt% H₂ for the 2015 target and 0–100°C) to put the material-based capacities in perspective (i.e., ignoring system weight additions). The limitations in temperature are mainly due to thermodynamic properties (e.g., enthalpies or binding energies that are either too high or too low) and kinetics (e.g., hydrogen absorption or release rates are too slow at the required operating temperatures). It should also be noted that there is typically a range of temperatures across which hydrogen is discharged (or charged). The values shown in Figure 4 have been updated for new candidates identified during FY 2010 and will be further modified by DOE as advancements are made in this rapidly progressing field.

This past year the HSECoE made significant strides in developing complete system models for the three material classes and identifying engineering and material property gaps and research needs. In order to determine the impact of storage system performance on vehicle performance, the HSECoE developed the Hydrogen Storage Simulator (HSSIM) as well as a fuel cell power plant model. Preliminary models for metal hydride, chemical hydrogen, and adsorbent systems were also completed. The various models were coupled through a MATLAB/COMSOL/Simulink environment so that effects of changes in one model on the other models could be determined. For the three material classes, parametric models were identified for thermal modeling. Thermal modeling of the material based systems is critical, due to the exothermic/endothermic nature of the hydrogen uptake and release reactions. The center was also able to develop acceptability criteria for the material classes for use in selecting materials with suitable properties in on-board automotive storage systems. To establish a baseline, a well-
characterized material from each class (NaAlH₄, NH₃BH₃ and AX-21) was selected for the initial system modeling to determine current system status versus the DOE performance targets for on-board hydrogen storage. Figure 5 shows a representative spider chart for a metal hydride system. The spider chart clearly indicates areas where there are knowledge gaps (i.e., zero values) as well as engineering and material property deficiencies. For example due to the material's low gravimetric and volumetric capacities, the system is unable to meet the gravimetric and volumetric system targets. Also, due to the combination of the material's intrinsic uptake kinetics and the system's heat transfer properties, the modeled system is unable to meet the refill-time target. The models can therefore be very useful in identifying areas to focus engineering R&D and material properties requiring additional development.

**FIGURE 5.** Spider chart for a representative modeled metal hydride system against the DOE 2010 system performance targets, showing technical and/or knowledge gaps in gravimetric and volumetric densities and cycle life.

**Metal Hydrides**

- Five distinct pathways for forming alane (AlH₃) from hydrogen gas and aluminum powder under relatively mild conditions were developed (Brookhaven National Laboratory).
- An electrocatalytic additive that approximately doubled the rate of electrochemical production of alane was identified (Savannah River National Laboratory [SRNL]).
- An efficient, low-temperature and low-pressure route to rehydrogenate spent LiAlH₄ in dimethyl ether was developed (University of Hawaii, University of New Brunswick).
- Stable, reversible capacity greater than 10 wt% in LiNH₂ was demonstrated through the introduction of nitrogen into the hydrogen phase (University of Nevada, Reno).
- The first example of a “kinetically coupled” destabilized system (LiBH₄/Mg₂NiH₄) with favorable thermodynamics (∆H=15 kJ/mol H₂ and ∆S=62 J/mol H₂) was discovered (HRL Laboratories).
- Additives to increase hydrogen release rates from Mg(BH₄)₂ and 2LiNH₂/MgH₂ were developed and demonstrated (Sandia National Laboratories [SNL]).
- Improved desorption kinetics through metal hydride incorporation into aerogels were demonstrated (United Technologies Research Center, HRL Laboratories, University of Hawaii).
- Partial reversibility of several metal borohydrides under mild conditions was demonstrated (University of Hawaii).
Chemical Hydrogen Storage Materials

- Demonstrated a new ammonia borane (AB) first-fill process with higher purity and yield and completed reactor scale up capable of providing 100-gram batches of high-purity AB to center partners (Pacific Northwest National Laboratory [PNNL]).
- Significant rate enhancements with reduced borazine formation and a high mat-wt% H2-release (up to 11.4%) were achieved with 20 wt% ionic-liquid/AB mixtures at 110°C (University of Pennsylvania).
- High release rates for liquid AB at temperatures as low as 70°C with non-platinum group metal catalysts were demonstrated (Los Alamos National Laboratory [LANL]).
- Impurities and their formation rates were quantified in hydrogen released from AB, which led to demonstration that impurity formation may be mitigated through proper choice of process conditions (LANL, PNNL).
- A one-pot AB spent-fuel regeneration cycle using hydrazine was developed with an overall yield through reduction steps exceeding 90% (LANL).
- The one-pot AB spent-fuel regeneration cycle was demonstrated to work for multiple spent-fuel forms, including spent-fuel from AB in ionic liquids (LANL).
- Costs analyses were performed that indicate the one-pot AB spent-fuel regeneration cycle substantially reduces process costs but may have higher raw material costs than a previous AB spent-fuel regeneration processes (Dow).
- Resource studies were carried out that indicates the U.S. boron supply is adequate to meet boron requirements for AB fuel for projected vehicle market penetration scenarios (US Borax).
- Demonstrated syntheses of endothermic/exothermic cyclo-carbon-boron-nitrogen compounds, pathways for regeneration of spent-fuel, first-fill syntheses, and measured thermodynamic parameters that have corroborated computational studies on these molecules (University of Oregon, University of Alabama).

Hydrogen Sorption Materials

- The HSCoE Materials Go/No-Go Recommendations Report was published with five specific recommendations for continued sorption materials R&D; the report provided tabulated data on 36 specific materials the center has investigated, and research on 26 of these has been discontinued (National Renewable Energy Laboratory [NREL]).
- Boron-substituted carbon materials were synthesized and demonstrated to have increased hydrogen binding energy as a function of coverage (isosteric heats of 9–11 kJ/mol) agreeing with theory predictions (The Pennsylvania State University, University of Missouri, Air Products and Chemicals, Inc., NREL).
- Polyetheretherketone material treated with CO\textsubscript{2} and steam at 900°C was demonstrated to have greater than 5 wt% excess hydrogen adsorption capacity with a binding energy of about 8 kJ/mol at 77 K and 20 bar (Duke University).
- An isoreticular framework material (PCN-68) was synthesized with a Brunauer-Emmett-Teller surface area of 5,109 m\textsuperscript{2}/g and 7.2 wt% excess hydrogen adsorption capacity at 77 K and 50 bar (Texas A&M University).
- Cs and Rb-intercalated graphite with narrow “slit-pore” geometries of 5.3 to 5.8 Å were shown to have nearly constant isosteric heats of adsorption (at low coverage) of 14 and 12 kJ/mole (Caltech).

System Engineering

- Completed programming of HSSIM, which will improve the speed of analyses and enhance the assessment of the tradeoffs involved in the use of different technologies (NREL, Ford, General Motors).
- Coupled vehicle, fuel cell power plant, and on-board storage system models through MATLAB/COMSOL/Simulink environment so that on-board system performance impacts on vehicle...
performance can be readily determined (NREL, Ford, General Motors, United Technologies Research Center, PNNL, SRNL).

- Developed candidate material matrix and acceptability criteria for the three material classes (LANL, United Technologies Research Center, Ford, BASF, General Motors, PNNL, L’Université du Québec à Trois-Rivières, SRNL).
- Developed and demonstrated a novel acoustic fuel gauge sensor for use with hydrides (LANL).
- Developed preliminary complete system models with baseline materials for the three material classes for comparison against DOE performance targets (LANL, PNNL, Jet Propulsion Laboratory, Caltech, L’Université du Québec à Trois-Rivières, General Motors, United Technologies Research Center, SRNL).

Compressed and Cryogenic Tanks

- Demonstrated a third generation cryogenic vessel with verified zero evaporative losses for day dormancy of more than eight days. The conversion of para-$\text{H}_2$ to ortho-$\text{H}_2$ was shown to double the dormancy for a nearly full vessel (Lawrence Livermore National Laboratory).

Testing, Materials Properties, and Analysis Cross-Cutting

- Performed system-level analysis of six hydrogen storage technologies, addressing all aspects of onboard storage targets including capacity, charge/discharge rates, greenhouse-gas emissions, safety, and cost. Technologies analyzed or updated included 350-bar and 700-bar compressed hydrogen, cryo-compressed hydrogen, liquid hydrogen, MOF-177 sorption systems, activated carbon sorption systems, and AB in ionic liquids chemical systems (Argonne National Laboratory [ANL]).
- Conducted independent cost assessments of MOF-177 sorption ($12/kWh), liquid hydrogen ($8/kWh), cryo-compressed hydrogen ($12/kWh), and 350-bar ($13/kWh) and 700-bar ($20/kWh) compressed hydrogen systems, all with 5.6 kg of useable hydrogen (TIAX LLC).
- Evaluated four potential mitigation strategies for hazards associated with flammable hydrogen storage materials; several were found to be promising (SRNL).
- Found polymer matrices to be a potential hazard mitigation strategy for materials-based systems by demonstrating a 70% reduction of heat generation and formation of little to no oxidation products when flowing air through a reactive metal hydride bed encapsulated within polystyrene (SNL).

Budget

The President’s FY 2011 budget request includes $40 million for hydrogen fuel R&D, of which $20 million is planned for hydrogen storage—compared with the FY 2010 congressional appropriation of $32 million for hydrogen storage. The reduction is primarily reflected in the completion of the three materials centers that are ending in FY 2010 in accordance with their five year plan. In FY 2011 the Hydrogen Storage sub-program will continue to focus on hydrogen storage materials discovery, new concepts, and systems analysis, as well as on continued system engineering R&D. The sub-program will also consider hydrogen storage requirements for early market applications and rebalance the portfolio to address near-term and longer-term R&D needs.

**FY 2011 Plans**

The technology portfolio for Hydrogen Storage emphasizes materials R&D to meet system targets for on-board and early market applications. The three Materials CoEs are ending in FY 2010 according to their five-year plans. In FY 2011 detailed reports of the research efforts carried out within the CoEs over their five year lives will be published and the materials data made available through an on-line searchable database. This information will be accessible to researchers, the fuel cell industry, and the general public. With the end of the three Materials CoEs, research and development on advanced hydrogen storage materials with improved material volumetric capacity, hydrogen uptake and discharge kinetics, overall system efficiency, durability, and life cycle cost will continue through independent projects. While a focus on light-duty vehicle applications will continue, increased emphasis will be placed on new materials and novel concepts to meet performance requirements for early market applications. In FY 2011, understanding of the hydrogen storage needs and performance requirements for early market applications will be further developed. Additionally, increased emphasis will be placed on developing lower-cost physical storage technologies that have the potential to meet customer requirements for some vehicle platforms for near-term commercialization. Specifically, the sub-program will coordinate with other efforts (e.g., Vehicle Technologies, Defense Advanced Research Projects Agency, etc.) on development of approaches to produce low-cost carbon fiber for composite cylinders. System engineering and analyses will continue through the HSECoE and ANL. Coordination with basic science efforts, including theory, characterization, and novel concepts, will continue during FY 2011. Coordination with the National Science Foundation and Advanced Research Projects Agency–Energy will also be investigated through activities such as workshops and joint meetings.
Introduction

The DOE Metal Hydride Center of Excellence (MHCoE) comprises 10 universities (Caltech, Georgia Institute of Technology, Stanford, University of Hawaii, University of Illinois-Urbana Champaign, University of Nevada-Reno, University of New Brunswick, University of Pittsburgh, The Ohio State University and the University of Utah), six national laboratories (Brookhaven National Laboratory, Jet Propulsion Laboratory, National Institute of Standards and Technology, Oak Ridge National Laboratory, Sandia National Laboratories, and Savannah River National Laboratory) and two industrial partners (HRL Laboratories, and United Technologies Research Center). SNL is the lead laboratory, providing technical leadership for the Center and a structure to guide the overall technical program and to advise the DOE.

The purpose of the MHCoE is to develop hydrogen storage materials with engineering properties that allow the use of these materials in a way that satisfies the DOE/FreedomCAR Program system requirements for automotive hydrogen storage. The Center is a multidisciplinary and collaborative effort with technical interactions divided into two broad areas: 1) mechanisms and modeling (which provide a theoretically driven basis for pursuing new materials) and 2) materials development (in which new materials are synthesized and characterized). Driving all of this work are the hydrogen storage system specifications outlined by the FreedomCAR Program for 2010 and 2015.

The organization of the MHCoE during the past year is show in Figure 1.

During the past year, the technical work was divided into four project areas. The purpose of the project areas is to organize the MHCoE technical work along appropriate and flexible technical lines. The four areas are summarized below.

Project A (Destabilized Hydrides) is led by Prof. Bruce Clemens, Stanford University. The objective of this project is to controllably modify the thermodynamics of hydrogen sorption reactions in light metal hydrides using hydride destabilization strategies. The technical approach involves altering the thermodynamics of the metal hydride by forming a stable alloy in the dehydrogenated stage. This effectively destabilizes the hydride, thereby reducing the energy...
needed to liberate hydrogen from the material, and reducing the desorption temperature. Project A also aims to enhance kinetics by evaluating nanoengineering approaches to minimize the required hydrogen diffusion distance by decreasing particle size and by incorporating the metal hydride reactants in nano-engineered scaffolds.

Project B (Complex Anionic Materials) is led by Prof. Craig Jensen (UH). The objective is to predict and synthesize highly promising new anionic hydride materials. The technical approach involves using theory and chemical intuition to select promising target complex hydrides. Candidate materials are then synthesized by a variety of techniques, followed by extensive structural and hydrogen sorption characterization. A particular focus the past year has been on borohydride materials.

Project C (Amides/Imides Storage Materials) is led by Prof. Zak Fang of the University of Utah. The objective of Project C is to assess the viability of amides and imides (inorganic materials containing–NH2 and–NH moieties, respectively) for onboard hydrogen storage. The technical approach is to reduce thermal requirements of these materials by alloying, to understand and elucidate the chemical pathways by which these materials release and absorb hydrogen, and to determine the initial engineering issues (thermal cycling) of these materials.

Project D (Alane, AlH3) is headed by Dr. Jim Wegrzyn of BNL. The objective of Project D is to understand the sorption and regeneration properties of AlH3 for hydrogen storage. The technical approach has been to synthesize the various structural forms of AlH3, and characterize the structure and hydrogen sorption properties of these forms. The emphasis the past year has been on regenerating AlH3 from Al, using solution-based and electrochemical methods. Project D also examines the properties and reversibility of LiAlH4.

In addition to these formal “Projects”, a Theory Group (TG), coordinated by Dr. Mark Allendorf (SNL), supports all of the experimental efforts in the Center. The TG makes use of first-principles methods to predict new materials and their thermodynamic properties, and suggests new directions for experimental investigations and interpretation of results. The TG consists of researchers at five institutions: SNL, U. Pitt/GT, UIUC, NIST and UTRC. To make maximum use of the different areas of expertise, joint TG efforts are guided by SNL not only in terms of technical direction, but also to ensure that TG efforts are complementary and have an effective synergy with the experimental efforts.

MHCoE Objectives

Our highest level objective is to:

• Develop new reversible hydrogen storage materials to meet or exceed DOE/FreedomCAR 2010 and 2015 system goals.

Technical Barriers

The MHCoE tackles well-defined technical barriers associated with reversible solid-state hydrogen storage for practical, on-board storage system applications. These barriers are reproduced below from the onboard Hydrogen Storage section of the Multi-Year Research, Development and Demonstration Plan (MYRDDP):

(A) Cost. Low-cost materials and components for hydrogen storage systems are needed, as well as low-cost, high-volume manufacturing methods.

(B) Weight and Volume. Materials and components are needed that allow compact, lightweight, hydrogen storage systems while enabling greater than 300-mile range in all light-duty vehicle platforms. Reducing weight and volume of thermal management components is required.

(C) Efficiency. The energy required to get hydrogen in and out of the material is an issue for reversible solid-state materials. Thermal management for charging and releasing hydrogen from the storage system needs to be optimized to increase overall efficiency.

(D) Durability. Materials and components are needed that allow hydrogen storage systems a lifetime of 1,500 cycles with tolerance to fuel contaminants.

(E) Refueling Time. There is a need to develop hydrogen storage systems for the refueling times of less than three minutes for 5 kg of hydrogen, over the lifetime of the system. Thermal management during refueling is a critical issue that must be addressed.

(G) System Life Cycle Assessments. Assessments of the full lifecycle, costs, efficiency, and environmental impact for hydrogen storage systems are lacking.

Technical Targets Addressed by MHCoE

While all of the targets detailed in the DOE MYRDDP are addressed, our main emphasis has been on the DOE specifications for system specific energy density (2.0 kWh/kg [2010], 3.0 kWh/kg [2015]) and system volumetric energy density (1.5 kWh/L [2010], 2.7 kWh/L [2015]). These targets, in an overall way, drive our “down-select” process for materials. The procedure used to select materials for further study has been documented in following report submitted to DOE:
Selected MHCoE Technical Highlights for Fiscal Year (FY) 2010

During the past year, the MHCoE has published 65 papers (29 of these collaborations between MHCoE partners) in the leading journals of chemistry, physics, materials science and crystallography. In addition, MHCoE scientists delivered 76 talks at national and international meetings and filed five patent applications. MHCoE scientists are professional leaders in the general field of hydrogen interactions with materials.

Selected highlights from the MHCoE technical work over the period March 2009 to June 2010 are presented in the following. We point out that the five-year scheduled lifetime of the MHCoE ends in 2010. Please consult the annual reports from individual MHCoE partners for specific details about technical activities in 2010, and the MHCoE final report which covers the five-year history of the Center.

MHCoE Technical Highlights (March 2009 to June 2010)

1. Five distinct pathways were identified for forming AlH₃ adducts from H₂ + Al, thereby increasing prospects for AlH₃ regeneration. (BNL)
2. An electro-catalytic additive was discovered that increased the rate of electrochemical production of alane. (SRNL)
3. A highly efficient, low-temperature and low-pressure method to regenerate LiAlH₄ from (LiH + Al[Ti]) using dimethyl ether was developed. (UH and UNB)
4. The cycling capacity of LiNH₂ was increased to 10 wt% by introducing 20% nitrogen into the hydrogen gas phase. (UNR)
5. The first example of “kinetic coupling” in the LiBH₄/Mg,NiH₄ destabilized system was discovered. The ΔH (15K J/moleH₂) and ΔS (62 J/moleH₂K) are the lowest reported so far for a reversible system. (HRL)
6. The structure of the important intermediate MgB₁₂H₁₂ in Mg(BH₄)₂ storage reactions was established by neutron vibrational spectroscopy studies. (NIST)
7. The rate of hydrogen release from Mg(BH₄)₂ was dramatically increased by adding TiF₃/ScCl₃. (SNL)
8. The rate of hydrogen absorption kinetics for the 2LiNH₂ + MgH₂ system was increased by introducing KH, confirming prior work by P. Chen. (SNL)
9. The hydrogen desorption kinetics of Ca(BH₄)₂, and to a lesser extent Mg(BH₄)₂, were enhanced by incorporating the metal hydrides into a C-aerogel. (UTRC, UH)
10. Mild conditions (<200°C, <100 atm) have been found for the reversible partial (2.4 wt%) dehydrogenation of Mg(BH₄)₂, which circumvents the unwanted formation of Mg(B₁₂H₁₂). Analogous effects are seen for LiSc(BH₄)₄, NaSc(BH₄)₄, and KSc(BH₄)₄. (SNL)

Special Recognitions & Awards

1. The MHCoE received a DOE Hydrogen Program 2010 “Special Recognition Award,” In Recognition of Outstanding Contributions to the Department of Energy.” This award was made June 8, 2010.

2. DOE Hydrogen Program Research Award was given to Ragaiy Zidan for his Electrochemical Studies of Alane Regeneration. The award was made June 8, 2010.

Acknowledgements

It is our pleasure to acknowledge funding for the MHCoE from the DOE Fuel Cell Technology Program.
Objectives

The objective of this project is to develop a new class of reversible materials that have the potential to meet the DOE 2010 kinetic and system gravimetric storage capacity targets. Current investigations include:

- The study of novel, high hydrogen capacity, borohydrides that can be reversibly dehydrogenated at low temperatures.
- The development of a method for the hydrogenation of Al to alane, AlH3, and/or LiH/Al to LiAlH4 at moderate pressures in non-conventional solvents.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- System Weight and Volume
- Charging/Discharging Rates
- Thermal Management
- Lack of Understanding of Hydrogen Physisorption and Chemisorption
- \( \text{IV.A.1b  Fundamental Studies of Advanced High-Capacity, Reversible Metal Hydrides} \)

Technical Targets

The work on this project is currently exclusively devoted to materials that have demonstrated available hydrogen capacities of 7.9-15 wt% hydrogen. We have developed a system for the full reversible dehydrogenation of Mg(BH4)2 to MgB2 that has shown a record 12 wt% reversible hydrogen capacity, but requires further development to meet kinetic performance targets within the target temperature. We have also developed a highly efficient method of the direct hydrogenation of LiH/Al to Ti-doped LiAlH4 (7.9 wt% hydrogen capacity, rapid dehydrogenation at 120-150°C) at moderate pressure and room temperature that has been estimated to have a well-to-tank (WTT) energy efficiency that approaches 60% and thus meets DOE targets.

Accomplishments

Borohydrides

- Demonstration of the reversible hydrogenation of MgB2 to Mg(BH4)2 with cycling of 12 wt% hydrogen.
- Nano-association of Mg(BH4)2 in a carbon aerogel found to improve dehydrogenation kinetics.
- Mild conditions (<200°C, <100 atm) found for the reversible dehydrogenation of 2.4 wt% hydrogen from Mg(BH4)2 as well as (~2.0 wt%) from LiSc(BH4)4, NaSc(BH4)4, and KSc(BH4)4.

Hydrogenation in Non-Conventional Solvents

- Demonstration of the full recharging of Ti-doped LiAlH4 by the direct hydrogenation of Ti-doped LiH/Al in liquefied dimethyl ether at room temperature under 100 bar of Me2O/H2. Calcautions show that this recharging process approaches 60% WTT efficiency.

Introduction

The development of high capacity hydrogen storage materials that can be recharged under moderate conditions is a key barrier to the realization of a hydrogen economy. Towards this end we have examined anionic transition metal borohydride complexes as hydrogen storage materials. The anionic character of these compounds was found to result in an increased stability and a reduced volatility when
compared to neutral transition metal borohydride complexes. We have found that group I and II salts of anionic transition metal borohydride complexes have several improvements over neutral transition metal borohydrides: including higher (9-13 wt%) hydrogen content, reduced volatility and increase stability. We have also found that the alkali metal salts of anionic transition metal borohydride complexes such LiMn(BH₄)₂ undergo rapid dehydrogenation at moderate (<150°C) temperatures. In some cases, only very minor the amounts of the undesirable, diborane side product are produced. However, we have not found the full dehydrogenation of any of these materials to be reversible. In order to see if the re-hydrogenation can be achieved even at high pressures, we conducted experiments in the range of 900 bar in collaboration with Sandia National Laboratories. Experiments involving the attempted hydrogenation of mixtures of Group I hydrides and transition borides proved unsuccessful. However, hydrogen uptake was found to occur at 400°C and 90 atm in experiments in which MgB₂ was present. Analysis of the product mixtures by X-ray diffraction (XRD) showed that the transition metal component was un-reactive while the MgB₂ was hydrogenated to Mg(BH₄)₂. The hydrogenation also occurred when starting with only ball-milled MgB₂. Our experiments provided the first demonstration of the full reversibility MgB₂ to Mg(BH₄)₂. In consideration of the >14 wt% hydrogen that is potentially cyclable with this system, it has become the chief focus of our efforts in the area of borohydrides.

In collaboration with the University of New Brunswick, we are also developing new approaches utilizing supercritical fluids and non-conventional solvents for the direct synthesis of AlH₃ and LiAlH₄. LiAlH₄ releases 7.9 wt% hydrogen according to the two reactions seen in equations 1 and 2.

$$3 \text{LiAlH}_4 \rightarrow \text{Li}_2\text{AlH}_6 + 2\text{Al} + 3\text{H}_2 \quad (1)$$

$$\text{Li}_2\text{AlH}_6 \rightarrow 3 \text{LiH} + \text{Al} + 1.5\text{H}_2 \quad (2)$$

The second reaction is endothermic ($\Delta H = +25$ kJ/mol H₂) but the first reaction is exothermic ($\Delta H = -10$ kJ/mol H₂). Since entropic change is strongly positive for hydrogen release, the first reaction is thermodynamically irreversible under all practical conditions and it has been widely accepted that LiAlH₄ cannot be recharged and there have been no reports of its use for reversible hydrogen storage. However, the unfavorable thermodynamics of Eq. 1 may be altered by carrying out the reaction in solution, with the solvation of LiAlH₄ contributing to an endothermic $\Delta H$ value. In 1963, Ashby et al. reported that a mixture of LiH and activated Al in tetrahydrofuran (THF) solvent reacted with 350 bar H₂ at 120°C to produce LiAlH₄. While this method results in the ultimate formation of LiAlH₄ from LiH, Al and H₂, it is impractical because of the requirements of high temperature and high pressure during the synthesis as well as subsequent heating for the removal the THF adduct. An improvement in the synthesis of the THF adduct was achieved by researchers at Brookhaven National Laboratory by using Ti additives to significantly lower the required pressure and temperature. However, the prolonged baking in vacuo that is required to remove THF results in the dehydrogenation of the majority of a Ti-activated product. We have discovered that this difficulty can be eliminated by utilizing liquefied dimethyl ether (Me₂O) as the reaction solvent. It is sufficiently coordinating to support the nascent LiAlH₄ in the reaction environment, yet also volatile enough to be removed easily once it has served this purpose. Through this approach, LiAlH₄ can be synthesized at room temperature under moderate pressures of H₂ (80-100 bar) in the presence of very low amounts of Ti catalyst (0.5-0.2 mol%). On completion of reaction, the volatile Me₂O solvent and excess H₂ are vented leaving only fine, dry Ti-doped LiAlH₄ in 95% yield. Thus we have found a highly efficient method for the direct synthesis of LiAlH₄ at low pressure and room temperature. Preliminary analysis conducted at Argonne National Laboratory has indicated that WTT energy efficiency of our regeneration process is great than 60% and thus approaches the DOE targets.

**Approach**

Having demonstrated the reversible elimination of over 11 wt% hydrogen from Mg(BH₄)₂, we wish to develop methods for hydrogen cycling in this system under less forcing conditions. In order to accomplish this, we required a more detailed understanding of the dehydrogenation reaction pathway. Thus we have monitored both the dehydrogenation and re-hydrogenation reactions by XRD and magic angle spinning boron-11 nuclear magnetic resonance spectroscopy (MAS ¹¹B NMR) and conducted quantitative thermal volumetric pressure-composition-temperature measurements. We have also attempted to improve the kinetics and/or thermodynamics of the dehydrogenation of Mg(BH₄)₂ through nano-confinement of the hydride in a carbon aerogel.

Our highly efficient, room temperature direct synthesis of LiAlH₄ in liquefied Me₂O shows great promise as a practical method for the re-hydrogenation of LiH/Al to LiAlH₄. We have found that nearly the entire 7.9 wt% theoretical cycling capacity can be restored in the first cycle of re-hydrogenation. However, the cycling capacity dramatically drops off over the first five cycles of dehydrogenation/re-hydrogenation. In order to overcome this limitation, we have explored the extension of the maximum cycling capacity of Ti-doped LiAlH₄ through variation of the dopant concentration, recharging conditions, and variation dopants.
Results

Task 1. Characterization of the Active Titanium Species in Ti Doped NaAlH\textsubscript{4}

This task has been completed.

Task 2. Spectroscopic Studies of Complex Hydrides

This task has been completed.

Task 3. Thermodynamic Properties of Complex Hydrides

This task has been completed.

Task 4. Kinetic Enhancement of “Thermodynamically Tuned” Binary Hydrides

We have merged the Task 4 and 5 efforts and examined whether, as we found for MgH\textsubscript{2}, the kinetics of the dehydrogenation of Mg(BH\textsubscript{4})\textsubscript{2} could be improved through nano-confinement. Following the exposure of the aerogel to the molten diethyl ether adduct of Mg(BH\textsubscript{4})\textsubscript{2}, the coordinated diethyl ether was removed by heating at 220°C en vacuo for 3 h. Mg(BH\textsubscript{4})\textsubscript{2} loadings of the aerogel 57–63 wt\% were achieved by this method. Figure 1, provides a comparison of the XRD patterns of the Mg(BH\textsubscript{4})\textsubscript{2} loaded aerogel with those observed for Mg(BH\textsubscript{4})\textsubscript{2} powder that was scraped from the surface of the aerogel. The diffraction peaks of the Mg(BH\textsubscript{4})\textsubscript{2} associated with the aerogel are clearly seen to be broader and much smaller. This indicates that the Mg(BH\textsubscript{4})\textsubscript{2} associated with the aerogel has nano dimensions. As seen in Figure 2, the 11B NMR spectrum of the Mg(BH\textsubscript{4})\textsubscript{2} incorporated aerogel contains only a single peak at the chemical shift of -41.5 ppm, thus verifying that Mg(BH\textsubscript{4})\textsubscript{2} is the only boron containing species present in the material. The nano-Mg(BH\textsubscript{4})\textsubscript{2} showed good kinetics during the first dehydrogenation. As seen in Figure 3, 2.7 wt\% H\textsubscript{2} was eliminated at 270°C in ca. 30 min. Overall, 4.94 wt\% H\textsubscript{2} was evolved as the temperature was increased to 400°C. Re-hydrogenation was carried out under 11-15 MPa of H\textsubscript{2} at 500°C for 10 h. The observation of a much slower rate for the second cycle of dehydrogenation strongly suggests that the nano-Mg(BH\textsubscript{4})\textsubscript{2} was not incorporated into the pores of the aerogel and was just associated with its surface.

Task 5. Synthesis and Evaluation of Novel Borohydrides

In order to confirm the uptake of over 11 wt\% hydrogen occurs in the high pressure hydrogenation of MgB\textsubscript{2}, the dehydrogenation of a sample of the Mg(BH\textsubscript{4})\textsubscript{2} product was monitored using an automated thermal volumetric analyzer (Sievert’s type apparatus). The dehydrogenation profile (seen in Figure 4) shows the release of 11.4 wt\% hydrogen. Longer reaction times would quite likely result in higher levels of hydrogenation MgB\textsubscript{2} and thus cycling of 14 wt\% hydrogen.

![FIGURE 2. MAS 11B NMR spectrum of carbon aerogel associated nano-Mg(BH\textsubscript{4})\textsubscript{2}.](image)

![FIGURE 3. First dehydrogenation of carbon aerogel associated nano-Mg(BH\textsubscript{4})\textsubscript{2}.](image)
B NMR studies of the dehydrogenation of Mg(BH$_4$)$_2$ have revealed that the dehydrogenation process involves multiple steps. We have found that the early steps do not require heating above 250°C and result in the release of 2.4 wt% hydrogen. The products of the dehydrogenation at this lower temperature have not yet been fully characterized. However, it is clear at that, in contrast to the large mixture of boranes that results upon high temperature dehydrogenation, the products resulting from the low temperature dehydrogenation of only MgH$_2$ and a single borane species. We have found that this species can be cleanly hydrogenated back to Mg(BH$_4$)$_2$ at 200°C under 100 atm of hydrogen. This represents a major step towards practically from the extreme (400°C and 900 atm) conditions under which we initially achieved re-hydrogenation of Mg(BH$_4$)$_2$.

The molecular structure of KSc(BH$_4$)$_4$ (seen in Figure 5) was determined as part of our continuing collaboration with the University of Geneva. We have now determined the crystal structures of the Li, Na, and K salts of [Sc(BH$_4$)$_4$]$^{1-}$. We have found that heating LiSc(BH$_4$)$_4$, NaSc(BH$_4$)$_4$, and KSc(BH$_4$)$_4$ to 250°C also results the elimination of significant amounts of hydrogen (2.4, 2.1, and 1.8 wt%, respectively) and give rise to a product mixture that can be re-hydrogenated to the starting borohydride at 200°C under 100 atm of hydrogen.

**Task 6. Recharging of Light Metal Hydrides in Non-Conventional Media**

Cycle performance experiments were carried out for the LiAlH$_4$ material doped with 0.05 mol% TiCl$_3$. The initial dehydrogenation of this material was seen to release 7.9 wt% hydrogen. Following the first re-hydrogenation in liquid dimethyl ether, the dehydrogenation half cycle was again found to release 7.9 wt% hydrogen. However, this value dropped to 5.9 and 4.1 wt% H in the third and fourth dehydrogenation half cycles, respectively. In an attempt to stabilize the cycling hydrogen capacity, we investigated the effect of the substitution of TiCl$_3$ with other dopants (e.g. ScCl$_3$ and CeCl$_3$). Our results indicate that the catalytic performance of ScCl$_3$ supersedes that of CeCl$_3$, but does not reach that of TiCl$_3$. We also explored whether the use of TiCl$_3$ supported on alumina (Al$_2$O$_3$), would enhance hydrogen cycling performance. As seen in Figure 6, the Ti-supported catalysts were consistently found to lower the H$_2$ desorption temperature of the hydride to ~125°C (opposed to 180°C for the undoped LiAlH$_4$). However, after dehydrogenation and subsequent re-hydrogenation, the hydrogen capacity dropped to 4.0 and 0.0 wt% in the second and third cycle respectively. Analysis of the sample after the third cycle dehydrogenation by transmission electron microscopy (TEM)/energy dispersive X-ray (EDX) showed that Ti was not uniformly distributed; there were areas where no Ti was detected (Figure 7). It is possible that Ti falls off the support upon cycling thereby reducing its effectiveness as a catalyst.

**Conclusions**

Our continuing studies of Mg(BH$_4$)$_2$ have confirmed the uptake of over 11 wt% hydrogen occurs in the...
high pressure hydrogenation $\text{MgB}_2$ to Mg($\text{BH}_4$)$_2$ and indicate that an optimized system might allow cycling of $>14$ wt% hydrogen. Our attempts to lower the temperature required for the hydrogen cycling in the Mg($\text{BH}_4$)$_2$/MgB$_2$ system through catalytic enhancement and nano-confinement of the hydride did not prove successful. However, nano-Mg($\text{BH}_4$)$_2$ was found to exhibit dehydrogenation kinetics that were significantly enhanced beyond those of bulk Mg($\text{BH}_4$)$_2$.

$^{11}$B NMR studies of the dehydrogenation of Mg($\text{BH}_4$)$_2$ at 250°C results in the release of 2.4 wt% hydrogen. The products that are obtained from the low temperature dehydrogenation can be cleanly hydrogenated back to Mg($\text{BH}_4$)$_2$ at 200°C under 100 atm of hydrogen. Dehydrogenation of LiSc($\text{BH}_4$)$_2$, NaSc($\text{BH}_4$)$_2$, and KSc($\text{BH}_4$)$_2$ under similar conditions also results the elimination of significant amounts of hydrogen (2.4, 2.1, and 1.8 wt%, respectively) and give rise to product mixtures that can be re-hydrogenated to the starting borohydride at 200°C under 100 atm of hydrogen. Thus earlier studies of the dehydrogenation anionic transition metal borohydrides under more forcing conditions were premature in concluding that this family of hydrides are “irreversible.”

We have developed a method whereby 95% yields of fully charged, Ti-doped LiAlH$_4$ are obtained from the direct hydrogenation of Ti-doped LiH/Al in liquefied Me$_2$O. Although the method is highly efficient method for the re-hydrogenation of LiAlH$_4$, cycling studies have shown the system’s hydrogen capacity dramatically drops off over the first five cycles of dehydrogenation/re-hydrogenation. Attempts to remedy this problem through substitution of TiCl$_3$ other dopants (e.g. ScCl$_3$ and CeCl$_3$) and TiCl$_3$ supported on alumina (Al$_2$O$_3$) have not proven successful.

**Future Directions**

**Borohydrides**
- Adjustment of conditions to maximize trade off between cycling capacity and reaction conditions (temperature/pressures) required for reversible dehydrogenation of Mg($\text{BH}_4$)$_2$, LiSc($\text{BH}_4$)$_2$, NaSc($\text{BH}_4$)$_2$, and KSc($\text{BH}_4$)$_2$.

**Hydrogenation in Non-conventional Solvents**
- Explore maintenance of cycling capacity of doped LiAlH$_4$ through variation of the dopants.
- Further evaluation of WTT efficiency of the dimethoxyethane/LiAlH$_4$ system to be examined in collaboration with Argonne National Laboratory.

Objectives

- Develop a high-capacity lightweight hydride for reversible vehicular hydrogen storage, capable of meeting or exceeding the 2010 DOE/FreedomCAR targets.
- Synthesize and study aluminoborane compounds and other lightweight, high-capacity boron hydrides for hydrogen storage.
- Perform detailed characterization of the decomposition mechanisms, desorbed gaseous species and structures of the synthesized compounds.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan:

(D) Durability/Operability

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

(E) Charging/Discharging Rates

(J) Thermal Management

Introduction

The DOE defines on-board hydrogen storage for mobile vehicles as a “Grand Challenge”. It is one of...
the biggest hurdles to the implementation of hydrogen-powered vehicles. Metal hydrides have the advantages of the highest volumetric density, relatively low working pressure, and reasonable working temperature range. The disadvantage of current reversible hydrides is a significant weight penalty. Metal borohydrides have among the highest gravimetric hydrogen storage capacities with the potential to meet the DOE gravimetric density targets and to offset the system weight penalties. However, desorption temperature, reversibility and diborane formation during desorption are challenging issues for these materials. This project attempts to develop a high-capacity lightweight hydride for reversible vehicular hydrogen storage, capable of meeting or exceeding the 2010 DOE/FreedomCAR targets.

**Approach**

- Explore aluminoborane compounds such as AlB$_4$H$_{11}$ and other high-capacity, lightweight boron hydrides.
- Study the crystal structures and the decomposition mechanisms using multiple techniques such as interrupted PCT tests, NMR, infrared (IR), DSC, and residual gas analysis.
- Develop reversibility strategy from detailed mechanistic understanding of the complex desorption processes (such understanding is crucial for reversibility of all borohydrides).
- Synthesize new hydrides and complexes in collaboration with Oak Ridge National Laboratory (ORNL), SNL, and National Institute of Standards and Technology (NIST).

**Results**

Aluminoboranes AlB$_4$H$_{11}$, AlB$_5$H$_{12}$, and AlB$_6$H$_{13}$ were reported by Himpsl and Bond in 1981 [1], but these compounds have eluded the attention of the worldwide hydrogen storage research community for more than a quarter of a century. They have very attractive properties for hydrogen storage: high hydrogen capacity (i.e., 13.5, 12.9, and 12.4 wt% H, respectively) and attractive hydrogen desorption temperature (i.e., AlB$_4$H$_{11}$ decomposes at ~125°C). In collaboration with ORNL, the Jet Propulsion Laboratory (JPL) and the California Institute of Technology (Caltech), we synthesized and studied AlB$_4$H$_{11}$ for hydrogen storage. AlB$_4$H$_{11}$ is an amorphous white solid that starts to release hydrogen around 125°C as demonstrated by both thermogravimetric analysis (TGA) and PCT tests. Mass spectroscopy analysis showed relatively clean desorption with a small amount of diborane (<1 mole%) [2]. A TiCl$_3$ catalyzed AlB$_4$H$_{11}$ desorbed 6.5 wt% H when it was heated to 220°C under 0.1 bar hydrogen pressure during a PCT test. The desorbed residue remained as amorphous. Re-hydrogenation was performed at 200°C, 100 bar hydrogen for the first run and 97 bar of hydrogen for the second run. About 2.5% hydrogen was re-absorbed each time based on the hydrogen pressure drop during the re-hydrogenation PCT tests (Figure 1). The observed reversibility (hydrogen absorption) during PCT tests was further confirmed by both IR and NMR analysis which both showed that signals associated with AlB$_4$H$_{11}$ re-appeared after the re-hydrogenation runs. The results clearly show that AlB$_4$H$_{11}$ is one of the very few boron-containing materials which show reversibility at mild conditions. DSC measurements also show that AlB$_4$H$_{11}$ dehydrogenates around 125°C with a broad endothermic peak, thus it is thermodynamically reversible (Figure 2). All these results together clearly show that is a very attractive candidate for reversible hydrogen storage. The key is to increase the reversibility weight% and improve both hydrogenation and rehydrogenation kinetics.
Based on the AlB₄H₁₁ synthesis experience, we explored the syntheses of other aluminoborane compounds such as AlB₆H₁₄ and AlB₁₀H₁₄ at OSU. Their syntheses require the both B₄H₄ and B₂H₆ as the starting materials – both are tedious to make. Tetraborane (B₄H₁₀) was prepared by a solid-liquid reaction of KB₄H₄ with BCl₃ at -78°C for 90 min followed by stirring at room temperature for 20 min according to the procedure reported by Hill et al. [3]. KB₄H₄ was prepared by the reduction of BH₃tetrahydrofuran (THF) with K-Hg amalgam. KB₄H₄ was washed with CH₂Cl₂ several times and recrystallized from THF solvent to remove all the impurities. A number of trials showed that it is very difficult to obtain pure B₂H₆ by this method. Inconsistent stirring (due to the high viscosity) was the main issue in this reaction which never proceeded to the completion. Apparatus and special methods were designed and reaction conditions were optimized to try to obtain pure tetraborane; but a small amount of BCl₃ impurity was always found in the end product. Since the boiling points of BCl₃ and B₂H₆ are very close, it’s very hard to separate them. The BCl₃ impurity affects the synthesis of AlB₆H₁₄ considerably by reacting with Al(BH₄)₃ to produce -BHCl₂ species. Hence this procedure cannot be used to synthesize pure B₂H₆ by this method. Another method involved a reaction between [N(n-But)₄][B₃H₈] and liquid BBr₃ at 0°C for 1h. This is an efficient method as it was easy to separate tetraborane from other products and the yield was 60%. KB₄H₄ was converted to a corresponding tetrabutyl ammonium compound by reacting with tetrabutyl ammonium bromide in THF. The tetraborane was then reacted with Al(BH₄)₃ in a benzene solution that was stirred for 67 h. The solution was then turned to a viscous liquid which was further heated to 100°C for 27 h to obtain an insoluble pale yellow color solid. Solvent was evaporated under dynamic vacuum for overnight to obtain AlB₄H₁₁. The product was characterized by XRD, IR and DSC. The XRD pattern revealed that it was an amorphous material (polymeric) similar to the literature result. The IR spectrum and DSC profiles closely resemble to those of AlB₄H₁₁. Detailed analysis is in progress.

OSU (Prof. Sheldon Shore) has some decaborane (B₁₀H₂₀) (probably the only source in the world). We explored its reaction with Al(BH₄)₃ to see whether the aluminoborane compounds can be extended beyond the Himpsl-Bond compounds (AlB₄H₁₁, AlB₆H₁₂ and AlB₁₀H₁₄). Decaborane has four bridging hydrogens compared to two for diboran. Reaction of Al(BH₄)₃ with decaborane (B₁₀H₂₀) was tried in 1:2, 2:1 and 4:1 mole ratios respectively. The 1:2 reaction gave a yellow solid but the 2:1 and 4:1 gave pale yellow solids with high yields (>80%). To confirm that the solids contain both Al and boron species, the solids were hydrolyzed and solution ¹¹B NMR and ²⁷Al NMR indicated the elemental presence. Elemental analysis of the product of the first reaction indicated that the Al:B ratio is 1:8 and there is 40% of carbon incorporated in the solid, which comes from the benzene solvent (¹¹H-MAS NMR indicated a peak at 7 ppm corresponding to benzene-type species). IR analysis indicated that the bridge hydrogens of the decaborane disappeared completely and a broad B-H peak emerged. ¹¹B MAS NMR of the solid showed a broad peak from 20 to -45 ppm that is centered at -15 ppm. ²⁷Al MAS NMR shows two Al peaks at 80 and 35 ppm. As the amount of Al(BH₄)₃ increased, more IR peaks corresponding to those observed in AlB₄H₁₁ become more evident in the 2:1 and 4:1 ratio reactions. Elemental analysis and solid state NMR characterization of the solids obtained from the 2:1 and 4:1 reactions are underway. Our results show that this family of aluminoborane compounds has a broad chemistry base and all of them form amorphous solids, which is very encouraging news.

The boron-cage compound (NH₄)₂B₁₀H₁₀ contains 11 wt% hydrogen and it is a crystalline compound. TGA measurements show that its desorption started ~190°C and ~9% weight loss was observed up to 400°C. PCT study showed a desorption of 8 wt% H at 400°C which is in reasonable agreement with the TGA result. Simultaneous thermogravimetric modulated beam mass spectrometer (STMBMS) analysis performed at SNL showed a small amount of ammonia release at temperatures between ~200°C and 280°C while H₂ release was observed from ~200°C all the way up to 1,000°C. No diborane was observed during the STMBMS analysis. STMBMS results show that the ratio of hydrogen to ammonia gas depends on the orifice size and the percentage of hydrogen in the gas mixture increases with the orifice size. At 35 mm orifice confinement, the ammonia in the desorbed H₂ gas from (NH₄)₂B₁₀H₁₀ was 3.3 mole% (Figure 3). Rehydrogenation of 1.8 wt% was observed at a mild condition (240°C and 93 bar hydrogen pressure) even without any catalyst. The ammonia formation needs to be addressed. The reversibility at mild conditions is very attractive, but the total amount of hydrogen released before the cage collapsing is relatively low.

(NH₄)₂B₁₀H₁₀ is another boron-cage compound we studied for potential hydrogen storage. STMBMS analysis also showed a small amount of ammonia release at temperatures between ~200°C and 560°C. Its behavior is very similar to that of (NH₄)₂B₁₀H₁₀. STMBMS
analysis showed both hydrogen and ammonia release at 200-365°C and pure H₂ at higher temperatures (Figure 4). No diborane was observed. Again the ratio of hydrogen to ammonia gas depends on the orifice size and the percentage of hydrogen in the gas mixture increases with the orifice size. At 35 mm orifice confinement, the ammonia in the desorbed H₂ gas from (NH₄)₂B₁₀H₁₂ was 0.9 mole%. The DSC curve (Figure 5) clearly shows endothermic desorption for the first step which can potentially be reversible based on thermodynamics. Similar to (NH₄)B₁₀H₁₈, the ammonia formation needs to be addressed and the total amount of hydrogen released before the cage collapsing is relatively low.

Non-cage boron compounds such as MₓB₃H₈ may be less stable and easier for dehydrogenation and rehydrogenation. To explore this class of compound, we have developed a safe and convenient method for the synthesis of the starting material, NaB₃H₈ (Figure 6). Using this compound, we have also developed a convenient and safe method for the synthesis of ammonium octahydrotriborate (NH₄B₃H₈) which has an very high H content (20 wt%). We were able to identify its crystal structure for the first time for both NaB₃H₈ and NH₄B₃H₈. More characterization is in progress. These compounds can potentially serve as both metal hydrides and chemical hydrides.

To synthesize more boron-containing lightweight hydrides for hydrogen storage, we need to synthesize starting materials such as B₉H₁₆, B₁₀H₁₉, and NaB₃H₈. One of the very active chemical reagents is aminodiborane (NH₂B₂H₅) that can be used to synthesize many compounds. It was first found serendipitously and then prepared through a tedious procedure using diborane gas at -130°C with a low yield in 1,938 [4,5]. Except for its structure determination, no further studies of its reactions or properties have been reported in the past 70 years, mostly due to its

![Figure 3](image3.png) **FIGURE 3.** STMBMS gas evolution rate of (NH₄)₂B₁₀H₁₂ showing hydrogen release in two steps and small amount of ammonia release associated with the first step.

![Figure 4](image4.png) **FIGURE 4.** STMBMS gas evolution rate of (NH₄)₂B₁₂H₁₂ showing hydrogen release in two steps and small amount of ammonia release associated with the first step.

![Figure 5](image5.png) **FIGURE 5.** DSC curve of (NH₄)₂B₁₂H₁₂ showing endothermic desorption which is essential for reversibility.

![Figure 6](image6.png) **FIGURE 6.** Crystal Structure of Unsolvated NaB₃H₈ (Na: violet, B: pink, H: grey)
unavailability. We recently developed a practical synthesis of aminodiborane using a new ambient temperature, catalyst-free reaction between ammonia borane and tetrahydrofuran borane [6]. The facile synthesis of aminodiborane will make this long-sought active chemical reagent readily available for both inorganic and organic syntheses. From aminodiborane, we synthesized an inorganic butane analogue NH₄BH₄-NH₃BH₃, which is a potential hydrogen storage material with 16.9 wt% hydrogen. It has been predicted as an intermediate during thermal decomposition of NH₃BH₃ [7,8]. Thus, its properties are relevant to NH₃BH₃ studies as well as hydrogen storage research. This compound is a white solid at room temperature with a melting point of 62°C. Further study of its properties is in progress.

Conclusions and Future Directions

The OSU hydrogen storage materials research team has synthesized and tested several new compounds for hydrogen storage. This was made possible by the availability of several vacuum wet-chemistry synthesis lines in Prof. Sheldon Shore’s laboratory, a group of dedicated researchers, the unique boron chemistry expertise and inorganic chemistry expertise in the group (especially single crystal structure identification expertise and NMR and IR expertise), and a dedicated hydride testing facility established in Dr. J.-C. Zhao’s laboratory. Close collaboration with ORNL, JPL, Caltech, and NIST made possible effective synthesis and characterization of these compounds.

The materials we are synthesizing and studying include AlB₆H₁₁, AlB₄H₁₄, (NH₄)₂B₆H₁₃, (NH₄)₂B₃H₁₀, Na₃B₄H₆, NH₃B₄H₉, NH₂B₃H₅, NH₄BH₃NH₂BH₃, and new aluminoborane compounds made with B₂H₆. A few of these compounds showed endothermic desorption at low temperatures, thus they are good candidates for further study as potential reversible hydrogen storage materials. We have observed reversibility at mild conditions for AlB₆H₁₁, which is very remarkable for a compound containing only Al, B and H.

We will perform more detailed study of these compounds for hydrogen storage in collaboration with ORNL, JPL/Caltech, Sandia, and NIST. Several compounds have been sent to ORNL, NIST, Sandia, and Ford for various analyses and testing. We will focus on more promising candidates as the properties of these compounds are tested.

FY 2010 Publications/Presentations

References

Objectives

- Discover and develop new materials with potential to meet the DOE 2010 targets for system weight percent and charge/discharge rates.
- Theoretically predict and synthesize new materials that release hydrogen with favorable thermodynamics.
- Screen catalysts and additives for their efficacy in improving the kinetic performance of metal hydrides.
- Provide theoretical understanding on metal hydride kinetic and regeneration problems.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(C) Efficiency
(E) Charge/Discharging Rates
(J) Thermal Management

Technical Targets

Work is progressing on improving the reversibility of metal hydrides, predicting and synthesizing new materials with high hydrogen capacity and promising thermodynamics and kinetics properties, and understanding metal hydride regeneration issues. The targets being addressed include:

- System Gravimetric Capacity: 0.06 kgH₂/kg system
- System Volumetric Capacity: 0.045 kgH₂/L system
- Fill Time (for 5 kg): 5 minutes

Accomplishments

Our major accomplishments in Fiscal Year (FY) 2010 are summarized below:

- Performed multi-phase equilibrium theoretical studies on LiBH₄, Mg(BH₄)₂ and 2LiBH₄ + MgH₂. Found that Li₂B₁₂H₁₂ and MgB₁₂H₁₂ species play important roles during decomposition. Revealed a pressure-dependent mechanism governing the reaction pathways of 2LiBH₄ + MgH₂.
- Predicted that the decomposition of LiBH₄, Mg(BH₄)₂ and 2LiBH₄ + MgH₂ is accompanied by low levels of gas-phase impurities. In contrast, 2LiNH₂ + C, LiBH₄ + C, and Mg(BH₄)₂ + C are associated with large levels of impurities because of the strong thermodynamic stability of CH₄ and other hydrocarbons.
- Completed comprehensive prototype electrostatic ground state (PEGS) predictions of Ti(BH₄)₅, M[PB₂H₈]ₓ for M = Li, Na, K, Mg, Ca; x=1, 2.
- Confirmed remarkable catalysis of 2LiNH₂/MgH₂ by KH and KNH₂. Demonstrated that in the presence of catalysts, the absorption is >90% complete within minutes at 200°C.
- Improved the desorption kinetics of Mg(BH₄)₂ using various additives. Found that in the presence of 4 mol% TiF₅/ScCl₃, 9.6% H₂ is released at 300°C in several hours.
- Observed low-temperature (<100°C) hydrogen evolution from Ti(BH₄)₅. However, the material was down-selected (removed from further study) due to irreversible hydrogen release.
- Developed a destabilization approach for releasing H₂ from [B₁₂H₁₂]²⁻ compounds at lower temperatures, confirming prior Metal Hydride Center of Excellence (MHCoE) theory.
- Experimentally demonstrated almost complete conversion of Li₃B₁₂H₁₆ and Na₃B₁₂H₁₂ to LiBH₄ and NaBH₄ in the presence of corresponding hydrides at high H₂ pressures.
• Successfully synthesized and studied hydrogen storage characteristics of several alkali and alkaline-earth bis(borano)hypophosphites of general formula \( M[PB_2H_8]_x \). \( Na[PH_2(BH_3)_2] \) was removed from further study due to formation of \( PH_3 \) and \( B_2H_6 \), along with \( H_2 \).

• Using simultaneous thermogravimetric modulated beam mass spectrometry (STMBMS) detected significant amounts of ammonia during the decomposition of \( M'M''(BH_4)_x \cdot yNH_3 \) and \( M'M''(BH_4)_x(NH_2)_y \) (\( M' \) and \( M'' = Li, Na, Ca and/or Mg \)). Found that small amounts of added \( LiH \) and \( MgH_2 \) significantly decrease the amounts of ammonia released.

**Introduction**

There are currently no materials that fully meet the DOE hydrogen storage performance targets. In order to address this problem, we at SNL have undertaken the prediction, synthesis and characterization of new high-hydrogen content complex metal hydrides for use as reversible hydrogen sorption materials. Also, we have further modified these hydrides through catalyst doping and cation substitution in order to improve their reversibility and sorption properties. Computational modeling has assisted in guiding these efforts, as well as understanding kinetic and regeneration issues for metal hydrides. In addition, we provide technical leadership and collaborate extensively with our partners in the MHCoE.

**Approach**

We are using an integrated theory/experiment approach to tackle the most challenging aspects of hydrogen storage in metal hydrides. Theoretical calculations are used to guide the search for better materials by (i) identifying promising metal hydrides, (ii) predicting their stability and crystal structure and (iii) estimating the thermodynamics of hydrogen release. We use both solid-state and solution techniques to make promising metal hydrides predicted by theory. The new materials are characterized by various traditional spectroscopic and diffraction techniques, including Fourier transform infrared (FTIR), Raman, nuclear magnetic resonance (NMR), mass-spectrometry, X-ray and neutron diffraction. The kinetics of hydrogen release are investigated using residual gas analysis (RGA), thermal gravimetric analysis (TGA), differential scanning calorimetry (DSC), Sieverts and pressure-concentration-temperature measurements.

**Results**

**Borohydrides**

During the current fiscal year our major focus has been on exploring the hydrogen sorption properties of magnesium borohydride and several transition metal borohydrides. We isolated the low-temperature \( Mg(BH_4)_2 \) phase and found that upon desorption in vacuum up to 7.8 wt\% \( H_2 \) is released. In the presence of a complex \( TiF_3/ScCl_3 \) additive, the amount of \( H_2 \) released increases to 9.6 wt\%. The doped \( Mg(BH_4)_2 \) sample also shows dramatic enhancement in the kinetics of hydrogen release compared to milled \( Mg(BH_4)_2 \), as shown in Figure 1.

The decomposition of \( Mg(BH_4)_2 \) to \( MgH_2 \) can be represented as the first step (I) of the multi-step process (I–III):

\[
\begin{align*}
6Mg(BH_4)_2 & \rightarrow 5MgH_2 + MgB_12H_{12} + 13H_2 \\
5MgH_2 & \rightarrow 5Mg + 5H_2 \\
5Mg + MgB_12H_{12} & \rightarrow 6MgB_2 + 6H_2
\end{align*}
\]

With \( TiF_3/ScCl_3 \) additives, there is X-ray diffraction (XRD) evidence for the presence of \( Mg \) and \( MgF_2 \) in addition to \( MgH_2 \). The presence of \( MgH_2 \) and \( Mg \) indicates that both reactions (I) and (II) are occurring to some extent. \( MgF_2 \) implies partial reaction of \( TiF_3 \) with \( Mg(BH_4)_2 \), possibly forming \( Ti \)-containing borohydride species which can then readily decompose to release hydrogen. However, the \( TiB_2 \) species were not observed in our study. We confirmed significant conversion of \( MgB_2 \) to fully hydrogenated \( Mg(BH_4)_2 \) for samples with and without additives.

We continued our efforts towards the understanding the role of dodecahydro-closo-dodecaborates in dehydriding/rehydriding reactions of metal borohydrides. In collaboration with our colleagues at the National Institute of Standards and Technology, we reported the structural aspects of the \( M_2B_{12}H_{12} \) series

**FIGURE 1.** Hydrogen Desorption from Doped and Undoped \( Mg(BH_4)_2 \)
(M=alkali metal). We also confirmed the MHCoE Theory Group prediction that MB₁₂H₁₂ compounds (M=Mg, Ca) can be destabilized in the presence of the corresponding metal hydrides. However, attempts to hydrogenate mixtures of CaB₁₂H₁₂ and CaH₂ into Ca(BH₄)₂ at 550-500°C and hydrogen pressures up to 900 bar were unsuccessful. Interestingly, under the same conditions both LiB₁₂H₁₂ and NaB₁₂H₁₂ react with the corresponding metal hydrides to form LiBH₄ and NaBH₄.

Stabilization of transition metal borohydrides through addition of alkali metal atoms has been explored both computationally and experimentally. Theory results for Li₅Ti(BH₄)₃ and Na₅Ti(BH₄)₃ indicate the compounds are unstable with respect to decomposition into LiBH₄, or NaBH₄, respectively. Although decomposition of pure titanium borohydride is calculated to occur spontaneously, in agreement with the observation of rapid decomposition at room temperature, it may be possible to stabilize the compound by incorporation within high surface area nano-frameworks.

Zak Fang in the MHCoE (University of Utah) recently reported up to 5 wt% H capacity at 90°C in the 3LiBH₄-TiF₃ system. We explored various molar ratios in the LiBH₄-TiF₃ and NaBH₄-TiF₃ systems. However, we found no indication that mixed Li-Ti-BH₄ or Na-Ti-BH₄ phases form, which is in agreement with theoretical predictions. We used various ball-milling techniques and found that high-energy milling at room temperature is not appropriate as a synthetic technique for mixed borohydride species in these systems, presumably due to facile decomposition of the in situ-formed Ti(BH₄)₃. Temperature-programmed desorption (TPD) studies of the LiBH₄-TiF₃ and NaBH₄-TiF₃ composites show that most of the H₂ is released at temperatures between 20 and 175°C. However, at 175°C the hydrogen uptake of the dehydrogenated LiBH₄-TiF₃ and NaBH₄-TiF₃ materials is below 1 wt%. Thus, neither of the two is suitable for reversible hydrogen storage applications.

An alternative approach to decrease the desorption temperatures of main group metal borohydrides is through “hydridic-protic” interactions in the presence of ammonia or metal amides. This FY we explored several mixed borohydride-ammonia and borohydride-amide compounds, M'M''(BH₄)ₓ(NH₃)y and M'M''(BH₄)ₓ(NH₂)y (where M' and M''= Li, Na, Ca and/or Mg). We isolated Mg(BH₄)ₓ(NH₃)y and confirmed prior MHCoE results that the major gaseous product of the reaction is hydrogen. Rehydrogenation attempts on the products of desorption of Mg(BH₄)ₓ(NH₃)y and MgCa(BH₄)ₓ(NH₂)y were performed at 90 MPa H₂ pressure and 350°C. The XRD investigation of the samples after rehydrogenation showed that the starting materials do not form under these conditions. However, our TPD measurements indicate that the rehydrogenated products release 3.5 (Mg-system) and 2.8 wt% H (Mg-Ca system) upon heating from room temperature to 350°C, suggesting partial reversibility in both systems. Another problem with the ammonia adducts is the contamination of hydrogen with impurity NH₃ gas. In an attempt to decrease the amount of ammonia released from the initial borohydride-ammonia materials, we isolated Mn(BH₄)ₓ and reacted the material with gaseous NH₃. Transition metals are known to display high affinity towards amine ligands. We found that the as-synthesized Mn(BH₄)ₓ sample can absorb two or more moles of ammonia at room temperature; however most of the NH₃ is released upon heating the adduct above 120°C.

In the area of mixed borohydride-amide materials we investigated several compositions in the M'M''(BH₄)ₓ(NH₂)y systems (where M' and M''= Li, Na, Ca or Mg). We focused only on the systems where new phases are formed during the ball-milling process. We explored various molar ratios of the binaries in several lightweight borohydride-amide materials. Powder XRD data revealed that the ball-milling of these binary and ternary precursors resulted in the formation of a series of related M'-B-N-H (M'= Li, Na and/or Ca) phases. All tested binary borohydride-amide phases release a significant amount of ammonia upon heating, typically starting at temperatures <100°C. Significant mass losses were found by TGA/differential scanning calorimetry (DSC) in the LiBH₄-Mg(NH₂)y and Mg(BH₄)ₓ-LiNH₂ systems, which indicates to significant impurity gas formation. In contrast, Ca(BH₄)ₓ-LiNH₂ and Ca(BH₄)ₓ- NaNH₂ decompose to produce H₂ as the major product of the reaction. Ca(BH₄)ₓ-LiNH₂ system is more promising of the two materials and shows the first peak of H₂ release between 80 and 210°C in the STMBMS data of Figure 2. Ammonia is released in several steps between 40 and 310°C. RGA and STMBMS investigations of several ternary Ca(BH₄)ₓ-LiNH₂-LiH and Ca(BH₄)ₓ-LiNH₂-MgH₂ compositions showed that the amount of ammonia can be significantly reduced when the corresponding metal hydrides are added before the ball-milling step.
RGA of the milled Mg(BH$_4$)$_2$-LiNH$_2$ sample revealed that ammonia is the major product at relatively low temperatures (up to 140°C). Upon heating to 180°C, both H$_2$ and NH$_3$ are released, while at 290°C and above hydrogen is the major product. Small amounts of boron hydrides were also detected. The presence of significant amounts of ammonia at relatively low temperatures suggests this process is energetically favorable. Interesting enough, after the first dehydriding/rehydriding cycle, the amount of NH$_3$ released decreases dramatically. This is associated with a significant loss in capacity (>50%). We also studied the effect of small amounts of MgH$_2$ and LiH on the impurity gas formation from the Mg(BH$_4$)$_2$-4LiNH$_2$ system. Our tests on the ball-milled Mg(BH$_4$)$_2$-4LiNH$_2$-0.1MgH$_2$ and Mg(BH$_4$)$_2$-4LiNH$_2$-0.1LiH composites indicate a decrease in the amount of NH$_3$ formed, presumably through formation of reactive amide species. As far as the reversibility is concerned, none of the borohydride-amide materials we studied so far display full reversibility, even at high temperatures (up to 500°C) and H$_2$ pressures (up to 100 MPa).

**Phosphorous Materials**

Syntheses of the various salts of [PH$_2$(BH$_3$)$_2$] are known. However, most methods use phosphine, ammonia, and diborane, are performed at temperatures as low as -196°C, and take upwards of seven days to complete. To avoid these hazards, a new method was developed from commercially available starting materials:

\[
\text{NaBH}_4 + \text{PCl}_3 \rightarrow \text{Na}^+ + \text{H}_2 + \text{B} \uparrow + \text{HCl} + \text{P} \uparrow
\]

Differential scanning calorimetry of the sodium salt 1 was carried out in order to determine the heat of decomposition. A multi-step process between 150 and 200°C for Na[PH$_2$(BH$_3$)$_2$] yields a $\Delta H$ of approximately +1 kcal/mol at 10°C/min (Figure 3, left). Interestingly, this process appears to be heating rate-dependent. With fast heating rates (>5°C/min), a sharp endothermic event is observed before a large, and long-lived, exothermic event occurs yielding the aforementioned value for $\Delta H$. If the heating rate is slowed to 1°C/min, the sharp endothermic event becomes much less pronounced, and the exothermic signal intensifies (Figure 3, right). The multi-step process in the same temperature range (150-200°C) becomes overall exothermic with a measured $\Delta H$ of roughly -10 kcal/mol. We hypothesize that fast heating rates allow the sample to melt before decomposing, whereas, a slow heating rate causes sample decomposition before undergoing the endothermic melting process. TGA shows a weight loss of approximately 6% over the same temperature range. No additional mass loss was observed up to 500°C.

**FIGURE 3.** DSC of Na[PB] Decomposition Showing Dependence on Heating Rate
The 6% mass loss observed during the thermal decomposition of Na[PH$_2$(BH$_3$)$_2$] was initially attributed to H$_2$ loss. To confirm this assessment, analysis of the volatile compounds released from the solid material was performed using STMBMS. Large amounts of H$_2$ were detected as the sample was heated through the temperature range of 150-200°C along with PH$_3$ and B$_2$H$_6$. The signal for hydrogen was qualitatively larger compared to other volatile species but the amount of phosphine and diborane were not negligible. Clearly, the loss of phosphorus and boron from the solid material is detrimental to achieving a reversible material.

To identify additional products formed during thermal decomposition, samples of the sodium salt were heated under vacuum to 150°C for fixed time intervals and then analyzed by attenuated total reflection-FTIR spectroscopy, NMR spectroscopy, XRD, DSC, and TGA. Regardless of the time interval (1h, 2h, 3h, 6h, and 18h) at 150°C, each reaction gave the same product, identified as sodium borohydride (NaBH$_4$):

![Diagram of NaBH$_4$ formation](image)

The sodium salt crystallizes in the orthorhombic space group Ama2, with lattice parameters $a = 13.77\,$Å, $b = 7.91\,$Å, and $c = 4.50\,$Å. The structure was predicted using the PEGS method that combines a simplified electrostatic Hamiltonian and Monte Carlo simulated annealing to find prototype structures that are further refined using state-of-the-art first-principles techniques. The Rietveld-refined XRD spectrum is shown in Figure 4, and indicates excellent agreement with the measured powder diffraction spectra.

**FIGURE 4.** Rietveld refined powder XRD spectrum of 1 in space group Ama2. The difference curve (black trace) is below the observed data (red +), and spectra of the predicted structure (green trace).

Amide Materials

The (2LiNH$_2$+MgH$_2$) system has been selected as a near-term candidate for further development in the Engineering Center of Excellence. This material has convenient characteristics (i.e., pressure and temperature) for an operational storage system, with extensive cycle life of ~220 cycles. While the promising thermodynamic features and the high desorption rate of this material are attractive, its absorption rate is poor. The goal of this project is to search for adequate method to improve the sorption kinetics of this material. Previously we tested the traditional catalysts for hydrogen sorption, such as Pd, Pt, TiCl$_3$, Nd$_2$O$_3$, and found that none of them made significant improvements in the sorption behavior of the material. Up to now there has been no theory that can guide the discovery of effective catalysts for the amide materials. It is common that new catalysts are discovered unexpectedly. Recently, Dr. Ping Chen (DaLian Institute of Chemical Physics, Chinese Academy of Science) discovered a non-traditional catalyst, KH, that led to performance improvements. This motivated our investigation of potassium compounds, such as KH and KNH$_2$, as candidate catalysts for (2LiNH$_2$ + MgH$_2$).

**FIGURE 5.** Absorption profiles for (2LiNH$_2$+MgH$_2$), with or without KH addition (at ~4 mole %), at 180, 200 and 220°C and...
initial H₂ pressure of 150 bar. The solid lines are for those with KH added and the dashed lines are for those without KH. It can be seen that with the addition of KH, the absorption rapidly achieves >90% completion at 200°C and above and more than 70% at 180°C. The van’t Hoff plot for this material is shown in Figure 6. The formation enthalpy was measured to be 40 kJ/mol, very close to the previously reported value, 39.4 kJ/mol, indicating that the KH additive does not change the sorption thermodynamics. So far, we have been unable to detect any improvement on desorption of 2LiNH₂+MgH₂ in the presence of KH.

Theory Group Coordination

The Theory Group (TG) of the MHCoE makes use of first-principles methods to conduct materials discovery, provide thermodynamic and kinetic data for use by engineering and modeling efforts, and suggest new directions for experimentalists and interpretation of their results. The TG consists of researchers at the following institutions:

- Sandia National Laboratories (Mark Allendorf, TG Coordinator)
- Georgia Institute of Technology (Prof. David Sholl)
- National Institute of Standards and Technology (Dr. Ursula Kattner).
- University of Illinois/Champaign-Urbana (Prof. Duane Johnson)
- University of Missouri, St. Louis (Prof. Eric Majzoub)
- University of Pittsburgh (Prof. Karl Johnson)

To make maximum use of the different areas of expertise, joint TG efforts are guided by SNL not only in terms of technical direction, but also to ensure that TG efforts are complementary and have an effective synergy with experimentalists. The TG communicates through regular monthly conference calls involving all members of the team. This format has worked quite well and is followed up with a set of minutes and action items emailed to all participants. Depending on the topics under discussion, the TG also involves experimentalists from the various projects to provide insights into verification of theoretical predictions and suggestions for additional work by the TG.

Multiphase Equilibrium Modeling to Predict Impurity Gases and Phases

We computed the thermodynamic equilibrium including the possible evolution of gases other than H₂ in hydride systems based on LiNH₂, LiBH₄, Mg(BH₄)₂ and their mixtures with LiH, MgH₂, or C. Although the majority of research on materials for reversible storage of H₂ has focused on issues associated with hydrogen capacity, the generation or absence of gaseous impurities from any storage system could be decisive in the value of such a system for practical applications. The extensive literature that has applied first-principles calculations to searching for metal hydrides and their mixtures with attractive properties for reversible storage has typically assumed that H₂ is the only gas phase product. The approach we introduced here couples first-principles (density functional theory) methods, which are used to obtain the thermodynamic properties of solid phases of interest, and free energy minimization incorporating a broad range of gaseous and liquid species to obtain a comprehensive thermodynamic picture of the metal hydride decomposition chemistry. This concept will be a valuable addition to computational efforts designed to aid development of reversible storage applications by screening large numbers of materials.

One useful way to categorize the systems we studied is to assess the purity of H₂ that is available at equilibrium in each case. To this end, we define R to be the fraction of H₂ that is observed at equilibrium relative to the amount of H₂ that would be predicted in the gas phase if H₂ was the only gaseous species considered in a thermodynamic calculation. The variation in R as a function of temperature at 1 atm pressure is shown for each system we considered in Figure 7. Interestingly enough, the decomposition of 2LiBH₄ + MgH₂ is pressure dependent. For LiNH₂, LiBH₄, and 2LiBH₄ + MgH₂, R is very close to 1; that is, these examples are associated with very low levels of gas-phase impurities. The mixture LiNH₂ + LiH, in contrast, generates an appreciable level of N₂ and NH₃ when LiNH₂ decomposes, especially at temperatures above 700 K. All three of the mixtures we considered that included

![van’t Hoff Plot](image-url)
C, namely 2LiNH2 + C, LiBH4 + C and Mg(BH4)2 + C, are associated with very impure H2 except at high temperatures because of the strong thermodynamic stability of CH4.

Conclusions

- Performed multi-phase equilibrium theoretical studies on LiBH4, Mg(BH4)2 and 2LiBH4 + MgH2. Found that Li2B12H12 and MgB12H12 species play important roles during decomposition. Revealed a pressure-dependent mechanism governing the reaction pathways of 2LiBH4 + MgH2.
- Predicted that the decomposition of LiBH4, Mg(BH4)2 and 2LiBH4 + MgH2 is associated with low levels of gas-phase impurities. In contrast, 2LiNH2 + C, LiBH4 + C, and Mg(BH4)2 + C, are associated with very impure H2 because of the strong thermodynamic stability of CH4.
- Completed comprehensive PEGS predictions of Ti(BH4)3, M[PB2H8]x for M = Li, Na, K, Mg, Ca; x=1, 2.
- Confirmed remarkable catalysis of 2LiNH2/MgH2 by KH and KNH2. Demonstrated that in the presence of catalysts the absorption is >90% complete within minutes at 200°C.
- Improved the desorption kinetics of Mg(BH4)2 using various additives. Found that in the presence of 4 mol% TiF3/ScCl3, 9.6% H2 is released at 300°C.
- Observed low-temperature (<100°C) hydrogen evolution from Ti(BH4)3. However, the material was down-selected (removed from further study) due to irreversible hydrogen release.
- Developed a destabilization approach for releasing H2 from [B12H12]5- compounds at lower temperatures, confirming prior MHCoE theory.
- Experimentally demonstrated almost full conversion of Li2B12H12 and Na2B12H12 into LiBH4 and NaBH4 in the presence of corresponding hydrides at high H2 pressures.
- Successfully synthesized and studied storage characteristics of several alkali and alkaline-earth bis(borano)hypophosphites of general formula M[PB2H8]x. Na[PH2(BH3)2] was removed from further study due to formation of PH3 and B2H6, along with H2.
- Using STMBMS, detected significant amounts of ammonia during the decomposition of M'M''(BH4)x·yNH3 and M'M''(BH4) x(NH2)y (where M' and M''= Li, Na, Ca and/or Mg). Found that small amounts of metal hydrides significantly decrease the amounts of ammonia released.

Special Recognitions & Awards/Patents Issued

1. Director Klebanoff accepted a DOE Hydrogen Program 2010 “Special Recognition Award,” made to the entire MHCoE, “In Recognition of Outstanding Contributions to the Department of Energy.” This award was made June 8, 2010.

FY 2010 Publications/Presentations

IV.A.1e Aluminum Hydride Regeneration

Objectives

Develop an onboard vehicle storage system meeting DOE’s targets that uses aluminum hydride for storing hydrogen:

- Produce aluminum hydride material with a hydrogen storage capacity greater than 9% gravimetric (kg-H₂/kg) and 0.13 kg-H₂/L volumetric.
- Develop practical and economical processes for regenerating aluminum hydride.
- Provide assistance in designing onboard fuel tank storage system for better than 6% gravimetric, 0.07 kg-H₂/L volumetric hydrogen storage capacities and well-to-wheels efficiencies greater than 60%.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(D) Durability/Operability
(E) Charging/Discharging Rates

Technical Targets

The current 2010 and 2015 hydrogen storage targets are listed in Table 1 along with our 2010 status using AlH₃. The well-to-wheels efficiency listed in Table 1 under the column for 2010 Status were taken from an independent analysis of an aluminum hydride storage system by R. K. Ahluwalia of Argonne National Laboratory. This analysis was presented at the 2008 Hydrogen Annual Program Review and was based, in part, on data supplied by Brookhaven National Laboratory. Argonne’s analysis assumes 70-wt% aluminum hydride slurry, and uses trimethylamine (TMA) as the stabilizing agent for regenerating aluminum hydride in determining the 55% well-to-wheels efficiency. The reactor temperature of 120°C listed in the row for full flow rate is the most recent value measured by Brookhaven that meets the DOE fuel flow target, and is for 40-wt% aluminum hydride slurry. The 0.036 gravimetric storage parameter listed in Table 1 is a measured value from 40-wt% slurry consisting of 9-wt% aluminum hydride particles.

Accomplishments

Progress was realized in Fiscal Year (FY) 2010 towards meeting DOE’s hydrogen storage targets by demonstrating the following three steps for the synthesis of AlH₃:

**Step 1: formation of NR₃-AlH₃ by direct hydrogenation**

- Five alane adducts formed by direct hydrogenation under mild conditions.
- Alane adducts also formed by reacting amine directly with alane.

**Step 2: transamination exchange NR₃ for triethylamine (TEA)**

- Transamination demonstrated starting with dimethylethylamine (DMEA) and TMA.

**Step 3: separation of TEA-AlH₃**

- Separation of TEA-AlH₃ successful with ~70% AlH₃ recovery (additional optimization is necessary to improve yields to achieve the target).
**Approach**

The research direction under the Metal Hydride Center of Excellence being pursued by Brookhaven is to form hydride materials on the aluminum particle surfaces, and then stabilize these surface hydrides with chemical agents such as amines, ethers and/or lithium hydride. This approach is very similar to the well-studied cycling of sodium alanate with aluminum, where sodium hydride functions as the stabilizing agent. The main difference being that this research focuses on forming the hydride on the aluminum surface in a liquid phase rather than a high-pressure hydrogen gaseous environment. The advantages are that surface alane formation lowers considerably the hydrogenation pressure, and the liquid phase offers better thermal management and mass transport. The research plan therefore calls for first identifying the appropriate adduct(s), solvents, catalysts, and temperature and pressure conditions for making and “stabilizing” the aluminum hydride adduct in an effective and energy efficient manner. The second step, necessary to complete the regeneration cycle, is hydride recovery from the newly formed hydride-adduct. In addition to the regeneration studies, we have recently started to investigate slurry aluminum hydride decomposition kinetics as a function of temperature, catalysts and slurry type. The use of slurries is one approach towards meeting the three-minute refueling target.

**Results**

In FY 2010 we continued to explore low-energy methods to regenerate AlH₃ from Ti-catalyzed aluminum and hydrogen gas. In the past we demonstrated, in the presence of hydrogen gas and an inert solvent, the direct reaction of catalyzed aluminum with many tertiary amines to form amine-alane adducts. The practice of Ti doping to catalyze the reversible formation of aluminum-based hydrides has been the subject of many studies. These catalyzed materials are known to possess improved reaction kinetics in regards to the formation of alane complexes and reversibility when compared with those formed with undoped materials. Our current model suggests that arrangements of Ti atoms on the surface of Al promote the chemisorption of hydrogen and the formation of transitory alane species. Based upon these calculations, it is believe that any alane formed on the surface of titanium-doped aluminum, survives long enough to react with a Lewis base, such as DMEA, to form an alane adduct. The alane adduct detaches from the aluminum surface and is significantly more stable than molecular AlH₃. Previously, we demonstrated the formation of dimethylethylamine alane (DMEAA) through the direct hydrogenation of Al* and DMEA in one of three solvents (Et₂O, tetrahydrofurran or toluene) using the following reaction:

\[
\text{DMEA} + \text{Al}^* + \frac{3}{2}\text{H}_2 \rightarrow \text{AlH}_3 \cdot \text{DMEA} \quad (1) \text{ Step 1}
\]

Attempts to produce a pure DMEAA adduct through direct hydrogenation without a solvent were not successful. DMEAA can also be synthesized by a direct reaction between AlH₃ and DMEA in a number of solvents including excess DMEA, Et₂O, tetrahydrofurran or toluene using the following reaction:

\[
\text{DMEA} + \text{AlH}_3 \rightarrow \text{AlH}_3 \cdot \text{DMEA} \quad (2)
\]

This year the focus was placed on recovering the alane from the amine-alane adduct with particular attention given to the (DMEA) adduct. The recovery of intact AlH₃ from most amine-alane adducts is difficult since the temperatures required for adduct separation are typically greater than the AlH₃ decomposition temperature (~100°C). The one known exception is triethylamine-alane (TEAA), which can be separated under a partial vacuum at 70°C. In this effort, we demonstrate that although TEAA is not easily formed by direct hydrogenation, it can be formed by an amine exchange reaction (transamination) using DMEAA and TEA. This gives us a low-energy regeneration reaction which initially involves the direct formation of DMEAA from DMEA, catalyzed aluminum (Al*), and H₂ gas under moderate conditions (Eq. 1). This step is followed by transamination with TEA (Figure 1), and then finally the separation of TEAA for the recovery of alane (Figure 2):

\[
\text{AlH}_3 \cdot \text{DMEA} + \text{TEA} \rightarrow \text{AlH}_3 \cdot \text{TEA} + \text{DMEA} \uparrow \quad (3) \text{ Step 2}
\]

\[
\text{AlH}_3 \cdot \text{TEA} \rightarrow \text{AlH}_3 + \text{TEA} \uparrow \quad (4) \text{ Step 3}
\]

**Step 2: amine exchange (transamination)**

![FTIR spectra confirming the exchange of DMEA with TEA](image)

**Figure 1.** Fourier Transform Infrared (FTIR) Spectra Confirming the Exchange of DMEA with TEA.
CONCLUSIONS AND FUTURE DIRECTIONS

At the close of this project we have concluded that many alanes of tertiary amines may be synthesized at relatively modest hydrogen temperatures and pressures. However, the technical barriers of improving yields and slurry mass loadings need to be addressed before an alane storage system can meet all of DOE’s hydrogen storage targets. These barriers define the future direction of alane research at BNL, and are listed as follows.

• Improve the well-to-tank efficiency from the estimate of 40-55% with TMA to the target efficiency of 70% with DMEAA.

Combining step 2 + 3: Separation of DMEA-AlH₃

• DMEA-AlH₃ separated by combining steps 1 & 2
• Analysis of recovered AlH₃ (XRD and decomposition) suggests ~35% AlH₃ with 65% Al when steps 1 & 2 are combined
• Improvements expected with optimization & washes to remove unwanted material

Figure 3 shows the recovery of aluminum hydride by starting with DMEAA synthesized using Equation 2, and then combining steps 2 and 3 together for the recovery of aluminum hydride.

Special Recognitions & Awards/Patents Issued

1. Jason Graetz was awarded the “Presidential Early Career Award for Scientists and Engineers” (PECASE) for innovative research in hydrogen storage for automotive fuel-cell applications, 2009.

FY 2010 Publications/Presentations

IV.A.1f  Reversible Hydrogen Storage Materials – Structure, Chemistry, and Electronic Structure

Objectives

- Advance the understanding of the microstructural characteristics of complex light-weight metal hydrides to ascertain controlling mechanisms.
- Develop and apply reliable theoretical methods to assess potential complex metal hydrogen-storage materials, including key issues limiting material performance.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.)3 of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(E) Charging/Discharging Rates

Technical Targets

**Catalytically Enhanced Hydrogen Storage Systems:** This project uses a combined theoretical and experimental approach to gain a fundamental understanding of the role of the catalytic species in several candidate complex hydride storage systems. Insights gained from these studies are applied toward identifying potential complex metal hydride storage systems as well as optimizing the design and synthesis of systems to meet or exceed the following DOE 2015 hydrogen storage targets:

- System gravimetric capacity in terms of usable, specific-energy from H₂ 1.8 kWh/kg.
- System volumetric capacity in terms of usable, specific-energy from H₂ 1.3 kWh/L.
- System fill time (for 5 kg H₂): 4.2 min (1.2 kg/min).

Accomplishments

The following accomplishments were made in this fiscal year:

- Improved electron tomography capability and used it to address the question of the dispersion of particles in nanoporous scaffolds.
- Showed in MgH₂ that there is no nanoparticle size effect for dehydrogenation enthalpies, although there is an effect on kinetic barriers with transition metal catalyst.
- Determined universal behavior for core-shell preference in binary nanoparticles.
- Demonstrated that the amount of Ti needed to activate the system is less than introduced initially.
- Established in the Ca(BH₄)₂ system the existence of numerous CaB₁₂H₁₂ polymorphs and the origin for the observed amorphous-structure in dehydrogenated material.

Introduction

The transition from a petroleum-based to a hydrogen-based fuel for automotive applications depends on finding a viable, reliable and economic means in which to store hydrogen on-board the vehicle. One option is the high-capacity lightweight, metal hydrides that includes aluminum, borohydrides, destabilized metal hydrides, binary hydrides, intermetallic hydrides, and modified lithium amides. This includes exploring the potential of making nanoscale systems and confining them within nanoporous structures to exploit the enhanced properties found in large surface area to volume conditions. However, the challenge was and remains that none of the candidate systems tested to date satisfy the thermodynamic and kinetic constraints imposed by the DOE targets.
Approach

State-of-the-art characterization tools, electron microscopy and X-ray diffraction for structural and phase characterization, energy dispersive and electron energy loss spectroscopy for chemical analysis, as well as atomic force microscopy to probe surface interactions, were employed to investigate the microstructural and microcompositional changes that occur in candidate material systems during the uptake and release of hydrogen. The characterization was coupled with first-principles, electronic-structure and thermodynamic theoretical techniques to predict and assess metastable and stable phases, as well as surface effects that can poison or limit kinetics. Electronic-structure and thermodynamic calculations were used to interpret and understand the experimental results on candidate systems. This combined theoretical/characterization effort provides fundamental insight to the processes governing hydrogen uptake and release.

Results

X-ray and electron diffraction of desolvated and dehydrogenated Ca(BH$_4$)$_2$ showed that after dehydrogenation the Ca(BH$_4$)$_2$ peaks are replaced with CaH$_2$ peaks only, no other crystalline phases were present. Electron diffraction from a single particle showed weak crystalline diffraction spots superimposed on a diffuse background, which is consistent with the particle being amorphous with a low volume fraction of small crystalline regions. Chemical analysis via electron energy loss spectroscopy, confirmed no significant compositional modifications occurred during dehydrogenation.

To interpret these experimental results, theoretical calculations of Ca(BH$_4$)$_2$ hydride and dehydride reactions that included possible intermediate CaB$_{12}$H$_{12}$ states were performed. A key finding was the discovery of the existence of numerous polymorphs of CaB$_{12}$H$_{12}$ that, at low temperatures, would lead to formation of a stable intermediate phase. It was demonstrated via ab initio molecular dynamics that these polymorphs arose from the varying bond length of Ca-Ca cations (as opposed to the Ca-B and B-B contained in the stable B$_{12}$H$_{12}$ unit). Significantly, a mixed state of several polymorphs explained the experimental diffraction pattern; that is, around 2θ = 22° more than two CaB$_{12}$H$_{12}$ polymorphs were needed to produce the weight at that scattering angle. Consequently, the weighted diffraction signal would produce a pattern that appears amorphous, as observed experimentally. The X-ray diffraction pattern along with the signals from the different polymorphs is shown in Figure 1. Phase segregation as well as complete extraction of all available hydrogen was possible only at higher temperatures.

To explore the interaction of molecular hydrogen with an aluminum surface with and without surface Ti atoms, a thin film of Al was deposited on Si(111) substrates both with and without a partial monolayer (0.02 ML) of Ti. Unlike the Al-only films, which exhibited no change when exposed to H$_2$, vacancy islands appeared and increased both in number and size under H$_2$ exposure of the Ti-dosed surfaces, Figure 2. The vacancy islands, an indication of hydrogen absorption by the Al, were one atom deep and randomly distributed across the surface. Shortly after the vacancy islands appeared, surface AlH$_x$ monomers formed next to a vacancy island. As exposure continued and the number of surface monomers increased, grouping of AlH$_x$ complexes formed. Future experiments will...
explore the interactions between Ti, the vacancy islands, and the AlHx complexes. The final series of experiments will explore how the responses differ if the surface is contaminated. In support of these scanning tunneling microscopy experiments, first principles calculations are being conducted to determine the surface projected electronic density of states to make a direct connection to the experimental results.

One possible strategy to improve the thermodynamics of the hydrogenation and dehydrogenation reactions is to reduce the particle size into the nanoscale regime. To explore this possibility, the size effect on desorption enthalpies of nanoparticles vs. bulk were calculated for MgH2-based systems with and without catalyst atoms of Ti and V. The results, reported in Table 1 show there is NO thermodynamic size effect for hydrogen release (except at very small [<10] atom clusters), although there is a catalytic effect with dopant in both bulk and nanoparticle cases.

An important aspect of developing nanoparticle hydrogen-storage systems is to employ light-weight scaffolds with nano-sized pores to control particle size and prevent agglomeration. A key question in using such scaffolds is determining if the storage medium actually impregnates the scaffold during the synthesis. To address this issue we have developed and applied compositional electron tomography to convert conventional two-dimensional compositional images to three-dimensional tomographs of scaffolds containing hydrogen storage materials. These tomographs enable visualization of the impregnated scaffold from any viewing angle. An example of a selection of snapshots from an electron tomogram of silver clusters that had been impregnated in a metalorganic framework are shown in Figure 3; silver is not a candidate system it is used here simply to demonstrate the technique capability.

Nudged Elastic Band calculations are being conducted to explore the kinetic barriers of hydrogen desorption from the [110] rutile surface of MgH2 with and without catalytic-dopants of Fe, V and Ti. Due to the large size of ball-milled and similar samples, we believe that surface calculations for facets are sufficient to obtain quantitative estimates of kinetic barriers. It is found that for H2 desorption, the lowest-energy structures involve dramatic local reconstructions around the catalyst site, with Ti (V) preferring a coordination number of 8 H (7 H) atoms. Thus, as one hydrogen molecule dissociates, hydrogen from the interior is drawn to the surface catalyst atom site so that the process can continue. This can be seen for V in the images shown in Figure 4a. The effects of nanosize and support interactions on H desorption are shown in Figure 4b and this shows the difference between the different catalytic-dopants and the effectiveness of Ti versus V at reducing the kinetic barriers, while no advantage was found by going “nano” with samples for dehydrogenation energies, i.e., no size-effects for thermodynamics.

Conclusions and Future Directions

- The core-shell behavior in transition-metal nanoparticles is governed by cohesive energy (or surface energy) and size differences, which predicts all observed structures.
- No nanoparticle size effect for dehydrogenation enthalpy exists although there is a reduction in kinetic barrier with catalyst.

Table 1. Dehydrogenation energy (kJ/mol-H2) from nanoparticle surface site vs. bulk surface site (defined has being bonded to two metal sites).
The role of Ti on clean Al surfaces appears to be to enhance the dissociation of molecular hydrogen to atomic hydrogen. Our continuing effort will focus on completing the following activities:

- Continue the study of the reaction of H$_2$ with clean and poisoned Al surfaces with and without catalytic species. We will explore creating small islands of Ti, as opposed to isolated Ti atoms, and, if successful reacting them to form Al$_{1-x}$Ti$_x$ islands. The interaction of H$_2$ with these islands will then be investigated. Electronic-structure methods will be used to support these surface-science experiments and to aid the interpretation of the experimental results.
- The electron tomography method will be used to identify the location of MgH$_2$ in a scaffold (collaboration with University of Hawaii) and LiBH$_4$ melt-infiltrated into nanoporous carbon (University of Missouri).
- The electronic structure studies involving the following systems will be continued:
  - Stability of bulk Ca(BH$_4$)$_2$ and clusters of Mg and MgH$_2$.
  - Nanocluster structures of MgH$_2$ and NaAlH$_4$ with and without interactions to a carbon support (approximating interactions with aerogels).
  - The effects of nanosize and support interactions on H desorption.

Project Start Date: October 1, 2006
Project End Date: October 1, 2011

Objectives

• Develop a low-cost rechargeable hydrogen storage material with cyclic stability and favorable thermodynamics and kinetics fulfilling the DOE onboard hydrogen transportation goals. Alane AlH₃ was identified as material of potential to meet the DOE targets.
• Avoid the impractical high pressure needed to form AlH₃.
• Avoid the chemical reaction route of AlH₃ that leads to the formation of alkali halide salts such as LiCl or NaCl.
• Utilize electrolytic potential to translate chemical potential into electrochemical potential and drive chemical reactions to form AlH₃.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:
(A) System Weight and Volume
(B) System Cost
(C) Efficiency
(R) Regeneration Processes

Technical Targets

In this project studies are being conducted to lower cost and improve efficiency of the electrochemical method to form AlH₃. This material has the potential to meet the 2015 technical target for on-board hydrogen storage as shown in Table 1.

Accomplishments

• Continued to produce gram quantities of alane with high purity.
• LiAlH₄ was also used to produce alane.
• The amount of dendrites was reduced by using LiAlH₄.
• Yield was increased and higher electrochemical cell efficiency was achieved.
• An electro-catalytic additive was discovered and found to greatly enhance the electrochemical process.
• Started improving efficiencies in every step of the regeneration method and achieved success.
• A pressurized electrochemical cell is being constructed for close material regeneration cycle and the use of more efficient separation.

Introduction

The DOE is supporting research to demonstrate viable materials for on-board hydrogen storage. Aluminum hydride (alane, or AlH₃), having a gravimetric capacity of 10 wt% and volumetric capacity of 149 g H₂/L and a desorption temperature of ~60°C to 175°C (depending on particle size and the addition of catalysts) has the potential to meet the 2010 and 2015 DOE targets.

In this report improvements to the electrochemical method to produce alane are discussed. Although many attempts in the past were made to make alane electrochemically [1-3] none of these attempts have isolated or characterized alane. These attempts were not directed at hydrogen storage. Our group is the first to demonstrate a reversible cycle utilizing electrochemistry and direct hydrogenation, where gram quantities of alane are produced, isolated and characterized [4]. Our regeneration method is based on a complete cycle that uses electrolysis and catalytic hydrogenation of spent aluminum Al(s).

DOE Hydrogen Program 394 FY 2010 Annual Progress Report
Approach

Electrochemical methods have been developed at SRNL to produce alane [4]. These methods avoid the impractical high pressure needed to form AlH₃ and the chemical reaction route of AlH₃ that leads to the formation of alkali halide salts such as LiCl. The process utilizes an electrolytic potential to drive the chemical reaction to form AlH₃. However, AlH₃ will be oxidized in an aqueous environment, forbidding the use of all protic solvents. For this reason, the use of a non-aqueous solvent system is required.

The electrolysis is carried out in an electrochemically stable, aprotic, and polar solvent such as tetrahydrofuran (THF) or ether. MAIH₄ (M = Li, Na) is dissolved in a polar solvent, forming an ionic solution. For example, sodium alanates dissolved in THF is used as an electrolyte.

NaAlH₄ / THF ↔ Na⁺ / AlH₄⁻ / THF

Though not directed at the regeneration of alane, elaborate research and extensive studies on the electrochemical properties of this type of electrolyte have been reported [5-6].

In addition ways to improve the electrochemical methods were considered, leading to the addition of chemicals that accelerate alane production. At this moment this species is referred as the electrocatalytic additive (ECA). Electrochemical techniques such as electrolysis, cyclic voltammograms (CV), and electrochemical impedance spectroscopy (EIS) were used to evaluate the effect of the ECA.

Results

Alane has continued to be produced in grams quantities, using the electrochemical method described in Zidan et al [4]. This method was improved by modifying the electrochemical cell setup and the electrochemical process. Increase in the alane production was obtained by increasing cell size, electrode size, minimizing resistance (by reducing electrode distance), and prolonging the electrolysis. Dendrites formation at the counter electrode has been reduced by the use of LiAlH₄ instead of NaAlH₄. Both solutions of NaAlH₄ in THF and LiAlH₄ in THF contain triple ions complexation. However, solutions of NaAlH₄ in THF produce more tightly solvated ions (Na⁺ and AlH₄⁻) than solvent separated ion pairs (Na⁺[AlH₄]⁻) whereas solutions of LiAlH₄ in THF contains more solvent separated ion pairs (Li⁺[AlH₄]⁻) than solvated ions (Li⁺ and AlH₄⁻) [6-7]. Consequently, there are less free ions in the solution of LiAlH₄ than in the solution of NaAlH₄ which can lead to less formation of Li₃AlH₆ and Al (dendrites). A new modified system is being developed to further reduce the dendrites formation. This system consists of a pressurized electrochemical cell in which a higher H₂ pressure is used to increase the H₂ in the solution in order to displace the reaction of Li to LiH avoiding in this way the reaction to form Li₃AlH₆. In addition, the electrochemical method was improved by the use of an ECA.

To test the effect of the ECA two cells were prepared using LiAlH₄ and triethylenediamine (TEDA) in THF and including the ECA in one of the cells. TEDA was incorporated in the solution to visually detect the formation of alane as AlH₃-TEDA (white precipitate) during the experimental test. AlH₃-TEDA was easily separated by filtering and weighted. Figure 1 shows the initial state of each cell and after 10 min of electrolysis. This figure clearly shows that cell 2 (cell with ECA) contains a larger amount of AlH₃-TEDA. Also, it should be notice that a minimal amount or no dendrites were produced in the counter electrode in either cell.

Figure 2 shows 10 min of bulk electrolysis at 2.1 V for alane production using the two comparative cells described above. The high potential used during the electrolysis was required to produce enough alane in those 10 min for visualization purpose and eventually yield comparison. This figure shows an increase of 80% in the current when the ECA was used. The total charge for cell 2 was twice the total charge obtained with cell 1. The amount of yield of AlH₃-TEDA was doubled when the ECA was used on cell 2. CVs for both cells are presented in Figure 3. It should be noted that the open circuit voltage (OCV) for cell 2 is shifted to -1.5 V from the original cell #1 (OCV = -1.9). This means that the overpotential required for cell 2 is less when performing the electrolysis at 2.1 V. Consequently, lower energy is required for cell 2 to produce AlH₃-TEDA, which implies that cell 2 is more efficient because it has more current with less energy input.

EIS was performed on the cells with and without the ECA. Figure 4 shows that real part of the impedance, which represents the resistance of the cells, is about 112 Wcm² for both cells. This shows that the ECA does not have a significant effect in the resistance (or conductivity) of the solution. That is, the ECA is not acting as an electrolyte. Consequently, the increase in current and efficiency discussed above are an electrocatalytic effect of the added species.

In additions to the improvements described above methods have been developed to extract alane from THF. These methods involve the heating and vacuum distillation of THF adducted alane solutions with subsequent crystallization of alane in toluene or other non coordinating solvents.

Conclusions and Future Directions

• The electrochemical cell setup was modified and larger quantities (grams) of alane were produced.
FIGURE 1. Two electrochemical cells showing the formation of AlH₃-TEDA. Cell 1 without the ECA (a) before and (b) after 10 min of electrolysis; and cell 2 with the ECA (c) before and (d) after the 10 min of electrolysis.

FIGURE 2. Comparison of the bulk electrolysis for the production of AlH₃-TEDA using two electrochemical cells: with and without the ECA.
The use of LiAlH$_4$ helped to reduce the dendrites formation. An electro-catalytic additive was discovered and found to greatly enhance the electrochemical process by increasing the cell efficiency and the alane production. Ongoing work and future direction include:

- Use of a pressurized electrochemical cell to further reduce the dendrites formation.
- Examine catalysts in accelerating formation and regeneration.
- Use other techniques (e.g. nuclear magnetic resonance, prompt gamma activation analysis and Raman) to quantify and characterize AlH$_3$.
- Design and construct a larger electrochemical cell capable of producing larger quantities of AlH$_3$.
- Develop closed and efficient AlH$_3$ extracting system based on new solvents.
- Optimize all parameters needed for producing several grams of AlH$_3$ efficiently.
- Explore, reversibly, forming other high capacity complex hydrides such as Mg and Ca-based complex hydrides using electrochemical methods.

**Special Recognitions & Awards/Patents Issued**

1. 2010 DOE Hydrogen Program Team Award in Storage. This award recognizes Dr. Ragaiy Zidan and his team at SRNL for their outstanding contribution to the development of electrochemical methods to regenerate alane.

Contract Number: DE-AI-01-05EE11104
Project Start Date: April 1, 2005
Project End Date: October 1, 2010

Objectives
- Characterize structures, compositions, hydrogen dynamics, and absorption-site interaction potentials for candidate storage materials using neutron scattering methods.
- Provide Calphad calculations of phase relationships of potentially promising hydrides.

Technical Barriers
This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:
(A) System Weight and Volume
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets
We support the development of hydrogen storage materials by providing timely, comprehensive characterization of Metal Hydride Center of Excellence (MHCoE)-developed materials and storage systems using state-of-the-art neutron methods and Calphad. This characterization helps speed the development and optimization of storage materials that can meet the following 2010 DOE hydrogen-storage system capacity targets:
- 6 wt% H
- 45 g H₂/L

Accomplishments
Key accomplishments for Fiscal Year (FY) 2010 are listed below for hydrogen-storage materials of interest to the MHCoE:
- The structures of SrB₁₂H₁₂ and BaB₁₂H₁₂, heavier alkaline-earth analogs to MgB₁₂H₁₂, were solved by a combination of X-ray diffraction (XRD), neutron vibrational spectroscopy (NVS), and density functional theory (DFT) calculations.
- NVS measurements of amorphous, partially solvated MgB₁₂H₉ yield a vibrational density of states suggestive of the predicted stable crystalline structure.
- Quasielastic neutron scattering (QNS) measurements of NaBH₄, KBH₄, and Cs₂B₁₂H₁₂ allowed us to characterize, in detail, the rotational dynamics of the corresponding BH₄⁻ and B₁₂H₁₁⁻ anions.
- NVS measurements of the direct high-pressure hydrogenation of Li₂B₁₂H₁₂ + 10LiH and Na₂B₁₂H₁₂ + 10NaH mixtures indicate the near complete formation of LiBH₄ and NaBH₄, respectively.
- Small-angle neutron scattering (SANS) measurements of partially LiBH₄-loaded carbon aerogels are consistent with the preferential filling of smaller pores and/or surface film formation.
- The structures of two new synthesized complex hydrides, Li₂{(BH₄)₂NH₃BH₃} and Ca{(BH₄)₂(NH₃BH₃)₂}, where solved by XRD.
- Neutron reflectometry of dehydrogenated of MgH₂ thin films suggests the formation of porous Mg.
- The thermodynamic Calphad database for Li-Mg-Ca-B-Si-H was expanded to include more gas phase species and ternary hydride phases.

Introduction
In search of a hydrogen storage medium that meets the DOE technical targets, the MHCoE has been investigating various materials, such as light-metal hydrides, borohydrides, and borohydride-amide mixtures. Moreover, considerable efforts have been focused on understanding the borohydrides’ decomposition pathways in order to improve their hydrogen-cycling
properties and enhance their reversibility. Using neutron-based probes, NIST has provided structural and/or spectroscopic characterization of such materials as NaBH₄, KBH₄, SrB₁₂H₁₂, BaB₁₂H₁₂, MgB₁₂H₁₂, xTHF (THF = tetrahydrofuran), Li₂(BH₄)₂(NH₃BH₃), Ca(BH₄)₂(NH₃BH₃), and LiBH₄ nanoconfined in carbon aerogels. Such detailed information is important for a more thorough understanding of these materials and their hydrogen-storage properties. In addition, neutron reflectometry has been used to characterize hydrogen-concentration profiles within light-metal thin films during hydrogen cycling in order to understand the fundamental hydrogen diffusion mechanisms during hydrogenation and dehydrogenation.

Calphad thermodynamic modeling provides critical assessments of hydrogen content, character and heats of reaction, and phase-reaction sequences during hydrogen charge-discharge cycling of MHCoe-developed metal-hydride systems. NIST has continued to update and expand the thermodynamic database, including the elements Li, Mg, Ca, B, Si, and H and their respective binary and ternary phases, for the Calphad modeling of metal-hydrogen systems. This database is being used to calculate the reactions in multi-component hydrogen systems. These results are the basis for the evaluation of dehydrogenation temperatures and pressures and the suitability of element additions for destabilization of the hydride phases.

**Approach**

The key to improved hydrogen-storage materials is a detailed understanding of the atomic-scale locations and lattice interactions of the hydrogen. We are applying our state-of-the-art neutron measurement capabilities and expertise at the NIST Center for Neutron Research to the promising materials being developed by the MHCoe. This work enables MHCoe partners to obtain unique insights into the atomic- and molecular-scale properties that are responsible for the hydrogen-storage properties of these candidate materials.

In addition, we are performing Calphad thermodynamic modeling. The available literature is evaluated for thermodynamic data and analytical descriptions of the thermodynamic functions of the relevant phases. The data and functions are compiled into a consistent database describing the multi-component systems. Missing quantities are identified and descriptions are being developed in collaboration with MHCoe partners.

**Results**

We have focused the majority of our neutron measurements on borohydride-based materials in order to provide structural and spectroscopic details where lacking. For example, we continued our collaboration with Sandia National Laboratories (SNL), the Jet Propulsion Laboratory, the California Institute of Technology (Caltech), and the University of Maryland to investigate the structures and bonding in the alkali and alkaline-earth dodecahydro-closo-dodecaborates, which are possible intermediates in borohydride decomposition. Adding to our previously determined Li₂B₁₂H₁₂, Na₂B₁₂H₁₂, and Ca₂B₁₂H₁₂ structures, we have solved the isomorphic P₃1c structures of the heavier alkaline earth analogs of MgB₁₂H₁₂, namely SrB₁₂H₁₂ and BaB₁₂H₁₂ by a combination of XRD, NVS, and DFT calculations. The MgB₁₂H₁₂ structure still eludes us since it has been impossible as of yet to synthesize the totally anhydrous compound. NVS results for MgB₁₂H₁₂, partially solvated by ~0.5 THF/MgB₁₂H₁₂ suggests some similarity with the predicted structure of Ozolins, et al., [1] but definitive results await a solvent-free sample.

We have collaborated with SNL and Caltech to investigate the hydrogenation behavior of A₂B₁₂H₁₂ + 10AH mixtures (A=Li and Na) because of the A₂B₁₂H₁₂ intermediate’s high stability during the cycling of alkali-metal borohydrides. Spectral comparison by NVS of hydrogenated Li₂B₁₂H₁₂ + 10LiH and Na₂B₁₂H₁₂ + 10NaH mixtures with pure LiBH₄ and NaBH₄ compounds indicates that 773 K and 90 MPa H₂ is sufficient to transform the reactant mixtures into the pure borohydride compounds.

We have collaborated with the universities of Maryland and Michigan to unravel the details of BH₄⁻ rotational dynamics in both the ordered and disordered phases of NaBH₄ and in the disordered phase of KBH₄ by QNS [2]. Model fits of the QNS data indicate that the BH₄⁻ tetrahedron in the NaBH₄ ordered phase rotates with a combination of two-site and three-site reorientations that preserve its crystallographic orientation. Data for the disordered phases are well described by a model assuming nearest-neighbor BH₄⁻ jumps from one corner to another of a cube formed by eight hydrogen positions of half occupancy. Distinguishing between likely mechanisms for reorientation was made possible by collecting data at sufficiently high Q values. The derived activation energies for reorientation for the NaBH₄ low-temperature and high-temperature phases are 13.4±0.8 and 11.9±0.5 kJ/mol, respectively, and 14.6±0.5 kJ/mol for the KBH₄ high-temperature phase.

We have collaborated with HRL Laboratories, Lawrence Livermore National Laboratory, and the universities of Maryland, and Michigan to characterize the properties of LiBH₄ nanoconfined in carbon aerogels. SANS measurements for LiBH₄-filled and partially-filled 15 nm aerogels (Figure 1) indicate significant scattering differences at the higher momentum transfer (Q) values and similar scattering behavior at intermediate Q values. This suggests that the smallest pores fill first with no change in apparent mesopore geometry with filling. Although NVS indicates
that the vibrational modes for LiBH$_4$ in a 13 nm carbon aerogel exhibit only a minor (~10%) broadening compared to those for bulk LiBH$_4$. QNS measurements of the BH$_4^-$ rotational jump frequency for nanoconfined LiBH$_4$ (Figure 2) indicate a step at ~360 K denoting the orthorhombic-to-hexagonal phase transition, which is nearly 30 K lower than the transition temperature for bulk LiBH$_4$. This suggests that nanoconfinement perturbs bulk thermodynamic properties.

We have collaborated with the University of Maryland and General Motors to synthesize and evaluate two new borohydride-ammonia borane complex hydrides, Li$_2$(BH$_4$)$_2$NH$_3$BH$_3$ (Figure 3) and Ca(BH$_4$)$_2$(NH$_3$BH$_3$)$_2$ [3]. Their structures were determined using a combination of XRD and DFT calculations. Both structures are composed of alternating layers of borohydride anions and ammonia borane. Examination of bond lengths indicates ammonia borane ligands are stabilized in the structures mainly via dihydrogen bonding and interactions with their surrounding cations. Our experimental results show that more than 10 wt% and 11 wt% hydrogen can be released from Li$_2$(BH$_4$)$_2$NH$_3$BH$_3$ and Ca(BH$_4$)$_2$(NH$_3$BH$_3$)$_2$, respectively. Negligible ammonia was detected compared to ammonia borane and its amidoborane derivatives. Further improvements are needed to reduce borazine emission. Cycling studies show that Li$_2$(BH$_4$)$_2$NH$_3$BH$_3$ and Ca(BH$_4$)$_2$(NH$_3$BH$_3$)$_2$ can be partially rehydrogenated under hydrogen pressures at high temperatures.

We have collaborated with the universities of Stanford and Maryland to help characterize hydrogen concentration profiles in thin Mg films. We have continued our measurements of the hydrogen cycling of a single (25 nm Pd-capped) 100 nm Mg layer on a sapphire substrate. Under typical conditions of 343-373 K and 0.1 MPa H$_2$, neutron reflectivity results indicate an expansion of the Mg layer upon hydrogenation to MgH$_2$. This expansion remains upon dehydrogenation of the MgH$_2$ layer, suggesting that the regenerated Mg layer possesses a porous morphology.

The thermodynamic Calphad database has been updated and expanded to include descriptions for the solid phases MgB$_{12}$H$_{12}$ and Li$_2$B$_{12}$H$_{12}$. Experimental data for the ternary hydride phases are extremely sparse. For developing the thermodynamic descriptions of these phases, data from first-principles calculations provided by members of the Theory Group were used to supplement the experimental data. The heat capacity was obtained from the previously developed modification of the Neumann-Kopp rule. The phase descriptions were refined by adjusting them to the available reaction enthalpies and temperatures. The
reported experimental dehydrogenation reactions differ greatly. This is caused by slow reaction kinetics and the potential for the formation of metastable reaction products. These complications result in reduced reliability of thermodynamic descriptions obtained from experimental desorption data. The dehydrogenation path of Mg(BH$_4$)$_2$ is depicted in Figure 4. The calculated reaction path of the desorption of Mg(BH$_4$)$_2$ gives an extremely favorable desorption temperature and released amount of hydrogen, however, this reaction has not been observed in experiments. This indicates that at least some of the reported dehydrogenation reactions are not equilibrium reactions.

The addition of nitrogen to the six component H-Ca-Mg-Li-B-Si databases results in the addition of 6 binary and 15 ternary sub-systems. The evaluation of the literature revealed that for the addition of nitrogen to the database, the descriptions of 49 intermediate phases and 16 gaseous species are needed, but very few data are available. Sufficient data are only available for 6 of the 49 intermediate compounds and 8 of the 14 gaseous species. The evaluation of the Gibbs energy functions of the complex borohydrides showed that the uncertainties from the experimental desorption data are significant. Similar or even larger uncertainties will affect the Gibbs energy functions of most of the nitrogen-containing phases. Therefore, the decision was made not to add nitrogen at this point to the database.

**Conclusions and Future Directions**

- Neutron methods and Calphad computations have provided crucial, non-destructive characterization and predictive tools for the MHCoE.
- X-ray and neutron powder diffraction, neutron spectroscopy, and DFT calculations continued to provide a powerful combination for characterizing the structures and bonding of the dodecahydro-closo-dodecaborates. Spectroscopy was particularly useful to test predicted structures. Work is still in progress to synthesize and characterize anhydrous crystalline MgB$_{12}$H$_{12}$.
- We characterized the rotational dynamics of BH$_4^-$ anions in bulk compounds as a baseline for comparison with the dynamics found for nanoconfined compounds. Changes in rotational dynamics due to nanoconfinement may signal changes in thermodynamic properties.
- We continued to characterize various aspects of nanoconfinement in an attempt to understand its effect on the hydrogen cycling of LiBH$_4$ and indeed observed non-bulk-like effects. We will continue to use SANS to understand the relationship between pore morphology and filling behavior of nanoconfined storage materials.
- We synthesized two examples of a new family of complex hydrides, the borohydrde ammonia boranes, that may have potentially favorable cycling behavior for hydrogen storage.
- We continued to characterize the hydrogen cycling of Mg thin films by neutron reflectometry to understand the fundamental mechanisms involved.
- The thermodynamic Calphad database for Li-Mg-Ca-B-Si-H was expanded to include more gas phase species and ternary hydride phases. Creating a database with Gibbs energy functions from first principles calculations and incorporating it with Calphad descriptions of solution phases will combine the strengths of both methods.

Project Start Date:  April 1, 2005
Project End Date:  Project continuation and
direction determined annually by DOE

Objectives

ORNL is conducting research to develop the
chemistry for a reversible hydrogen storage system
based on complex hydrides, chosen mostly from the
metal borohydrides and ammine/amides/imides of
metal borohydrides, with particular emphasis on the
aluminum complexes of these materials.  These materials
are expected to achieve the DOE/FreedomCAR
performance targets for 2010 as well as 2015.  Research
at ORNL focuses on high hydrogen content materials
(>10 wt%).

Technical Barriers

This project addresses the following technical
barriers from the Hydrogen Storage section of the
Fuel Cell Technologies Program Multi-Year Research,
Development and Demonstration Plan for Fiscal Year
(FY) 2010 and FY 2015:
(A) System Weight and Volume
(P) Lack of Understanding of Hydrogen Chemisorption
and Physisorption

Technical Targets

ORNL is investigating high wt% materials, and
efforts are directed toward making the release and
uptake of hydrogen reversible.  The materials in Table 1
are related materials for reference or materials that have
been investigated by ORNL in the last year (percentages
in table below are for H₂ release only).  The DOE
system targets to which we want to compare are 4.5% hydrogen for 2010 and 5.5% hydrogen for 2015.  The material of interest must allow for a weight penalty for the container.

Accomplishments

Progress was made toward defining the structure
and understanding the mechanism of hydrogen release
from aluminum ammine borohydrides:
• NH₃ adducts of Al(BH₄)₃ are formed both in
  solution and under solvent-free conditions and the
  products depend on reaction conditions (solvent/
solvent-free).
• Quantity of hydrogen desorbed from aluminum
  ammine borohydrides indicates both NH₃ and BH₄⁻
  contribute to hydrogen evolution reaction, and the
  product formed in toluene solvent, Al(BH₄)₃⋅3NH₃⁻,
  evolves as much hydrogen as a function of
temperature as ammonia borane, NH₃BH₃.
• Structure of product formed during reaction of
  Al(BH₄)₃ with NH₃ in diethyl ether gives insight into
  the reaction mechanism for hydrogen desorption,
  and the use of deuterated ammonia (ND₃) shows
  first hydrogen evolved is deuterium hydride
  (indicating equal contributions from ND₃ and BH₄⁻).
• Solid state magic angle spinning-nuclear magnetic
  resonance (MAS-NMR) spectroscopy (collaboration
  with the California Institute of Technology
  [Caltech] and Jet Propulsion Laboratory [JPL]) of
  the hydrogen desorption reaction products show
  definitively that (1) Al metal is not a product and (2)
  a boron-nitride polymer is formed.

☐ ☐ ☐ ☐ ☐ ☐ ☐ ☐
Introduction

The focus of work at ORNL is the development of new materials, synthetic methods for materials, and studies of chemical reactions and processes that will lead to materials that will achieve the DOE/FreedomCAR performance targets for 2015. ORNL is developing new materials, developing synthetic methods to prepare materials, and studying chemical reactions that will lead to materials that reversibly store hydrogen. Our research takes advantage of expertise in handling oxygen and moisture sensitive reagents, knowledge of reaction pathways in solution, and insight into mechanisms of reactions and catalytic pathways. The research at ORNL emphasizes high hydrogen content materials (>10 wt% hydrogen).

In past work the thermal decomposition of Al(BH₄)₃ was studied in some detail in an effort to determine the dehydrogenation mechanism. In these studies we concluded that Al(BH₄)₃ follows a step-by-step loss of BH₃ during pyrolysis, ultimately producing AlH₃ and diborane (or higher borohydride clusters) which undergo their own thermal decomposition to form hydrogen, aluminum and a (BH)n polymeric residue. At 150°C, diborane is the predominant product but hydrogen becomes the dominant product as the temperature is increased. At 300°C and higher, the rate of decomposition of AlH₃ and diborane to form products (H₂) is fast compared to loss of BH₃ from Al(BH₄)₃.

Approach

Our research involves materials from both known synthesis as well as those from newly designed synthetic procedures. The primary method used to follow the progress of reactions which release hydrogen is temperature programmed pressure measurements where gaseous reaction products other than hydrogen are analyzed using a mass spectrometer or by infrared spectroscopy. Hydrogen desorption and uptake are investigated in a traditional Sieverts apparatus. Fourier transform infrared (FTIR) spectroscopy, X-ray diffraction (XRD), and elemental analysis by inductively coupled plasma atomic emission spectroscopy as well as solution NMR are available at ORNL to characterize solid reaction products, and Raman and solid-state NMR are available through collaboration with Metal Hydride Center of Excellence partners. During this year ORNL obtained a thermogravimetric analyzer (TGA) which is housed in a glove box (<1 ppm H₂O and O₂) with capability of analysis of the evolved gas by mass spectrometry. Structural determination using high resolution synchrotron-based XRD is available through internal collaboration at ORNL. Each material will initially be examined in a dehydrogenization study, both with and without catalysts. Those materials found to be suitable hydrogen storage material candidates will then be examined for regenerative (hydrogen absorption) capability. From these results, chemical (and-or procedural) adjustment to the most promising of the materials will be made in order to obtain the optimal in hydrogen de/absorption capacity.

Results

Most of the experimental work in the last year has been concerned with characterization of the products of the reaction of ammonia with aluminum borohydride. We have previously reported that a rapid, solvent-free reaction occurs between Al(BH₄)₃ and NH₃

\[ \text{Al(BH₄)₃} + 2 \text{NH₃} \rightarrow \text{Al(BH₃)₂}2\text{NH₃} \]

The structure of the product is not known with certainty but it is thought to be a trigonal bipyramid with axial NH₃ ligands and equatorial BH₃ ligands. The separation of ammonia with aluminum borohydride in solvents gives different products from the solvent-free reaction. Al(BH₄)₃ was previously reported by Bird and Wallbridge [1] to react with anhydrous ammonia in a 1:2 ratio in the absence of solvent to form Al(BH₃)₃(NH₃)₂ which is believed to have a trigonal bipyramidal geometry about the Al(III) center with axial NH₃ groups. The theoretical hydrogen content of this material is 17.2 wt% and we have observed that hydrogen is evolved at a lower temperature than from the parent compound, Al(BH₄)₃. The total hydrogen evolved is 15.2 wt% upon heating to 550°C. From the large amount of H₂ evolved it is apparent that both the BH₄⁻ and NH₃ groups are reactive.

This Al(BH₃)₃(NH₃)₂ compound was also prepared using N-15 enriched ammonia, ¹⁵NH₃, and deuterated ammonia, ND₃. The normal isotopic composition ammonia and N-15 enriched compounds was supplied to our collaborators at JPL and CalTech for analysis by solid-state NMR. Solid-state NMR measurements of ²H, ¹¹B, and ²⁷Al as well as the ¹⁵N resonances were determined for the starting diamine as well as at various stages of dehydrogenation. At complete dehydrogenation the ¹⁵B MAS-NMR signal is clearly consistent with the formation of a (BH-NH₃)ₙ polymer, and there do not appear to be any clearly distinguishable intermediates with distinctly different resonances between the starting material and the final product. The ²⁷Al NMR indicates that Al metal is not a product of thermal degradation under the circumstances of gas evolution into a vacuum. Unfortunately the ¹⁵N NMR of the enriched ammonia adduct was not definitive.

Mass spectrometry of the evolved gas from the ND₃ derivative is particularly helpful in assigning observed peaks to individual chemical species. The initial hydrogen which is evolved has mass 3, indicating one hydrogen atom originates from ND₃ and one originates from BH₄⁻. We observe trace amounts of borazine, a cyclic six membered ring species in which three of
the hydrogen atoms are deuterium, (ND-BH)_4. It is interesting that up to approximately 200°C, there is no definitive evidence for exchange of hydrogen between B and N. The challenge of future work is stop the reaction at a stage that will allow the reaction to be reverse, and that will be the focus of work in the latter part of FY 2010.

The reaction of Al(BH_4)_3 with NH_3 in toluene gives a product which has an XRD pattern different from the ammonia adduct in the solvent free reaction; the elemental analysis of the product suggest the composition is Al(BH_4)_3•5NH_3. Bird and Wallbridge [1] indicate two moles of NH_3 react with aluminum borohydride in the stoichiometric ratio. However, the species [Al(NH_3)_6](BH_4)_3 in which aluminum is octahedrally coordinated by six ammonia ligands, is formed with excess ammonia. Both the FTIR spectrum and the XRD pattern of our product show the hexamine is not formed. High resolution XRD of this compound was obtained at the National Synchrotron Light Source at Brookhaven National Laboratory. A preliminary solution of the structure which was reported at the annual merit review meeting last year is now believed to be in error. The correct structure is now believed to have two coordinated borohydride groups and three coordinated ammonia groups along with one ionic borohydride group, [Al(BH_4)_2(NH_3)_3][BH_4]. The tentative structure is shown in Figure 1. Preliminary calculations by B. P. Hay [2] confirm that this structure is an energy minimum with additional stabilization provided by hydrogen bonding between the ionic borohydride group and the coordinated ammines.

The infrared spectra of the compounds we prepared from reaction of NH_3 with Al(BH_4)_3 either in the absence of solvent or using toluene as the solvent are roughly in agreement with the spectrum which was reported in the literature by Bird and Wallbridge for Al(BH_4)_3(NH_3)_2 or for Al(BH_4)_3NH_3. Figure 2 shows the normalized FTIR spectra of our two compounds along with the difference spectrum. As a first approximation, the spectra of the two compounds have a lot of peaks in common, and we anticipate that the structures of the two compounds are not vastly different. The infrared spectrum of [Al(NH_3)_6](BH_4)_3 as reported by both Bird and Wallbridge and by Semenenko is quite different from what we have observed, and along with the XRD serve as definitive evidence to prove that our compounds are not [Al(NH_3)_6](BH_4)_3. The spectrum of the material synthesized from toluene, Al(BH_4)_3(NH_3)_3, has less bands than the solvent free preparation. The high resolution XRD structure determination shown in Figure 1 has the chemical composition [Al(BH_4)_2(NH_3)_3](BH_4). It is anticipated that if this structure is correct, distinctive B-H stretching vibrations characteristic of uncoordinated borohydride will be observed, but these vibrations appear to be absent. Thus further

FIGURE 1. Structure of [Al(BH_4)_2(NH_3)_3](BH_4) with B and N atoms shown as green and blue spheres respectively. The position of H atoms was not refined.

FIGURE 2. The FTIR spectra of the solvent free preparation Al(BH_4)_3•2(NH_3) (green) and the synthesis from toluene [Al(BH_4)_2(NH_3)_3]BH_4 (red) are shown (KBr pellets, protected from air) Calculated difference spectrum (black) is shown at the bottom as negative peaks.
characterization of this very interesting and high hydrogen content material is warranted.

Conclusions and Future Directions

The adducts of ammonia with aluminum borohydride are high hydrogen content materials in which both the ammonia and borohydride groups contribute to hydrogen evolution, but the product depends on the reaction conditions:

- Refine the elemental analysis of the aluminum ammine borohydrides and precisely determine the amounts of gaseous products in the reaction of ammonia with aluminum borohydride in solvents (toluene and ether).
- Multinuclear solution and solid MAS-NMR of aluminum ammine borohydrides will be used to identify intermediates in desorption reactions.
- TGA with evolved gas analysis by mass spectrometry will be implemented to follow reactions of ammine metal borohydrides and identify intermediates.
- Continue study of aluminoboranes in collaboration with J.-C. Zhao, Ohio State University.

California Institute of Technology (Caltech),
Solid-State NMR Facility, Pasadena, CA
Project Start Date: April, 2005
Project End Date: September, 2010

Objectives

- Develop and demonstrate light-metal hydride systems that meet or exceed the 2010/2015 DOE goals for on-board hydrogen storage.
- Validate initial storage properties and reversibility in light element hydrides by providing identification of phases and reaction pathways.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (MYRDDP):

(A) System Weight and Volume
(D) Durability/Operability
(E) Charging/Discharging Rates
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

The clearest representation of technical progress would probably be given by the maximum reversible fraction of the material systems investigated, with the relevant 2010 target listed in the MYRDDP as 4.5% reversible H₂ content by weight in the engineered system. The material encapsulated in that system, obviously, must possess a higher content of H₂, perhaps in the 9-12% range. For several reasons, the Ca(BH₄)₂ system (theoretical 12 wt%) that was promising in prior years has shown several serious issues with its development. Turning to other systems as described below, some attention has been given to elucidating reaction processes and answering questions about capacities and charge/discharge rates (i.e., kinetics).

Accomplishments

- Via magic angle spinning – nuclear magnetic resonance (MAS-NMR) and thermo-volumetric methods, provided phase characterization, kinetics (i.e., diffusion behavior), and reversibility assessments in numerous systems (i.e., Mg-B-H, Ca-B-H + C-aerogel, Al-B-N-H).
- Investigated the effectiveness of specific additives (ScCl₃, TiF₃) on the desorption/absorption kinetics of the Mg(BH₄)₂ system by the use of MAS-NMR. Positive effects on the desorption kinetics were seen with 5 mol% of either additive, as well as an effect on the Mg(BH₄)₂ α to β phase transition and the production of borohydride (BH) intermediates.
- Determined that several pathways for boron products exist in the reaction pathways of hydrogen-metal BH systems. NMR is capable of determining the presence and activity of such products as MgB₂, MgB₁₂H₁₂, and amorphous boron “composites” within the Mg(BH₄)₂ system.
- Investigated the reactivity, capacity, and kinetic performance of the Al(BH₄)₃·2(NH₃) system. The total available H₂ capacity of this system has been shown to exceed 9% H₂ by mass at 350°C, with 7% available at 250°C.
- Continuing an Oak Ridge National Laboratory (ORNL)/Caltech/JPL study on the Al-B-N-H system, utilized ¹⁵N in the form of preparing labeled chemistries suitable for ¹⁵N NMR spectroscopy. Such detail proved necessary for elucidating the N-environments in the product, the precise chemical structure of which is still difficult to determine.

Introduction

Activities at JPL under the auspices of DOE’s Metal Hydride Center of Excellence (MHCoE) are designed to contribute to the development of light-
metal hydride systems that meet or exceed the DOE/FreedomCAR technical targets for on-board reversible hydrogen storage. JPL performs in several different roles in the Center. The major portion of the effort at JPL is dedicated to validating initial storage properties (2010 target: >4.5 wt% reversible gravimetric, 28 g/l volumetric hydrogen capacity) of novel light element metal hydrides including destabilized hydride systems containing LiH, MgH₂, and LiBH₄, complex amide/imides, BH₃, and AlH₃-based hydrides as well as other promising samples provided by many MHCoE partners; significant attention in the latter part of the project has been paid to the metal BHs with Mg, Ca, Sc, and Al cations, as well as dual-cation systems. Along the way, the fundamental role of the B₁₂H₁₂₂⁻ anion and associated intermediate reaction pathways in preventing reversibility has been elucidated. Throughout, JPL has had a role within MHCoE to assess the reversibility and durability of the more promising hydrides during cycling.

In the course of these tasks, various solid-state NMR studies and other analytical techniques were used to assess promising “catalyzed” complex hydrides including alanates and BHs for their kinetics and reversibility to improve their practical hydrogen storage potentials. Such techniques have proven quite powerful for characterization of hydrogen and metal diffusion behaviors as well as critical phase transformation processes, often providing insight into chemical processes, configurations, and reaction pathways otherwise impossible to determine via other analytical spectroscopic methods.

**Approach**

JPL’s participation in the MHCoE continues as a widespread effort, involving all the individual projects within the Center scope. In the area of complex anionic materials, JPL continues to work closely with Sandia National Laboratories as an investigation into the Mg(BH₄)$_2$ system enters its final phases; metal BHs from ORNL and Ca(BH₄)$_2$ from United Technologies Research Center (UTRC) have also been part of JPL’s recent collaborative role.

A comprehensive materials development and characterization project continues to be the central focus of JPL’s many roles in MHCoE. Of primary importance is the use of thermo-volumetric measurements to determine hydrogen storage capacities and equilibrium pressures on destabilized nanophase and complex metal hydrides. In addition, powder X-ray diffraction may be used at JPL to determine material compositions where applicable. In collaboration with the Solid-State NMR Facility at Caltech, MAS-NMR measurement techniques can be applied; these measurements are crucial for gaining an understanding of phase compositions and bonding characteristics in these material systems. Caltech also provides the capability for Raman spectroscopy measurements for the elucidation of additional material characteristics; some of these, such as hydration state and bond parameters, are subtle and can provide good correlation with other techniques applied by the JPL-Caltech team.

**Results**

Under the guidance of MHCoE Project B (Complex Anionic Materials), JPL performed work relating to phase identification and reaction pathway discovery of various BHs. Samples of Ca(BH₄)$_2$ scaffolded with carbon aerogel were provided by partners at UTRC; these samples represented materials both as-made (38% by weight of the BH) and following several cycles of hydrogenation. JPL/Caltech were unable to determine a definitive effect on the use of C-aerogel as a scaffolding/encapsulation agent. In Figure 1, MAS-NMR shows the presence of the now familiar [B₁₂H₁₂⁻] intermediate as well as localized B-O bonding following several cycles of hydrogen absorption. Other than a partial peak shift, no improvement in performance was seen. It should be noted that the B-O bonding could be due to contamination of the parent sample by air.

Together with partners at Sandia National Laboratories, JPL/Caltech engaged in the study of the effects of various additives (ScCl₃, TiF₃) on the kinetics and reversibility of the Mg(BH₄)$_2$ system. Figure 2 shows a marked effect on the room-temperature stability of Mg(BH₄)$_2$, where an α to β phase transition is interpreted as a positive effect on reaction kinetics in this system due to the presence of the additives. Similarly, Figure 3 shows a high-temperature phase transition at 413 K, 40 K lower than the neat parent material; improved kinetics are a result. NMR has also elucidated the family of intermediates in this

![FIGURE 1. $^{11}$B MAS NMR spectra illustrating the presence of the \([\text{B}_12\text{H}_{12}]^{2-}\) intermediate as well as localized B-O bonding in the Ca(BH₄)$_2$ + C-aerogel system.](image-url)
system; Figure 4 suggests that the presence of additives in this system have differential effects on the possible intermediates.

JPL has continued to investigate novel Al-B-N-H chemistries with partner ORNL; during 2009-2010 the focus has been on the compound Al(BH$_4$)$_3$·2(NH$_3$)$_2$, which was synthesized at ORNL using wet chemistry methods. This material was characterized using JPL’s Sieverts’ apparatus. For the purposes of NMR investigation, versions of this system were also synthesized in the form Al(BH$_4$)$_3$·2(15NH$_3$)$_2$, as the 15N is a more NMR-active nucleus than the normal isotopic form. Several of these samples were reacted at ORNL and characterized using Caltech’s NMR facilities. Figure 5 shows the results of the desorption of the as-made material at JPL in two steps, allowing...
for intermediate NMR sampling; the total available H₂ content was greater than 9% by mass. Figure 6 shows the \(^1\)H and \(^{11}\)B NMR spectra of the samples reacted at ORNL; \(^{11}\)B MAS NMR of the samples show a trend similar to Mg(BH₄)ₓ•2(NH₃) cases where BH₄ units release hydrogen to form B-N-H polymeric species. Investigations of specific samples enriched with \(^{15}\)N show two distinct NH₃ bonding environments as well as apparent B-N-H bonding activity at higher temperatures (~200°C), but more study is required to resolve these details. As also shown in Figure 7, there is the suggestion of multiple Al bonding sites as well, suggesting perhaps a medium-range order to the material. Again, more study is desired. This material system continues to prove interesting, even though the formation of the dodecaborane intermediate still seems difficult to avoid.

**Conclusions and Future Directions**

As currently planned, this is the last year of record for JPL’s participation in the MHCoe project. As the effort closes out, JPL plans to continue...
certain specific lines of investigation while preparing closeout documentation and ensuring the archiving of information produced under this effort. Special attention will be given to feeding information to the Hydrogen Storage Engineering Center of Excellence, a parallel DOE project that also includes JPL.

E-mail: Ned.Stetson@ee.doe.gov

Project Start Date: Oct. 1, 2007
Project End Date: June 30, 2010

Objectives

- Determine the sorption kinetics for the transition metal-catalyzed 2LiH+Mg(NH$_2$)$_2$+MgH$_2$ system under the full spectrum of temperatures and pressures required for hydrogen storage system design.
- Explore the effect of catalyst loading on both charge and discharge reaction pathways and kinetics as well as ammonia release.
- Identify reversible hydrogen storage compounds in the mixed metal/amide-borohydride system.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan in descending order of impact:

- System Weight and Volume
- Charging/Discharging Rates
- Fuel Purity
- System Fill Time
- Minimum Hydrogen Delivery Rate

Accomplishments

- Desorption products in all cases considered appear to be the same (mixture of LiCl, Mg$_3$N$_2$, LiMgN and a minor amount of an unidentified phase [<5%]).
- All chemical modifications tested thus far, while significantly increasing desorption rate in the first cycle, have been shown to have no effect on sorption kinetics after the third cycle.
- A characteristic charging time (t$_{80}$) of 30 minutes, calculated for the isothermal charging results, is faster than those presented for this material elsewhere in the literature.
- Processing methods have been shown to greatly affect sorption kinetics and capacity with high energy processing leading to formation of NH$_3$ and loss of capacity (6.66 wt%) while lower energy processes minimizing NH$_3$ release and resulting in higher capacities (8.0 wt%) and sorption kinetics.
- Additions of TiN have been shown to increase the release temperature of NH$_3$ from 220 to 250°C.
- The formation of mixed bi-metallic amides/borohydrides have resulted in lower dehydrogenation temperatures and reduced ammonia release compared to the individual amide or borohydride materials.

Introduction

In an effort to identify and synthesize a reversible metal hydride material capable of meeting the 2010 and 2015 DOE FreedomCar technical targets, researchers are investigating various metal hydrides/catalyst combinations. To date, the most promising in situ reversible compound stemming from the Metal Hydride Center of Excellence (MHCoE) is 2LiH/MgH$_2$/Mg(NH$_2$)$_2$ [1,2]. This compound resides among a series of similar compound stoichiometries ranging from Li:Mg ratios of 1:1 through 4:1 [1-7]. It has been found that the greatest hydrogen absorbing material is 2LiH+Mg(NH$_2$)$_2$+MgH$_2$ which decomposes to LiMgN plus 8.1 wt% H$_2$ [1] with a calculated enthalpy of desorption of 32 kJ/mole H$_2$. This composition has
been reported to be reversible under fairly moderate conditions (160°C – 220°C for dehydriding, 160°C and 2,000 psi for rehydridding) [1]. This study of the LiMgN used an autoclave-type high-pressure charging apparatus and transient thermogravimetric analysis (TGA) measurements to confirm hydrogen storage capacities. The work reported here was designed to compliment the work of Lu et al. [1], by thoroughly measuring the isothermal kinetic hydrogen charge and discharge rates and further optimizing the kinetics through compositional adjustments.

Additionally, materials of the form $M^1M^2(BH_4)\text{y}(NH_2)_z$, where $M^1=\text{Li, Na, K and } M^2=\text{Mg, Ca, Ti and/or other}$ transition metals are of interest for their high hydrogen storage as well as potential novel phase properties. New materials of these di-anionic species such as Li$_2$BH$_4$(NH$_2$)$_2$, Mg$_2$NH$_2$, and Ca$_2$NH$_2$ have been identified, which have been found to discharge initial hydrogen from the amide complex at lower temperatures with the borohydride present.

**Approach**

**LiH/Mg(NH$_2$)$_2$**

The previously identified LiMgN material was studied by ball milling the precursor LiNH$_2$ and MgH$_2$ materials with the various modifiers to ensure a well-mixed and controlled initial state in terms of particle size. Material for this study was Frisch milled with a ball mass to material mass ratio of 30:1, following the work of Lu [1]. A Seivert’s apparatus was used to measure the isothermal kinetic rates of hydrogen charge and discharge. The present studies are intended to provide a detailed understanding of the isothermal kinetics of charging and discharging of the material, in addition to tabulations of the weight percent of hydrogen stored under specified conditions. The parameters that are explored in the current study are charge and discharge temperature, charge pressure, and the composition of the modifiers used to activate the material.

**Mixed Amide/Borohydrides**

The synthesis of materials was accomplished by ball milling one component metal borohydride (Ca(BH$_4$)$_2$, Mg(BH$_4$)$_2$) with another metal amide (LiNH$_2$). This is also extended for metal amides (Ca(NH$_2$)$_2$, Mg(NH$_2$)$_2$) with lithium borohydride (LiBH$_4$). These precursors such as LiNH$_2$, LiBH$_4$, and Mg(BH$_4$)$_2$ are available commercially through Aldrich, with others such as Mg(NH$_2$)$_2$ and Ca(NH$_2$)$_2$, prepared by the ammoniation of Mg and Ca inside a high pressure reactor. Once the desired metal hydrides are ball milled, powder X-ray diffraction (XRD) was used as the initial screening tool. Furthermore, thermo-gravimetric analyses, in conjunction with mass spectroscopy, was used to verify mass loss vs. temperature and identify the gas decomposition products as a function of temperature. Fourier transform infrared (FTIR), Raman scattering and nuclear magnetic resonance were used to verify investigate the characteristics of new formed compounds.

**Results**

**LiNH$_2$/MgH$_2$ Kinetics**

Previously, this study reported the charge and discharge profiles for precursor materials LiNH$_2$ and MgH$_2$ in a 1:1 mole ratio with 0.67 m% TiCl$_3$ catalyst loading. These profiles were measured using a Sievert’s apparatus under isothermal conditions. Previous MHCoE work [1,2] on this material indicated the presence of a LiMgN phase which was not confirmed in this work. Instead, a Mg$_x$N$_y$ partially substituted (Li,Mg)$_x$N$_y$ phase was detected using powder XRD. Other researchers have observed the presence of alternate discharge products in this system as well [8]. A standard discharge condition of 280°C into a nominal 1 bar back pressure for ~8 hours was selected (D-280°C/1 bar/8 hrs), along with a standard charge condition of 180°C under a nominal 150 bar pressure for 6 hrs (D-180°C/150 bar/6 hrs). These conditions were selected to reach maximum charge and discharge capacities in a single work day and were used to compare differing compositions, catalysts etc. A traditional kinetic analysis on the 0.67 m% TiCl$_3$ doped material yielded an activation energy for hydrogen discharge of ~60 kJ/mol. A Johnson-Mehl-Avrami approximation was performed that indicated the reaction mechanism changes at least once during discharge cycle. Preliminary isocconversional kinetic analysis is consistent with the Johnson-Mehl-Avrami analysis, indicating that the discharge reaction occurs via a multi-step mechanism.

In order to investigate the effect of various modifiers, material was prepared at the stoichiometric ratio of LiNH$_2$:MgH$_2$ (1:1) with 1.5 mol% TiCl$_3$, VCl$_3$, ScCl$_3$, NiCl$_2$, or TiN added. The initial decomposition data for the modified material are shown in Table 1. By adding a modifier, the initial hydrogen desorption temperature of the began between 105°C and 120°C, lower than the 135°C release temperature for the unmodified material. Compositional additions also greatly affect ammonia release. As seen in Table 1, the mixtures with TiCl$_3$, VCl$_3$, ScCl$_3$, and NiCl$_2$ released ammonia at temperatures lower or equal to the unmodified material, approximately 230°C. Through a metathesis reaction between LiNH$_2$, and transition metal chlorides, modification resulted in the formation of LiCl and a transition metal through the release of NH$_3$. For all additions other than TiN, the H$_2$ and NH$_3$ peaks were coincidental. TiN additions decoupled the these two peaks, substantially increasing the NH$_3$ peak by
20°C while maintaining the H₂ peak at 270°C. Lai-Peng Ma, et al. have reported that for the 2:1 LiNH₂:MgH₂, the defective metal-N pairs in transition metal nitrides (specifically TaN and TiN) act as active sites in favor of dissociating the N-H bond of the amide in the system, which then promotes the generation of reactant species [9]. This suggests that TiN is not only effective at reducing the temperature of hydrogen release but also as acting as an ammonia mitigant.

The bed discharge rates were calculated on a mass-specific basis, determining from data the quantity of hydride bed that would be required to store 5 kg of hydrogen. From these data, it was observed that after two sorption cycles (see Figure 1), the modifier composition has little effect on the discharging rate. This was determined to be due to the metathesis reaction between the metal chlorides and LiNH₂.

To optimize the cycling conditions, a desorption temperature study was conducted on the unmodified LiNH₂:MgH₂ mixture, as seen in Figure 2.

A strong effect of discharging temperature on the discharge rate is observed, with a more linear rate observed for the 200°C. The discharge rate associated with 200°C is a third of the 2010 DOE technical target of 3 gH₂/s.

**Mixed Amide/Borohydrides**

Figure 3 shows the TGA results of Ca(NH₂)₂, LiBH₄, and various mixtures of Ca(NH₂)₂/LiBH₄. The unmodified samples show a much higher onset of decomposition with respect to the mixtures. The addition of more Ca(NH₂)₂ resulted in a single decomposition similar to the starting amide material. This was also true for 3LiBH₄:Ca(NH₂)₂, which had a 2-step decomposition reaction, but at a significantly lower temperature than pure LiBH₄. These samples were characterized using mass spectroscopy and XRD. From mass spectroscopy, the addition of LiBH₄ reduces the release of ammonia and increases the amount of hydrogen released. Similar results were found with the addition of Mg(NH₂)₂, but the initial decomposition of

**TABLE 1.** Summary of TGA/residual gas analysis decomposition data of the as-milled 1:1 LiNH₂:MgH₂ samples without and with various additions while heating from 30°C to 400°C at 5°C/min.

the mixtures occur at a higher temperature. Isothermal Sievert's measurements were also conducted to evaluate the mixture's cyclic characteristics compared to their respective starting materials.

Conclusions

LiMgN

- Desorption of LiMgN at 200°C resulted in a constant discharge rate over four isothermal cycles.
- Discharge rate of a hydride bed at 200°C is a third of the 2010 DOE technical target of 3 gH₂/s.
- Desorption at 260°C and above leads to the loss of essential nitrogen.
- Metathesis reaction between LiNH₂ and metal chlorides resulted in the loss of nitrogen through ammonia release and the loss of capacity with the formation of LiCl.
- Desorption products were identified as a mixture of Li₅Ca(BH₄)ₓ(NH₂)ᵧ, Mg₃N₂, LiMgN with a minor amount, <5% of an unidentified phase.
- TiN shows promise as a modifier by increasing the temperature of ammonia release.

Mixed Amide/Borohydrides

- Ca(NH₂)₂ and Mg(NH₂)₂ have been successfully synthesized with >95% purity through direct ammoniation.
- Mixtures of Mg(BH₄)₂ and LiNH₂ have shown good absorption capabilities but limited kinetically on desorption through two cycles.

- Mixtures of Mg(BH₄)₂ and LiNH₂ contain multiple H₂ releases, with reduced release of NH₃.
- Raman has confirmed that a new compound is formed in mixtures of NH₃BH₃ to Ca(BH₄)₂ and LiNH₂.
- Initial results show desorption of H₂ as low as 150°C for the mixture of Ca(BH₄)₂:LiNH₂:NH₃BH₃.

Future Directions

- Complete temperature and pressure dependence on absorption rates.
- Test other catalysts to render faster kinetics, lower temperatures of operation (e.g. KH, LiH, LiBH₄, nano-Ti, etc…).
- Analyze the purity of the discharged H₂ as a function of temperature using FTIR.
- Identify structures and compositions of Li₅Ca(BH₄)ₓ(NH₂)ᵧ, Mg₃N₂, LiMgN with a minor amount, <5% of an unidentified phase.
- Synthesize and characterize LiMg(BH₄)ₓ(NH₂)ᵧ, LiCa(BH₄)ₓ(NH₂)ᵧ, and LiBH₄ as precursors for synthesis of Mg(NH₂)₂ and Ca(NH₂)₂ with LiBH₄.
- Characterize structures and compositions of LiCa(BH₄)ₓ(NH₂)ᵧ, Mg₃N₂, and LiMgN with a minor amount, <5% of an unidentified phase.

Project Start Date:  October 1, 2005
Project End Date:   September 2010

Objectives

- Determination of the effect of ppm level impurities in H₂ gas as well as the effect of impurities and defects in light-weight storage materials.
- Evaluate the long-term durability of light weight Li-N-based compounds.
- Understand the reaction pathways for both developing new materials with enhanced hydriding properties, modifying or controlling reaction pathways for improved performance.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(D) Durability/Operability
(E) Charging/Discharging Rates

(K) System Life Cycle Assessments
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

This project is conducting fundamental studies of light-weight hydrogen storage materials, particularly of the Li-N-H system. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2010 hydrogen storage targets:

- System Gravimetric Capacity: 1.5 kWh/kg
- Storage System Cost: $4/kWh net
- Cycle Life (1/4 tank to full): 1,000 cycles

Accomplishments

- Determined causes for loss of cycle in Li₃N-H₂ system, using calculation of phase diagrams (CALPHAD) thermodynamic modeling and experiments.
  - It was determined that there was continuous loss of nitrogen from solid phases during the dehydrogenation cycle, leading to formation of rather stable LiH phase which traps the hydrogen at operating temperature of 528 K (255°C), consequently los of cycle life.
  - Significant cycle life improvements were achieved by using mixtures of H₂ and N₂ gases; using 80/20 molar mixtures of H₂/N₂; we obtained near starting Li₃N-H₂ reversible capacity of ~10 wt% H at 255°C after 516 cycles.
  - Critical phase reaction pathways determined using progressive incremental loading of hydrogen in Li₃N, supported by CALPHAD developed Li-N-H phase diagrams.
  - Determined the formation of the Li₃NH phase at room temperature; this phase is stable up to 5 wt% H and is a peritectically decomposed phase observed at 25°C.
  - Details of the amount of LiH phase formed under equilibrium loading of hydrogen determined.
  - New higher capacity cubic phase of Li₁₂₋ₓNH₁ₓ type was found.
  - Improved kinetics observed at higher pressures in the Li-N-H system.

IV.A Hydrogen Storage / Metal Hydride CoE

Introduction

Trace amount (ppm levels) of gaseous impurities in ultra-high purity (UHP) hydrogen may lose in hydrogen capacity in solid state storage of hydrogen in complex hydrides. To evaluate these effects we performed extrinsic thermal cycling with impure hydrogen; these tests are rather long. We also performed thermal aging where necessary. These tests are important for long-term reliability of metal hydrides that is important for working towards achieving DOE technical targets for a hydrogen economy. In general, hydrogen is used in research laboratory for the development of metal hydrides. However, the commercial hydrogen will always have some very low level impurities (ppm levels); typically O₂, H₂O, CH₄, N₂, hydrocarbons, and others in hydrogen. Typical industrial grade hydrogen, that we used showed: “Hydrogen min % (v/v) 99%, others in industrial grade hydrogen, hydrogen. Typical hydrocarbons: 10 ppm, CO₂ ~10 ppm, CO ~10 ppm, water ~32 ppm, O₂ ~400 ppm, total hydrocarbons: 10 ppm, CO ~10 ppm, CO ~10 ppm, argon may be present, reads as oxygen.” We also used special 100 ppm O₂, mixed with UHP hydrogen in this study. These low level impurities affect the performance of hydrogen storage materials in the hydride beds that are installed in automobiles. The purpose of the pressure cycling experiments (with fresh charges of impure hydrogen) is to simulate the long-term performance of metal hydrides if there are trace amounts of impurities in the hydrogen. Parallel contamination studies are essential for evaluation impurity effect, before design of any hydride bed for a vehicular application containing complex hydride materials. The degradation of the hydriding properties are generally associated with disproportionation or decomposition of hydrides surface or bulk properties of the material during normal periodic charges of impure hydrogen. These studies are expected to lead to the understanding of mechanisms that occur after “hydrogen filling” in tanks numerous times. In another situation, for example, a hydride bed is left unused for a prolonged period of time, i.e., hydrogen is fully loaded in a hydride bed from a gas station, this type of test is called thermal aging; performed at elevated pressures and temperatures.

The objective of this research is to investigate the effect of trace impurities in complex hydrides which can be potentially used for fuel cell and other applications and aid in the development of materials solutions to potential hydrogen sorption degradation problems. The relevance to the Metal Hydride Center of Excellence (MHCoE) is that, trace impurities in hydrogen gas will have an impact on the hydrogen loading capacities during periodic recharging with fresh hydrogen in practical applications. These tests are being performed by accelerated laboratory testing which are extremely useful to understand the reliable use of hydrogen fuel.

The central problem is that Li₃NH will not reverse easily to either Li₄NH or Li₃N, at 255°C, leading to approximately 5.8 wt% H reversible capacity. In addition, a LiH phase forms during hydriding of Li₃N which is difficult to reduce back to Li₃N at 255°C. However, Huq et al. [1] showed that at ~320°C decomposition of LiH→Li,NH was possible. To elucidate the various phase transition mechanisms we developed ternary phase diagrams of Li-N-H at various pressures and temperatures.

We also found that during repeated cycling there was a loss of nitrogen in the system [2]. The data indicated that during the desorption cycle (under dynamic vacuum) we were desorbing nitrogen and hydrogen or possibly LiN gas. Thus, we decided to use mixtures of N₂-H₂ to compensate for the lost nitrogen. Nitrogen compensation cycling results that show up to 10 wt% H reversibility are discussed.

Approach

In this research, we are conducting experiments on cycling and aging tests of materials (as described in the above section) developed by the MHCoE partners. Pressure cycling apparatus was constructed at UNR for hydrogen loading and unloading. The overall approach to perform cycling on currently reversible complex hydrides such as imide/amide system (using Li₃N as precursor), Li amide-alanate that has theoretical hydrogen capacity ranging from ~7 to ~10.5 wt% hydrogen. The specific tasks were to determine the changes in the pressure-composition isotherm after cycling with impure hydrogen. A reference temperature of 255°C and a hydrogen pressure range from vacuum to 2 bar was chosen, based on pioneering research of Prof. Ping Chen’s Nature paper [3].

We have studied the Li-N-H system in which an unusual improvement of hydrogen capacity is observed during pressure cycling at 528 K using mixed nitrogen/hydrogen gases. Without mixing in nitrogen, we observe a loss in hydrogen capacity, from ~10.2 to 3.1 wt% H after 501 cycles, during cycling due to the formation of a small amount of liquid lithium metal which forms a stable LiH phase during each cycle; this leads to a loss of nitrogen that significantly degrades the reversible hydrogen capacity of the Li,N-H system. In this paper we report results from data obtained by prolonged pressure cycling of Li₃N with H₂/100 ppm N₂ and 80/20 H₂/N₂ mixed gases. We observe a significantly enhanced reversible capacity of up to ~10 wt% H after 516 cycles with 80/20 H₂/N₂ mixtures, an improvement of ~7.1 wt% H as compared to using hydrogen with nitrogen additives. We attribute this enhancement to the reaction of nitrogen with liquid lithium during cycling as the Gibbs energies of formation of Li₃N (∆G° = -100.16 kJ/mol) are more negative than that of LiH phase (∆G° = -50.74 kJ/mol). We propose that there is continuous accumulation of the Li₃NH phase and minimizations of LiH formation as these materials...
are subjected to many cycles. The cyclic behavior mechanism of Li₃N with H₂/N₂ gas mixtures is quite a different phenomenon as compared to mechanisms occurring in classical hydrides.

Results

In this study we present the results of hydriding of Li₃N, with no catalyst, under different conditions. In our previous work (Chien et al. Ref. [2]) the results from Li₃N and industrial hydrogen with ppm levels of impurities were discussed. It was found that during pressure cycling of Li₃N with H₂ (under similar conditions as this study) there was a loss of nitrogen during cycling, and LiH formation increased with the number of cycles.

Pressure Cycling With Industrial Hydrogen

Pressure cycling under hydrogen without nitrogen additions showed a steady decline of the hydrogen capacity from ~10.1 to 3.2 wt% H after 501 cycles [2]. The mechanism suggested for this is the formation of LiH due to the loss of nitrogen, possibly in the form of LiN or NH₃, during the (dynamic vacuum) desorption cycle.

To mitigate the effect of lost nitrogen, we used mixtures of hydrogen and nitrogen to observe if the loss of hydrogen capacity was affected. Initially, we used 100 ppm levels of nitrogen in hydrogen. Then we increased the amount to 80/20 H₂/N₂ molar ratio, and finally to an excess of nitrogen 25/75 H₂/N₂.

Nitrogen Compensated Cycling Results

Initial experiments were performed by hydriding Li₃N with (2 bar) hydrogen mixed with 100 ppm nitrogen at 528 K followed by dynamic vacuum desorption for half hour each, in the cycling apparatus. The sample was then transferred to a Sieverts apparatus to obtain isotherms using UHP hydrogen gas after 345, and 853 cycles. Isotherms taken at 528 K and loading up to ~10 bar hydrogen showed that the cycling with 100 ppm nitrogen improved the hydrogen capacity as illustrated in Figure 1. We include data from our previous work designated as “1 cycle H₂,” which was taken after the “zeroth cycle.” When the hydrogen is added to Li₃N for the very first time, we refer to this as “zeroth cycle.” We obtained ~10.5 wt% H capacity, similar to reported by Chen et al. [2]. Then during the very next cycle, referred to as “1 cycle H₂,” the majority of the hydrogen could not be desorbed from the solids; only ~5.8 wt% H is reversibly absorbed. This is due to fact that the rest of hydrogen is trapped in LiH and Li₂NH phase that did not revert back to the Li₃N phase at 528 K. This “1 cycle H₂,” is used as a bench mark isotherm for comparison purposes. We now compare results obtained by cycling Li₃N with H₂-100 ppm N₂ mixed gases, up to 345 cycles, and noted an increase in capacity from 5.8 to ~7 wt% H. A further increase in the number of cycles to 853 led to a further enhancement from ~7 to ~8.5 w.% H (Figure 1). This trend in the increase of the capacity as a function of cycles is quite opposite to what we observed using hydrogen gas with no nitrogen.

In the next set of experiments, we increased the amount of nitrogen by mixing hydrogen with 20 mol% nitrogen (80/20 H₂/N₂ molar mixtures) for the reaction with Li₃N, and obtained an isotherm after 345 cycles as shown in Figure 2. The same sample was used to cycle up to 516 cycles whose results are also shown in Figure 2. In this case we include the data from “zeroth cycle,” from reference [2]. Results show that our 516 times cycled data with 80/20 H₂/N₂ is comparable with “zeroth cycle” data, showing ~10.5 wt% H reversible absorption capacity.

Later, the samples from both the H₂-100 ppm N₂ and 80/20 H₂/N₂ samples were subjected to 1,359 and 850 cycles respectively. We used the samples that were used earlier for these mixtures. However, the results showed a decrease in reversible capacity as compared to the “1 cycle” with industrial hydrogen (not shown, available from the principal investigator on request). Although reversible capacity is 7.2 wt% H after 1,359 cycles, these are better than “1 cycle” (~5.8 wt% H) with no nitrogen additions to hydrogen gas. The decrease at a high number of cycles is thought to be caused by oxygen contamination in the nitrogen gas.
X-ray diffraction (XRD) patterns of the products from desorbed samples obtained from the Sieverts experiments, after cycling, are presented in Figure 3. In the XRD pattern after “1 cycle” with industrial hydrogen, we detected Li₂NH as the major phase along with LiH and Li₂O as minor phases. After 501 cycles with industrial hydrogen, we found a significant increase in the LiH and Li₂O phases, and a decrease in the amount Li₂NH phase (noting that the reversible hydrogen capacity dropped to ~ 3.8 wt% H) [2]. Next, we compare the 516 cycle product from the 80/20 data with the 501 cycle data of industrial hydrogen. It can be seen in Figure 3c that the amount of Li₂NH is significantly higher than the 501cycled hydrogen and also the Li₂O phase is lower in amount, as indicated by the increased intensities of the Bragg peaks. Figure 4(d) show the XRD patterns from 850 cycled 80/20 H₂/N₂ gases, and Figure 4(e) form the 1,359 cycle H₂-100 ppmN₂, taken after the desorption isotherm, yielding similar powder patterns with much higher amount of Li₂O phase. It is possible that the increase in Li₂O phase was responsible for the decrease in H-capacities after prolonged cycling. A plausible reason for this is accidental trapping of air in the volume between the valve and the sample holder of the Sieverts apparatus during switching from the cycling to Sieverts apparatus. But it is surprising and coincidental that both the high cycled materials show similar XRD patterns.

To understand this phenomenon of increased reversibility we constructed ternary Li-N-H phase diagrams using the CALPHAD approach. Results from the FactSage software are shown in Figure 4. The Li-N-H phase diagram at 528 K and 2 bar hydrogen is shown in Figure 4(a). During absorption of hydrogen along the “Absorption pure H₂” line with the arrow pointing towards H, the phases formed in regions where the line intersects in the phase diagram progress as follows in Equation 1:

\[
\text{Absorption at 528 K, 2 bar H}_2 (\text{Figure 4(a)}):
\]

\[
\text{Li}_3\text{N}(s) + \text{H}_2(g) \rightarrow \text{Li}_3\text{N}(s) + \text{Li}_2\text{NH}(s) + \text{Li(liq.) (up to 2.5 wt% H)} \quad \rightarrow \quad \text{LiHp} + \text{Li}_2\text{NH}(s) + \text{gas (>~5 wt% H)}
\]

During desorption, along the H-Li₃N in Figure 4(b) under dynamic vacuum we ideally can go back in a reverse fashion. From the experiments, we note that the reversibility is not complete, in other words there persists always LiH phase as Li₂NH in the residual products. It can be noted that the maximum capacity reported so far is ~11 wt% H [2-6] in the Li₃N-H system. The LiH phase contains ~12.4 wt% H. Theoretically, Equation 1 shows ~8.58 wt% H but the trapping of hydrogen in the LiH phase increases the amount of hydrogen to about 11 wt% H as reported by Chen et al. [3,7,8]. The XRD patterns in Figure 4 are all taken after cooling the...
Cycling lithium nitride with hydrogen containing 100 ppm nitrogen gas showed improved hydrogen storage properties over that cycled without the nitrogen addition. Specifically, the reversible capacity approached ~10 wt% H after 516 cycles, and showed improved cycling stability. We propose that the ability of the nitrogen to have an effect in such small quantities is due to formation of Li,N which transforms to Li,NH. As the number of cycles increases, more Li,NH is formed that leads to an increased hydrogen capacity.

- Cycling with hydrogen containing 20 mol% nitrogen was able to improve the cycling stability over a large number of cycles and allowed the lithium nitride to maintain a capacity close to its starting capacity. A reversible capacity of ~10 wt% at 255°C was observed up to 516 cycles. However, the capacity decreased to ~5.8 wt% H at ~10 bar pressure after 850 cycles; we attribute this to oxidation of the particles due possible entrapment of air during sample transfer.
- CALPHAD modeling showed formation of pure lithium, which reacts with nitrogen to form Li,N in preference to Li,H. The modeling also enabled us to determine the path of reaction at different temperature and pressures.
- In a practical sense, when we load the hydrogen mixed with nitrogen, in batches, in a hydride bed (as opposed to continuous supply) there is always partial pressure of nitrogen gas, but the majority of hydrogen gas is absorbed in the solid complex hydride phases.
- Isothermal data collected using a 25/75 H2/N2 mixture showed that these high nitrogen concentrations tend to stop hydriding processes prematurely, which is thus not desirable.

**Conclusions and Future Directions**

- Cycling lithium nitride with hydrogen containing 100 ppm nitrogen gas showed improved hydrogen storage properties over that cycled without the nitrogen addition. Specifically, the reversible capacity approached ~10 wt% H after 516 cycles, and showed improved cycling stability. We propose that the ability of the nitrogen to have an effect in such small quantities is due to formation of Li,N which transforms to Li,NH. As the number of cycles increases, more Li,NH is formed that leads to an increased hydrogen capacity.

Objectives

- Achieve tunable thermodynamics for high-gravimetric-capacity metal hydrides by creating and stabilizing nanoparticles with controlled size, composition, and properties.
- Develop synthetic routes for reactive metal nanoparticles within crystalline nanoporous materials and block copolymer templates.
- Systematically probe the effects of size and composition to determine the onset and extent of nanoscale effects on the thermodynamics and kinetics of hydrogen sorption.
- Benchmark theoretical approaches to modeling the thermodynamics metal hydride nanoparticles and develop computational tools to guide synthesis.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cells section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(C) Efficiency
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

This project is directed toward developing hydrogen storage materials with desorption thermodynamics and kinetics that can be tuned to meet specific system requirements. The project is based on the hypothesis that confinement of metal hydrides within the chemically and geometrically well-defined pores of nanoporous framework materials such as metal-organic frameworks (MOFs) will destabilize the materials, thereby reducing their \( H_2 \) desorption temperatures and accelerating the kinetics. If successful, the project will address the following DOE technical targets, as outlined in the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

<table>

Accomplishments

- Synthesized a suite of MOF and nanoporous carbon templates with <1 nm to 20 nm pore sizes.
- Developed and refined infiltration methods for simple metal hydrides, e.g. LiH, MgH\(_2\) using
organometallic precursor route, achieving loadings of up to 5.8 wt% Li.

- Demonstrated that both the thermodynamics and kinetics of melt-infiltrated LiBH₄ nanoparticles in 2-nm highly porous carbon are greatly improved with respect to bulk LiBH₄. The onset desorption temperature decreases from 460°C to 220°C (1 bar) and no B₂H₆ impurity is detected.
- Showed that no destabilization of LiH nanoparticles in MOF templates occurs relative to bulk, consistent with quantum Monte Carlo predictions.
- Predicted that (MgAlH₅)ₙ, where n = 1–8, are stable, suggesting that synthesis of this unknown compound in the form of nanoclusters within templates should be feasible.
- Computed the phase diagram of nanocluster NaAlH₄ from first-principles density functional theory (DFT) and nano-PEGS cluster prototypes.
- Predicted that small clusters of AlH₃ increase in stability dramatically, with 1 formula unit of AlH₃ predicted to have a decomposition enthalpy of about 150 kJ/mol H₂.

**Introduction**

Some of the most attractive hydrogen storage materials, such as MgH₂, AlH₃, and LiBH₄, have unfavorable desorption thermodynamics and are either too stable (e.g. MgH₂) or too unstable (e.g. AlH₃) in bulk form to be practical, particularly for vehicular transport applications. However, recent theoretical and experimental results indicate that decreasing particle size can substantially reduce the stability of metal hydrides, leading to lower desorption temperatures. The key challenges that must be addressed are to:

1) develop synthetic routes that provide controlled size and composition;
2) stabilize particles over time; and
3) develop computational tools to guide synthesis that can accurately address particle sizes spanning the micro-to-meso length scales. This project addresses all three challenges and, if successful, will create for the first time nanoscale hydrogen storage materials with tailorable composition and size compatible with fuel-cell materials over a wide range of operating temperatures.

**Approach**

We are using highly ordered, chemically tailorable nanoporous templates to create particles ranging in size from <1 nm to 20 nm, the critical size range at which nanoscale effects are anticipated. These templates are infiltrated with hydride precursors or hydrides themselves, using mild synthetic routes that eliminate template degradation. The resulting template-saturated nanoparticles, are characterized to determine particle size, composition, and desorption thermodynamics and kinetics. Validated computational modeling tools guide synthesis. This approach allows nanoparticle dimensions and hydride composition to be systematically varied, enabling the effects of nanoscale dimensions on hydride thermodynamics to be determined.

**Results**

**LiH@MOF Hydrogen Desorption**

The H₂ desorption behavior of LiH nanoparticles is not very different from the corresponding bulk-phase materials (Figure 1). Using the simultaneous thermogravimetric modulated beam mass spectrometer (STMBMS), which provides mass data for evolved gas-phase species as a function of time under highly controlled temperature conditions, we obtained a detailed picture of the a series of processes occurring during nanoparticle-composite decomposition.

STMBMS data for EtLi infiltrated sample reveal that desorption of C₂H₄ occurs at temperatures between 50-200°C, indicating formation of LiH (Figure 1,
IV.A Hydrogen Storage / MH-Independent Projects

Allendorf – Sandia National Laboratories

The MOF template decomposes at ≈260-350°C. Hydrogen desorption from bulk LiH peaks at ≈580°C in this experiment (Figure 1, bottom). Similarly, H₂ desorption from MOF-confined LiH occurs at approximately the same temperature. This indicates that neither the thermodynamics nor the kinetics of nano-LiH are significantly altered by nanoconfinement. These observations are consistent with our quantum Monte Carlo calculations (see below), which suggest that only clusters as small as (LiH)ₙ, n=1,2 are destabilized. Moreover, these results indicate that, contrary to predictions based on a Wulff construction model [1] (see following), nanoscale LiH is not significantly stabilized by nanoscale confinement. Experiments to quantify the thermodynamic properties of the LiH@MOF are currently underway.

Controlling the Decomposition Pathway of LiBH₄ via Confinement in Highly Ordered Nanoporous Carbon

The decomposition behavior of LiBH₄ has been investigated in the presence of highly ordered nanoporous carbon (NPC) with columnar pores of average pore diameter 2.0 nm and a narrow size distribution with surface area and pore volume of about 594 m²/g and 0.35 cm³/g, respectively. The columnar pores are packed in a hexagonal geometry. X-ray diffraction and infrared spectroscopy measurements confirm that infiltrated samples result in non-crystalline LiBH₄ within the pore structure of the carbon. In contrast to previous studies of LiBH₄ confined in 12 nm and larger carbon aerogel pores, the non-crystalline LiBH₄ embedded in 2.0 nm pores not only results in the disappearance of the structural phase transition at around 100°C, and the melting transition, but also the significant decrease of the onset desorption temperature from 460°C to 220°C. Diborane release is suppressed or eliminated in the decomposition of non-crystalline LiBH₄ in the 2.0 nm pores, and only forms during the infiltration process.

Theoretical Modeling of Hydride Nanoparticles

Quantum Monte Carlo Modeling: Computational modeling of Li and (LiH)ₙ clusters (n = 1-20) clusters was completed, in which quantum Monte Carlo calculations were compared with the results of DFT obtained from a variety of functionals and the literature. These results enabled us to conceptually test the predictions of a Wulff construction model of hydride destabilization [2]. Comparing the diffusion Monte Carlo (DMC) predictions to the Wulff construction (Figure 3), we find that DMC predicts very little change in the hydrogen absorption energy over most values of n, with only LiH and (LiH)₂ destabilized relative to bulk. In contrast, the Wulff construction predicts that LiH is stabilized as its particle radius decreases below ~9 nm. In fact, of the hydrides examined by Kim et al., only MgH₂ and NaH are predicted to be destabilized at the nanoscale. Our previous DMC results for MgH₂ are consistent with this, although the destabilization occurs at much small particle sizes (<1 nm diameter). Unfortunately, we cannot perform comparable simulations for NaH clusters because of the lack of high-quality effective core potentials for sodium. Nevertheless, these results suggest that size affects the energetics of hydride nanoparticles only at extremely small sizes. The corollary, however, is that altered chemistry of hydrides, in particular a change in the thermodynamics observed by the group of de Jongh et al. [3], as well as changes in kinetics observed by several
groups, are connected in some way to the local chemical environment of the scaffold pores.

We also explored the possibility of alloying magnesium and aluminum to tune the hydrogen desorption energy. MgAlH<sub>5</sub> is a hypothetical compound, capable of storing up to 8.5% hydrogen by weight. However, DFT studies by Akbarzadeh et al. indicate that the bulk material is unstable relative to MgH<sub>2</sub>+Al+1.5H<sub>2</sub> [4]. We hypothesize that the stability of Mg-Al clusters will be intermediate between that of AlH<sub>3</sub> and MgH<sub>2</sub>, assuming that a stable cluster can form. In our initial DMC calculations, shown in Figure 4 for MgAlH<sub>5</sub> clusters with up to eight formula units, we find that the desorption energy scales quite differently from that of the Li clusters. This energy is highest for MgAl and progressively decreases until it reaches values near the appropriate range for hydrogen storage (~20-60 kJ mol<sup>-1</sup>) for an eight formula-unit cluster. These clusters are also of the correct size to be made within a MOF, having diameters around 1 nm. We are currently exploring different alloying concentrations to further enhance the tunability of these clusters and are initiating an experimental plan to determine if such clusters can be formed.

**Phase Diagram of Nano-Cluster NaAlH<sub>4</sub> from First-Principles DFT and Nano-PEGS Cluster Prototypes:** We have calculated the phase diagram of small clusters of atoms in the Na-Al-H ternary system using first-principles and determine the decomposition pathway of NaAlH<sub>4</sub> as a function of Na:Al ratio and cluster size up to 8 formula units. We included as decomposition products clusters of Na, Al, mixed NaAl, and ionic clusters AlH<sub>3</sub>, NaH, and NaAlH<sub>4</sub>. Cluster geometries for ionic clusters were obtained by relaxing prototype electrostatic ground state (PEGS) structures using density-functional theory calculations; vibrational free energy was also calculated for each of the clusters. We find that small clusters of AlH<sub>3</sub> increase in stability with smaller cluster size from enthalpies of around 51 to 160 kJ/mol H<sub>2</sub> for 8 and 1 formula units, respectively. In contrast, small clusters of NaH have an enthalpy of decomposition of about 70 kJ/mol H<sub>2</sub> and show no destabilization with size until the cluster is two formula units or smaller when they spontaneously decompose. Clusters of NaAlH<sub>4</sub> also show increasing stability with decreasing cluster size with an enthalpy of decomposition that increases from 80 kJ/mol H<sub>2</sub> for 8 f.u. clusters) to 150 kJ/mol H<sub>2</sub> for 1 f.u. clusters. Most interestingly, NaAlH<sub>4</sub> clusters are found to decompose directly into mixed metal AlNa clusters in one step. The lack of intermediate Na<sub>3</sub>AlH<sub>6</sub> in the decomposition path is in agreement with recent experimental work on nanoconfined NaAlH<sub>4</sub> in nanoporous carbons.

**Conclusions and Future Directions**

**Conclusions**

- Both thermodynamic and kinetic effects are observed when metal hydrides are confined within nanoporous templates.
- Simple hydrides (e.g. LiH and MgH<sub>2</sub>) are not destabilized until very small cluster sizes (<5 formula units). This is confirmed by both theory and experiment, invalidating the Wulff construction model for at least these two materials.
- Two complex hydrides we examined, NaAlH<sub>4</sub> and LiBH<sub>4</sub>, are kinetically destabilized by nanofocusing. In addition, thermodynamic destabilization is either observed (LiBH<sub>4</sub> at ~2 nm) or predicted (NaAlH<sub>4</sub> at 8 formula units, or ~1 nm), suggesting that both size and pore environment influence hydride stability.
Future Directions

- Complete an investigation of nanoscale LiBH$_4$ using both MOF and NPC templates with overlapping pore sizes so that the effects of size and pore chemistry can be systematically evaluated.
- Investigate LiBH$_4$ decomposition on graphene sheets for comparison with hard carbon framework experimental results.
- Complete Mg-Al-H cluster phase diagram (collaboration with MIT).
- Complete investigation of compositional tuning within the Mg-Al-H system.
- Complete and submit journal articles on:
  1) nanocluster thermodynamics of complex hydrides using nanoPEGS+DFT computational framework;
  2) experimental and theoretical tests of the Wulff construction model, using simple hydrides; and
  3) the influence of size and pore environment on complex hydride stability, using LiBH$_4$ as a model material.
- Complete infiltration of nanoporous hard carbons with Ca(BH$_4$)$_2$, Mg(BH$_4$)$_2$, and LiAlH$_4$.

Objectives

The objective of this project is to discover novel mixed hydrides for hydrogen storage, which enable the DOE 2010 system-level goals. Our goal is to find a material that desorbs 8.5 wt% H₂ or more at temperatures below 85°C. The project will combine first-principles calculations of reaction thermodynamics and kinetics with material and catalyst synthesis, testing, and characterization. We will combine materials from distinct categories (e.g., chemical and complex hydrides) to form novel multicomponent reactions. Systems to be studied include mixtures of complex hydrides and chemical hydrides (e.g. LiNH₂+NH₃BH₃) and nitrogen-hydrogen based borohydrides (e.g. Al(BH₄)₃(NH₃)₃).

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

(A) System Weight and Volume

(E) Charging/Discharging Rates

Technical Targets

This study is aimed at fundamental insights into new materials and the thermodynamic and kinetic aspects of hydrogen release and reabsorption from them. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2010 hydrogen storage targets:

• Specific energy: 1.5 kWh/kg
• Energy density: 0.9 kWh/L

Accomplishments

• Used computational methods (density functional theory [DFT], prototype electrostatic ground state [PEGS], grand-canonical linear programming [GCLP]) to scan through and predict all possible reactions in Li-Mg-B-N-H system with reversible thermodynamics.
• New high-capacity reactions predicted, including those involving (NH₄)₂B₁₂H₁₂ (preliminary experimental verification underway).
• Used PEGS method to predict amido-borane structures. Good agreement with experiment where available (e.g., LiAB and KAB) and good prediction of structure for many other cases.
• NHBH₃NH₃BH₄ dianion as ammonia-borane (AB) intermediate product supported by DFT calculations.
• Computational prediction and experimental observation of new mixed BH₄/NH₂ compounds in Na and Ca systems.
Introduction

The 2010 and 2015 FreedomCAR/DOE targets for hydrogen storage systems are very challenging, and cannot be met with existing materials. The vast majority of the work to date has delineated materials into various classes, e.g., complex and metal hydrides, chemical hydrides, and sorbents. However, very recent studies indicate that mixtures of storage materials, particularly mixtures between various classes, hold promise to achieve technological attributes that materials within an individual class cannot reach. Our project involves a systematic, rational approach to designing novel multicomponent mixtures of materials with fast hydrogenation/dehydrogenation kinetics and favorable thermodynamics using a combination of state-of-the-art scientific computing and experimentation. Specifically, we focus on combinations of materials from distinct categories (e.g., chemical and complex hydrides) to form novel multicomponent reactions.

Approach

We use the accurate predictive power of first-principles modeling to understand the thermodynamic and microscopic kinetic processes involved in hydrogen release and uptake and to design new material/catalyst systems with improved properties. Detailed characterization and atomic-scale catalysis experiments elucidate the effect of dopants and nanoscale catalysts in achieving fast kinetics and reversibility. And, state-of-the-art storage experiments give key storage attributes of the investigated reactions, validate computational predictions, and help guide and improve computational methods. In sum, our approach involves a powerful blend of: 1) hydrogen storage measurements and characterization, 2) state-of-the-art computational modeling, 3) detailed catalysis experiments, and 4) in-depth automotive perspective.

Results

First-Principles Prediction Of Novel Storage Reactions in the Li-Mg-B-N-H System

Metal borohydrides and amides exhibit some of the highest hydrogen capacities among the known solid-state materials. Compounds with Li, Mg, B, N, and H are particularly interesting as they involve numerous compounds of potentially high relevance for hydrogen storage:

1. Borohydrides: LiBH₄, MgBH₄, Li₂B₁₂H₁₂, MgB₁₂H₁₂
2. Amides and imides: LiNH₂, Mg(NH₂)₂, Li₃NH, MgNH, Li₃Mg(NH)₂, etc.
3. Borohydride-amide mixed compounds: Li₂BNH₄, Li₂BN₅H₁₀
4. Ammoniated borohydrides: Mg(BH₄)₂·2NH₃
5. AB and derivatives: BH₃NH₃, BH₃NH₂, LiBH₂NH₃, etc.
6. B-N-H and B-H compounds: B₂H₆, B₄H₁₀, B₁₂H₂₀, B₂₀H₁₆, (NH₄)₂B₁₂H₁₂, etc.
7. Various reaction products: elements (Li, Mg, B, N₂), metal hydrides (LiH, MgH₂), metal borides (MgB₂, MgB₄, MgB₇), metal nitrides (Mg₂N₃, Li₃N, LiMgN), boronitrides (BN, Li₃BN₅, LiMgBN₅), etc.

Using DFT methods, we have calculated the total crystal binding energies and vibrational free energies of all currently known compounds in the Li-Mg-B-N-H system (approximately 50 compounds). The structures of most of these compounds have been taken from the Inorganic Crystal Structure Database. To these, we have added the theoretically predicted compounds whose structures have been obtained using the PEGS search and other structure prediction methods. The calculated free energies have been used as inputs to the GCLP approach for determining reaction pathways in multinary systems [1]. Using the GCLP method, we have rigorously determined all the thermodynamically allowed reversible reactions in the Li-Mg-B-N-H system which involve the currently known (or predicted) compounds (some of these predictions may change with the discovery of new, currently unknown Li-Mg-B-N-H compounds). Our predictions for the DOE targeted range of temperatures and pressures are given in Table 1, and the corresponding van’t Hoff plots are shown in Figure 1.

Three of the five reactions in Table 1 were found by us in an earlier paper [2]. Two of these reactions (#2 and #3 in Table 1) involve Mg(BH₄)₂ and LiBH₄ as reactants and MgB₁₂H₁₂ and Li₂B₁₂H₁₂ as end products. In Ref. [2] we showed that both these reactions possess excellent thermodynamic properties that combine low reaction enthalpies with low entropies. They remain the two most-promising single-step reversible reactions in the Li-Mg-B-N-H system.

Interestingly, we now predict a novel two-step reaction involving ammonium dodekahydro-closo-dodekaborate as the starting material:

\[(\text{NH}_4)_2\text{B}_{12}\text{H}_{12} \leftrightarrow 2\text{BN} + 0.5\text{B}_{20}\text{H}_{16} + 6\text{H}_2 \leftrightarrow 2\text{BN} + 10\text{H}_2 + 10\text{H}_2\]

These reactions releases 11.3 wt% H₂ over both steps. At p=1 bar H₂ pressure, the first step (decomposition of (NH₄)₂B₁₂H₁₂ into BN, B₂₀H₁₆,

and H₂) occurs at -120°C, while the second step (decomposition of B₂₀H₁₆ into B and H₂) proceeds at 20°C. In contrast to the conventional complex hydrides that contain metal cations and complex anions, the above reaction represents a new paradigm where the storage material contains both anionic and cationic complexes.

First-Principles Studies of Metal Amidoboranes

Metal amidoboranes, M(NH₄BH₄)₃ (M=metal atoms) or MAB, are interesting candidates for on-board hydrogen storage materials with promising properties, like high gravimetric capacity, low hydrogen release temperature, and the ability to suppress toxic borazine emission. But details about the intermediate products are largely unknown and these products are often categorized as amorphous. Armed with the PEGS+DFT methodology, we have searched for crystal structures of possible intermediate phases with [NHBH₄]₂, [NHBH₄], [NHBH₄]₃, polymer-[NHBH₄] anion groups in the decomposition of LiAB and CaAB. All of these anion groups were selected in analogy with the decomposition sequence and products for NH₄BH₄. However, all these reaction pathways produce high-endothermic hydrogen release enthalpies, which are far away from the experimental suggested nearly thermoneutral values, (-3~ -5 kJ/mol H₂ in LiAB and 3.5 kJ/mol H₂ in CaAB).

Recently, proposals in the literature have pointed towards the possibility of a new dianion group [NHBHNHBH₃], which might be formed in the decomposition of CaAB. For the cases of LiAB and CaAB, we used PEGS+DFT to predict crystal structures of this new metal-dianion intermediate compounds. For the static energies, these reaction pathways are much lower in energy than the above anion groups, lending credibility to the possible stability of the dianion group as an intermediate product. Hydrogen release enthalpies are calculated to be (static) 27.56 kJ/mol H₂ in LiAB and 27.33 kJ/mol H₂ in CaAB. Introducing the entropy effects from phonon calculations, the enthalpies are shifted down by a roughly constant amount, ~25 kJ/mol H₂ at 0 K and ~20 kJ/mol H₂ at 300 K. With these shifts due to vibrations, we successfully obtain calculated enthalpies that are in good agreement with the experimentally suggested nearly thermoneutral data at finite temperatures. This good agreement gives confidence in the ability of PEGS+DFT to determine MAB reaction products, and also provides strong evidence that the dianion phases are highly probable products in the decomposition of metal amidoboranes.

Exploration of Catalyst for Improved Hydrogen Absorption/Desorption Kinetics

Hydrogen evolution from complex hydrides is dictated by an inter-related sequence of chemical reaction steps including decomposition of the hydride, diffusion of hydrogen atom/ion and counter ions in the solid lattice, surface diffusion of these atoms/ions, recombination of hydrogen atoms, transformation of lattice phases, and desorption of hydrogen molecules. Reversing these step would lead to formation of the hydride. Improving kinetics in these reaction steps allows complex hydrides to evolve hydrogen under milder operating conditions (i.e. temperature and
pressure). For this funding period, we explore the concept that the hydrogen evolution kinetics can be facilitated by a catalyst external to the complex hydride. Furthermore, the effectiveness of the catalyst depends on the contact area between the catalyst and the complex hydride. Our hypothesis is that a light-weight, effective catalyst could be constructed with a known transition metal hydrogenation catalyst, that dissociatively adsorb and associatively desorb hydrogen molecules readily, highly dispersed on a carbon support on which hydrogen atoms can diffuse rapidly. By dispersing such a composite catalyst in a mixture with complex hydride, we can attain a high contact area between the catalyst and the hydride with minimal weight penalty. The contact points would serve both for hydrogen transfer between the catalyst complex and the hydride and as potential nucleation points for phase transformation of the hydride.

To test our hypothesis, we used a well characterized hydride, calcium borohydride Ca(BH$_4$)$_2$, that decomposes at a high temperature (380-420°C). It was mixed with a series of composite catalysts comprising non-precious metal nanoparticles and multi-walled carbon nanotubes (MWCNTs). Non-precious metals were used for lower costs, and MWCNT was chosen because of their low density and their aromatic nature permits facile hydrogen diffusion. The hydrogen desorption behavior of these mixtures was characterized by their hydrogen pressure-temperature profiles. The metal-decorated MWCNTs catalytic matrix was prepared by sonication-assisted impregnation. The metal precursor containing Co, Ni, or Fe (usually metal nitrates) was dissolved in a solvent and sonicated by their hydrogen pressure–temperature profiles. The metal-decorated MWCNTs catalytic matrix was prepared by sonication-assisted impregnation. The metal precursor containing Co, Ni, or Fe (usually metal nitrates) was dissolved in a solvent and sonicated with MWCNTs. The resulting solid mixture was thermally treated in a H$_2$-Ar stream, which converted (by decomposition and reduction) the loaded metal precursor to metal nanoparticles on the MWCNTs. The thermal treatment was carried out in a special sample holder that allows the reduced sample being transferred into a glove-box with no further surface oxidation.

Figure 2 shows the pressure change-temperature profiles for the pristine Ca(BH$_4$)$_2$ and the catalyst-Ca(BH$_4$)$_2$ mixtures. It was found that the addition of either carbon nanotubes or metal-decorated carbon nanotubes lowered the decomposition temperature of Ca(BH$_4$)$_2$ by 15-20°C. Among the Ni-, Fe-, and Co-MWCNT composites, Co-MWCNT was most effective and showed the lowest initial decomposition temperature.

The preliminary results show that the addition of the metal-decorated carbon nanotubes can lower the decomposition temperature of Ca(BH$_4$)$_2$ complex hydride. At this moment cobalt is the most promising among Co, Fe, and Ni, metals that were investigated. Future work will include optimization of the preparation parameters for the Co-decorated MWCNT matrix, as well as the parameters for operating the catalytic matrix for a more well-characterized complex hydride, for instance, NaAlH$_4$.

Several rate-controlling mechanisms have been proposed for the hydrogen desorption/recombination in complex hydrides. Overall, in order for hydrogen to desorb/recombine more efficiently, the hydride should have: (1) smaller particle size to obtain larger surface areas for gas phase exposure; (2) shorter diffusion length for its reaction species; (3) nucleation sites for the formation of the decomposition product phases.

The present catalyst composite can be further modified to better meet the above requirements. Our proposed reaction model involves complex hydrides in contact with the multi-functional catalytic matrix under development. The high surface area provided by the carbon nanotubes and the hydrogen spillover effect by the metal nanoparticles will increase the hydrogen gradient on the interfaces. The metal catalyst particles will serve as nucleation sites can enhance the kinetics of the subsequent reactions. Alternatively, product seeding could be attempted. For the complex hydrides with a low melting point, for example, NaAlH$_4$, a solid-liquid region can be retained between the interfaces of the hydride and the catalytic matrix by capillary action. Such region benefits the overall kinetics by facilitating the chemical bond breakage as well as the mass transfer of the product nuclei, which can be dispersed homogeneously via the liquid phase. In addition, carbon nanotubes, an excellent thermal conductor, can transfer heat effectively during the thermal decomposition of the hydrides. This working model cannot be realized if the hydride particles lose contact with the catalytic matrix, possibly due to the volume/morphology change in the hydride during its decomposition. Thus, to supplement the carbon nanotubes, two-dimensional graphene layers
will also be introduced into the catalytic matrix to help maintain the hydride/matrix interfaces.

Conclusions and Future Directions

- Extend computational search for all possible promising reversible reactions in Li-Ca-B-N-H system.
- Experimentally characterize storage properties/reactions of (NH₄)₂B₁₂H₁₂ and other predicted reactions.
- Extend experimental catalyst studies to (NH₄)₂B₁₂H₁₂ and other predicted promising materials.
- Continue computational exploration for: 1) novel BH₄/NH₂ compounds and reversible reactions, 2) mixed metal borohydrides, and 3) AB reaction products.

IV.A.4 Hydrogen Storage Materials for Fuel Cell-Powered Vehicles

Objectives

- Study new destabilized complex hydrides that have been predicted by first principles calculations to be suitable hydrogen storage materials.
- Develop methods for the synthesis, characterization, and modeling of new complex hydrides.
- Identify the most promising types of complex hydrides and develop new catalysts and engineering techniques for increasing reaction rates and lowering reaction temperatures.
- Extend studies to include carbon materials, metal organic frameworks (MOFs), and possibly other nanostructured and porous materials as potential hydrogen storage materials using hydrogen spillover.
- Perform cycling studies to test the durability of destabilized complex hydrides and MOFs.
- Design, fabricate and test a hydride-based hydrogen storage system for fuel cell applications.

Technical Barriers

This project addresses the following technical barriers taken from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(D) Durability/Operability
(E) Charging/Discharging Rates

Technical Targets

This project is conducting fundamental studies of complex borohydride materials and other promising hydrogen storage materials. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet DOE’s 2015 goal of 4.5 weight percent hydrogen storage for the system. The following table summarizes the targets:

Accomplishments

- We have determined that several destabilized borohydride systems based on Mg(BH₄)₂ can absorb hydrogen reversibly starting at temperatures less than 200°C.
- We used thermodynamic measurements, based on van’t Hoff plots to determine the reaction enthalpies of the destabilized systems.
- We have also determined that mixed catalysts are most effective in catalyzing the MgH₂ system and they may be effective for destabilized systems as well.
- We have determined the activation energies for the CaH₂/LiBH₄ system using the Kissinger analysis.

Introduction

Developing safe, cost-effective, and practical means of hydrogen storage is essential for the advancement of hydrogen and fuel cell technologies. Materials such as sodium alanate were a vast improvement in storage capacity over most traditional hydrides. However, even the alanates fall short of meeting DOE’s long term hydrogen storage goals. Therefore interest has now focused on destabilized hydrides which have even greater potential for hydrogen storage.

During the next several years we propose to perform hydrogen storage studies on some new destabilized complex hydrides that have been predicted by first principles calculations to be suitable hydrogen storage
IV.A  Hydrogen Storage / MH-Independent Projects

Materials. We will develop methods for the synthesis, characterization, and modeling of these new complex hydrides as well as developing new catalysts and engineering techniques for increasing reaction rates and lowering reaction temperatures. Nanotechnology will be used to reduce or eliminate the release of any diborane. We will also extend these studies to include carbon materials, MOFs and possibly other nanostructured and porous materials as potential hydrogen storage materials. There have been recent reports that some MOFs had a hydrogen storage capacity of 7.5 wt% H2 at 77 K and 70 bar. Unfortunately, the hydrogen adsorption capacities of most carbon materials at ambient temperature and pressure are quite low, generally being less than 1 wt%. Scientists are seeking materials that can absorb and release significant quantities of hydrogen near room temperature. Most recently it was found that IRMOF-8 could adsorb 4.0 wt% at room temperature and 100 bar using hydrogen spillover. This is significant because there is a good possibility that other MOFs could be made that might have even greater capacity at room temperature using the spillover technique. We will thus explore this possibility.

Once a suitable material has been identified for hydrogen storage it will be necessary to design, fabricate and test a hydride-based hydrogen storage system for fuel cell applications. A partner institution will be involved in this aspect of the research. This phase of the research will include using flow, reaction kinetics and thermal modeling, followed by system design, fabrication and performance evaluation.

Approach

To achieve the project objectives, new materials are being developed and characterized using a variety of techniques. Sample preparations prior to analysis were done in an argon-filled glove box (Vacuum Atmosphere Company). The hydrides were made by first ball milling the raw materials in a SPEX 8000 Mixer Miller and then directly combining them with hydrogen in a Sieverts apparatus. X-ray powder diffraction in a Panalytical X’pert Pro MPD Analytical X-Ray Diffractometer was used to confirm the formation of product and to determine phase purity.

Thermogravimetric analyses (TGA) and temperature programmed desorption (TPD) were used to determine the thermal stability and the hydrogen capacity of the mixtures. The TGA analyses were done in a Lab System-Diamond TG/DTA. This instrument was placed inside of an argon-filled glove box so that samples can be analyzed with virtually no exposure to air and moisture. The TPD analyses were carried out in a pressure composition isotherm (PCI) unit. The instrument was supplied by Advanced Materials Corporation. Kinetic measurements were done to determine the overall reaction rates. Cycling measurements were done to determine the stability of the materials when subjected to repeated hydrogenation and dehydrogenation cycles.

The B-H bond strength of the various synthesized double-cation borohydrides were compared via Shimadzu IR Prestige-21 Fourier transform infrared spectrophotometer. This instrument operates in a single-beam mode and is capable of data collection over a wave number range of 7,800 cm⁻¹ ~ 350 cm⁻¹. Residual gas analyses were done in a RGA Pro 2000. The instrument was produced by Stanford Research Systems and distributed by Hy-Energy LLC in Newark, CA.

Results

Last year we reported that the destabilized borohydride system described by the equation

\[ 6 \text{LiBH}_4 + \text{CaH}_2 \rightarrow 6 \text{LiH} + \text{CaB}_6 + 10 \text{H}_2 \]

absorbed hydrogen in a reversible manner. Further studies have been done to determine the effect of various additives on the desorption temperatures and activation energy of this system. The additives studied were TiCl₃, TiF₃, and TiO₂. It was found that the TiCl₃ additive lowered the dehydrogenation temperature more than the other additives. Furthermore, higher amounts of TiCl₃ were more effective in reducing the desorption temperature than lesser amounts. Kissinger plots were used to determine the activation energies of the catalyzed systems. The activations energies for mixtures containing 4, 10 and 25 mol% of TiCl₃ were 141, 126 and 110 kJ/mol, respectively.

The following six systems based on Mg(BH₄)₂ have also been studied to determine their reversibility and thermodynamic behavior:

- \[ 3\text{Mg(BH}_4)_2 + \text{CaH}_2 + 3\text{NaH} \rightarrow 3\text{NaMgH}_3 + \text{CaB}_6 + 10\text{H}_2 \]
- \[ 3\text{Mg(BH}_4)_2 + \text{CaH}_2 \rightarrow 3\text{MgH}_2 + \text{CaB}_6 + 10\text{H}_2 \]
- \[ 3\text{Mg(BH}_4)_2 + 3\text{Ca(BH}_4)_2 \rightarrow \text{CaB}_6\text{H}_{12} + 5\text{MgH}_2 + 13\text{H}_2 \]
- \[ 2\text{Mg(BH}_4)_2 + \text{NaH} \rightarrow \text{NaMgH}_3 + \text{MgB}_4 + 7\text{H}_2 \]
- \[ 3\text{Mg(BH}_4)_2 + \text{CaH}_2 + 1.5\text{Si} \rightarrow \text{CaB}_6 + 1.5\text{Mg}_2\text{Si} + 13\text{H}_2 \]
- \[ \text{Mg(BH}_4)_2 + 2\text{C} \rightarrow \text{MgB}_2\text{C}_2 + 4\text{H}_2 \]

The systems described in the first three equations are reversible with some releasing as much as 8 wt% hydrogen at temperatures beginning at less than 200°C (see Figure 1). The last three reactions did not show any well defined plateau region. Therefore, thermodynamic measurements were done only on the systems described by the first three equations. Cycling studies showed that these systems are only partially reversible. The hydrogen-holding capacities diminished to about
2 wt% upon continued cycling. Thermodynamic measurements, based on van’t Hoff plots showed that the reaction enthalpies were in the 82-88 kJ/mol range. Results are given in Figure 2. Thermodynamics and kinetics measurements were done using MgH₂ as a model system. The goal was to determine what catalysts work best in lowering reaction temperatures and increasing reaction rates. It was found that a mixture of two catalysts was more effective than either catalyst alone. Larger amounts of catalysts were more effective in lowering reaction temperatures but the hydrogen-holding capacity was significantly diminished as the amount of catalyst increased. Results are shown in Figures 3-4.

Conclusions and Future Directions

This work has shown that several destabilized borohydride systems based on Mg(BH₄)₂ can absorb hydrogen reversibly starting at temperatures less than 200°C. We have also determined that mixed catalysts are most effective in catalyzing the MgH₂ system and they may be effective for destabilized systems as well. In Fiscal Years 2010-2011, the following are planned:

- Prepare and characterize several Mg(BH₄)₂-based destabilized systems using ball milling, X-ray diffraction, TPD and TGA.
- Perform thermodynamic measurements, such as PCI analyses, on destabilized systems found to be reversible.
- Perform kinetics and modeling studies on the destabilized systems at constant pressure driving forces in order to establish the rate-controlling process.
- Use techniques such as residual gas analysis to determine if dehydrogenation is accompanied by the release of other gaseous byproducts.
- Use various catalysts and combinations of catalysts to lower reaction temperatures and increase reaction rates. MgH₂ will be used as a model system in these efforts.

Objectives of the Center

- Implement a coordinated approach to identify, research, develop, and validate advanced on-board chemical hydrogen storage systems to overcome technical barriers and meet DOE Hydrogen Storage 2010 system goals.
- Design, synthesize, and test materials and compositions to control the thermochemistry and kinetics of hydrogen release.
- Develop energy and chemically efficient off-board spent fuel regeneration for the complete fuel cycle.
- Assess concepts and systems for hydrogen release and spent fuel regeneration using supporting engineering analysis and validation to rank viable candidates.
- Down-select most promising chemical systems for more detailed materials and engineering development.
- Develop most promising chemical hydrogen storage materials with potential to meet 2010 targets.
- Perform engineering analyses to evaluate cost and efficiency of hydrogen storage materials and spent fuel regeneration processes.
- Develop life cycle analysis.
- Transfer chemical hydrogen storage systems information to the Hydrogen Storage Engineering Center of Excellence, and receive feedback from its analyses.

Technical Barriers

This project addresses the following technical barriers from Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (MYRDDP):

(A) System Weight & Volume
(B) System Cost
(C) Efficiency
(D) Durability/Operability
(E) Charging & Discharging Rates
(J) Thermal Management
(K) System Life-Cycle Assessments
(R) Regeneration Processes
(S) By-Product/Spent Material Removal

Technical Targets

While all of the relevant targets detailed in the DOE MYRDDP have been addressed during the Center's activity, the Center's main emphasis focuses on the material and efficiency requirements for storage of hydrogen in chemical bonds. The Center has developed interim technical guidelines to facilitate down-selection of promising materials for further development. The Center's key criteria for down-selection of storage materials include gravimetric and volumetric hydrogen capacities, as well as hydrogen release rate and temperature. The Center's criteria for materials down-selection, which are mapped to the DOE technical targets for storage systems, are tabulated in Table 1. Gravimetric capacity of materials must exceed 7 wt%, with the potential to exceed 9 wt%. The goal for temperature is for hydrogen release to occur with high rate below 100°C, with an interim goal of release occurring at high rates below 200°C. The Center’s criterion for the rate of hydrogen release, 0.02 gH₂/s/kW, is the DOE 2010 target. A tabulation of all of the Center's interim targets are published in “2008 Overview - DOE Chemical Hydrogen Storage Center of Excellence”, http://www.hydrogen.energy.gov/annual_progress08_storage.html#b.

The targets for regeneration of spent fuel include an interim target of 40% energy efficiency, with an ultimate goal of 60% energy efficiency, with chemical efficiencies approaching 100%, e.g. minimum losses to byproducts.

Accomplishments

Accomplishments for 2010 from across the Center are organized into four main areas: 1) Hydrogen Release, 2) Spent Fuel Regeneration, 3) New Materials, and 4) Engineering Supporting Research and Development.
Hydrogen Release from Ammonia Borane (AB):
- Demonstrated increased rates at temperatures below 100°C for release from AB in ionic liquids using metal ion catalysts.
- Kinetics data for ionic liquid/AB mixtures delivered to Argonne National Laboratory (ANL) for preliminary onboard release system analysis.
- Development of new ionic liquid fuel compositions with greater than 10 wt% hydrogen.
- Demonstrated high rates at temperatures as low as 70°C with non-platinum group metal heterogeneous catalysts demonstrated.
- Deselected amine borane/AB liquid fuels for further consideration because of unresolved catalyst deactivation issues.
- Quantification of impurities and their rates of formation lead to demonstration that impurities may be mitigated by proper choice of process conditions.

Spent Fuel Regeneration, First-Fill Processes, and Boron Resources Studies:
- A complete one pot regeneration cycle has been proven with overall yield of spent fuel digestion through reduction steps exceeding 90%. This method works for multiple spent fuel forms including spent fuels from ionic liquids giving ammonia borane, and is chemically simple relative to previous regeneration schemes.
- Cost analysis on this new regeneration process is underway in collaboration with Dow Chemical Company. Preliminary analysis indicates substantially reduced costs as compared to Dow’s previous analysis of the thiocatechol route ($7-8/gasoline gallon equivalent, gge), but higher raw materials costs.
- AB first-fill reactor capable of 100 gram batch.
- Their work is to provide updated boron minerals reserves estimates that indicate U.S. supply of B is adequate to meet B-fuel requirements of DOE hydrogen vehicle market penetration scenarios.

New Materials Development:
- All metal amidoborane materials currently known show exothermic hydrogen release. It is not possible to regenerate these materials efficiently and thus they are not considered further for onboard applications, but these materials are useful for stationary near-term applications.
- University of Oregon demonstrated additional syntheses of endothermic/exothermic cyclo-carbon-boron-nitrogen (CBN) compounds, pathways for regeneration of spent fuel, first-fill syntheses, and measured thermodynamic parameters that have corroborated computational studies on these molecules.

Engineering-Supporting R&D
- First order estimation of U.S. and global borate reserves completed, taking into account consumption by competing applications through initial fill timeframe.
- Developed cost analyses of most promising first fill pathways to prepare sodium borohydride and AB.
- Parametric studies to understand engineering scale up of first-fill reactor; semi-continuous flow reactor being designed.
- Eliminated plasma-based process for NaBH₄ production due to irreproducibility.
- Identification of a scalable, solid-solid reactive milling technology has been met with challenges because of poor yields of NaBH₄.
- Identified alternative, scalable solution route to NaBH₄ that has implications for successful scale up of any boron hydride-based fuel.

**Introduction**

Chemical hydrogen storage involves storing hydrogen in molecular chemical bonds where an onboard chemical reaction is used to release hydrogen. Currently, the resulting spent fuel may be regenerated off-board using chemical processing. In addition to the importance of on-board storage capacity and hydrogen release rates, the energy efficiency of the off-board regeneration of spent fuel is a key contributor to the overall energy efficiency of the fuel cycle. Chemical hydrogen storage provides a diversity of options to enable hydrogen for transportation as well as other niche and stationary applications, and could also be used for hydrogen delivery where it offers the opportunity for a liquid or solid fuel infrastructure with the potential for no direct hydrogen handling by the consumer.

During the five years of this project, CHS-SoE researchers have made substantial strides toward developing nitrogen-boron based molecular hydrogen storage compounds that can meet DOE technical targets for on board hydrogen storage. The boron-nitrogen (BN) materials, such as AB and related compounds, have unique chemical properties that enables facile hydrogen release at temperatures around 100°C using a number of approaches that give rise to high rates of release. The CHS-SoE has also made dramatic strides in demonstrating that spent fuel from AB may be chemically regenerated off-board. Recent process modeling work from our partner Dow Chemical (formerly of Rohm and Haas) has shown that recycle may be done with an initial estimated cost of $7-8/kg of AB. A recent hydrazine-based one pot regeneration scheme has been demonstrated in the lab, and has substantially reduced separations and processing costs relative to prior regeneration schemes. The major cost in this scheme is the cost of the hydrazine, indicating that research to reduce this cost could lead to a very cost-effective regeneration of spent fuel.

The Center is the team comprised of researchers at LANL, the University of Pennsylvania, Dow Chemical Company, Pacific Northwest National Laboratory (PNNL), Pennsylvania State University, the University of California, Davis, the University of Alabama, the University of Washington, the University of Oregon, U.S. Borax, and the University of Missouri. The Center has been supported in our work through analyses performed by ANL and TIAx, and our interactions with the Hydrogen Storage Engineering Center of Excellence.

**Approach**

The overall Center approach capitalizes on its broad spectrum of expertise ranging from chemical synthesis and characterization to catalysis to chemical engineering to molecular modeling and simulation to carry out R&D in chemical hydrogen storage. The Center’s activities fall into four general areas of hydrogen release from AB or its mixtures, regeneration of spent fuel from AB, materials discovery, and engineering supporting R&D. The goals of these four parallel approaches is to increase the rates of hydrogen release from BN compounds at moderate temperatures, regenerating the spent fuel that results from dehydrogenation of boron-nitrogen-hydrogen (BNH) compounds, and discovering new release materials with more favorable thermodynamics that may enable direct rehydrogenation of the spent fuel. All of these activities are supported and guided by modeling and simulation of the related molecular processes and engineering-based analysis that provides direction to the experimental efforts that are focused on developing a practical hydrogen storage material that meets DOE’s 2010 technical targets.

**Results**

Because of space limitations, this report will describe only two of the major overarching accomplishments of the Center. More detailed and complete results from the Center’s activities may be found in the individual reports of the CHS-CoE partners.

**Hydrogen Release**

During previous years, the Center has demonstrated many compounds and processes that can release greater than 7 wt% hydrogen, with many compounds yielding in excess of 10-13 wt% hydrogen. For example, AB in solid form, can readily release 13-15 wt% hydrogen. Because of the engineering issues surrounding the handling of solids onboard, the Center has focused significant effort at developing stable liquid fuels comprising AB in ionic liquids, or AB in liquid alkylamineboranes. The latter approach, while potentially realizing greater hydrogen capacity because of the contribution of the dehydrogenation of the liquid alkylamineborane, has run into difficulty because of catalyst deactivation for which the Center at present has no straightforward solution.

The Center this year has provided ANL with kinetics data for the dehydrogenation of AB/ionic liquid mixtures. With this data, ANL has provided a preliminary onboard hydrogen release system analysis. Their preliminary findings are that the exothermicity of hydrogen release drives adequately rapid release of hydrogen, but the heat released provides a challenge for onboard heat management. Several configurations of onboard release reactor are suggested to accommodate these features, but more work is necessary.

**New Materials**

By synthesizing metal-substituted derivatives of AB, a wide array of new metal amidoborane (M-AB) storage materials have been previously discovered...
and characterized by researchers at PNNL, LANL, and Missouri. As one example, PNNL has shown that Li-AB releases 5 wt% hydrogen in 2 minutes at 100°C. This year, additional thermodynamics data have been obtained on a subset of these compounds. The thermodynamics of release indicate that all of the mono metalamidoborane compounds studied to date are still too exothermic to enable direct rehydrogenation of spent fuel (Figure 1). Because of this, and the fact that there are no energy-efficient pathways to regenerate spent fuel from metal amidoboranes, that this line of research should be curtailed. There remains the possibility that multimetallic metalamidoboranes may have more favorable thermodynamics. Also, some of these metal amidoboranes may find use in small niche non-vehicular applications such as portable power.

Another line of research into new materials by our University of Oregon partner has shown that exothermic release of hydrogen from the BN segment of a cyclo-CBN compound coupled with the endothermic release of carbon-carbon (C-C) segments achieves more thermodynamically favorable release of hydrogen as compared to highly exothermic ammonia borane (Figure 2). The thermodynamics of release in these systems that was previously explored using theoretical techniques in collaboration with our University of Alabama partner have been corroborated experimentally. Because of the more favorable thermodynamics, regeneration of spent fuel using H₂ directly in concert with H⁺ and H⁻ reagents under mild conditions has been demonstrated.

**Regeneration**

Center researchers have previously described and/or demonstrated several chemical reprocessing schemes to convert spent fuel back to ammonia borane. The best developed scheme involves the use of thiocatechol to ‘digest’ the spent fuel to a more reactive form, followed by subsequent amine exchange for ammonia, and a reduction using a tin hydride. Replacing the amine with ammonia regenerates AB. Recycling the tin reagent back to tin hydride completes the cycle. Last year, process engineers at Rohm and Haas (now Dow) performed process modeling of this regeneration scheme to obtain a baseline estimate of the cost of this process that indicated that AB regeneration could cost as little as $7-8/gge. Based on our lessons learned from this process, the Center has discovered a very simple, one-pot regeneration of AB spent fuels using hydrazine in liquid ammonia that results in fast, high conversions back to AB (see Figure 3). Dow has performed a preliminary cost analysis of this hydrazine route, and has found that because of the simpler process that requires far fewer separations steps, that process energy and capital equipment costs are substantially reduced vs. the multistep thiocatechol route. They also find that the most significant cost is in the cost of hydrazine. An

**FIGURE 1.** Measured heat flow during hydrogen release for a series of metal amidoboranes M(NH₂BH₃)ₙ compounds. Hydrogen release temperature, rate of release, and heat released vary with the identity of the metal ion. All of the heat flow measurements indicate that these compounds release hydrogen exothermically.
FIGURE 2. Cyclo-CBN compounds such as shown in this figure may be interconverted using chemical approaches. The intermediates along the hydrogenation-dehydrogenation pathway have been structurally characterized using single crystal X-ray diffraction techniques, and are depicted at the bottom of the figure.

FIGURE 3. One-pot regeneration scheme using hydrazine as the digestion and reduction agent. Digestion of spent fuel in a mixture of hydrazine and ammonia results in near quantitative conversion to ammonia borane. This approach also works for regeneration of other forms of BNHx spent fuels that arise from ionic liquid/AB mixtures, and from the ‘pentamer’ that results from the release of one equivalent of hydrogen from AB using specific homogeneous transition element catalysts.
additional feature of the hydrazine route is that multiple spent fuel forms may be readily regenerated, such as the spent fuel from ionic liquid/AB liquid mixtures, or the 'pentamer' spent fuel that results from rapid room temperature release of one equivalent of hydrogen using certain homogeneous Co and Ir pincer ligand catalysts. This latter observation may be interesting for certain stationary applications, where rapid release at room temperature is required and where only the heat related to the release of one equivalent of hydrogen is generated.

Conclusions and Future Directions

Research within the CHSCoE has demonstrated that chemical hydrogen storage may be a viable approach to on board storage. Materials with high hydrogen capacities having high rates of release, good stability, and proven recycle have been synthesized, characterized, and demonstrated in the laboratory. Liquid fuels that have the potential to remain liquid during the dehydrogenation cycle may enable simplified reactor designs. Heat management of these exothermic processes will remain a challenge. Preliminary baseline costs for off board regeneration have been modeled, and may be reduced further, and energy efficiencies may still be improved.

Remaining issues include:

- Regeneration – develop inexpensive hydrazine synthesis routes, or develop alternative regeneration schemes.
- New materials – continue search for reversibility in covalent materials such as the cyclo-CBNs or multimetallic amidoboranes with goal of discovering on board regenerable materials, or materials that are less exothermic. Search for liquid hydrogen storage materials.
- Hydrogen release – measure and understand any catalyst deactivation or lifetime issues, develop and describe mitigation of any and all impurities and their impact on fuel cell operation if any, develop stable optimal liquid fuels, develop reactor schemes to handle the exothermicity of hydrogen release from this class of materials.

Special Recognitions & Awards/Patents Issued

All Awards, Patents, Publications and Presentations resulting from work within the Chemical Hydrogen Storage Center are given in the accompanying partner reports.
Objectives

The objective of this project is to develop novel boron-nitrogen heterocycles as liquid-phase hydrogen storage materials with storage capacities and thermodynamic properties that have the potential to lead to rechargeable systems capable of meeting DOE targets. We seek to:

- Develop new materials that:
  - are structurally well-defined along the desorption/absorption processes
  - exhibit appropriate enthalpy of H₂ desorption
  - are liquids at operating temperatures
  - possess high H₂ storage capacities
- Identify catalysts that will release hydrogen from these materials at temperatures <200°C.
- Develop conditions that will readily recharge the spent fuel.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- System Weight and Volume
- Efficiency
- Charging/Discharging Rates
- Regeneration Processes

Technical Targets

This project is developing new liquid phase materials for hydrogen storage that can be readily regenerated. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2015 hydrogen storage targets:

- Specific energy: 1.8 kWh/kg (5.5 wt%)
- Energy density: 1.3 kWh/L (4.0 vol%)

Accomplishments

- Selected two materials with favorable thermodynamics to move forward.
- Synthesized all intermediates along the proposed desorption pathway for Material (1).
- Developed a first-fill synthesis of fully charged fuel for Material (1).
- Demonstrated a pathway for regeneration of the spent fuel for Material (1).
- Performed preliminary thermodynamic measurements that corroborate computational predictions for Material (1).

Introduction

Hydrogen storage is a vital component in the development of a hydrogen-based energy infrastructure. Boron-nitrogen containing compounds, e.g., ammonia-borane (H₃N–BH₃ or AB), have attracted much attention as chemical H₂ storage materials because of their high gravimetric hydrogen densities and fast kinetics of H₂ release. This project is developing structurally well-defined liquid carbon-boron-nitrogen (CBN) hydrogen storage materials (i.e., heterocycles containing carbon, boron, and nitrogen) that have the potential to be reversibly regenerated using molecular hydrogen. A liquid phase, hydrogen storage system that can be regenerated using molecular hydrogen is highly desired for many reasons, including versatility, lower cost and improved efficiency, and durability. Such a storage material will allow on-board hydrogen storage. It can also be applied as an off-board energy carrier for vehicle and stationary applications that takes advantage of the existing liquid fuels infrastructure.
Approach

In order to accomplish reversibility, neutrality in free energy of the hydrogen release process (i.e., $\Delta G \approx 0$ kcal/mol) at the operating temperature is pivotal. The dehydrogenation of AB is exergonic by $-13$ kcal/mol at 298 K (eq. 1). In contrast to AB, the dehydrogenation of its isoelectronic organic counterpart, ethane ($\text{CH}_3-\text{CH}_3$), is endergonic by $+25$ kcal/mol (eq. 2). The coupling of endothermic dehydrogenation from carbon-carbon with exothermic dehydrogenation from BN in a cyclic six-membered framework could lead to a reversible $\text{H}_2$ storage system. Indeed, high-level computational analysis indicates that the release of $\text{H}_2$ from CBN heterocycles such as (1) has favorable overall thermodynamics conducive to reversibility, (e.g., see eq. 3). The potential for reversible hydrogen release/uptake and the relatively high gravimetric hydrogen density of CBN heterocycle materials (e.g. 7.1 wt% for 1) render their preparation and development an important goal. In a collaborative effort with the Chemical Hydrogen Storage Center of Excellence, this project is investigating several CBN heterocycle materials for $\text{H}_2$ storage applications using a synergistic theoretical and experimental approach. Synthesis will be a crucial component of this project given the relatively unexplored nature of these CBN heterocycles. The structurally well-defined nature of these CBN heterocycle materials will facilitate their characterization and mechanistic investigation of the proposed desorption/absorption processes.

Results

Thermodynamic Analysis of CBN Heterocycle Materials

We used theory to guide our initial target selection for synthesis. Scheme 1 illustrates the calculated thermodynamic data for $\text{H}_2$ desorption for seven proposed CBN materials. Theory predicts that Materials (1), (3), and (7) have the potential for reversibility ($\Delta G \approx 0$ kcal/mol). With the help of theory, and based on availability of synthetic methods, we conclude that our synthetic efforts should be initially directed toward Materials (1) and (7).

Synthesis of Model CBN Heterocycle Materials

The hydrogen release from heterocycle 1 can potentially involve partially spent-fuel intermediates 3-6 (Scheme 2, top). Synthetic access to all compounds on the pathway from the fully charged material 1 to the discharged fuel 2 will be essential to understand and improve the $\text{H}_2$ release and uptake properties of this particular storage system. We pursued the preparation of N-protected derivatives 2'-6' ($R = \text{t-Bu}$, Scheme 2, bottom) as models for 2-6 due to their ready availability. High-level calculations show that the thermodynamic properties of CBN Material (1) do not change significantly when the nitrogen is protected with a t-Bu group (Scheme 2).
Scheme 3 illustrates the synthesis of 2'-6'. We previously reported the preparation of heterocycle 7, which ultimately serves as the universal precursor to 2'-6'. The yields described in Scheme 3 have not been optimized. Compounds 2'-6' are all liquids with melting points below –30°C.

We also developed a first-fill synthesis of the fully charged model fuel 1', thus making all the materials/intermediates along the proposed dehydrogenation pathway synthetically available for further experimental investigation. Scheme 4 describes our synthesis.

Reaction of homoallyl bromide 12' with t-butylamine produced homoallylamine 13'. Treatment of this amine with BH₃•THF furnished the amine-borane complex 14. Subsequent intramolecular hydroboration yielded the desired model charged fuel 1' (R = t-Bu) with a storage capacity of 4.3 wt%. Replacement of the t-butylamine with methylamine gave a material with 6.1 wt% storage capacity, an increase of 42%. The yields described in Scheme 4 have not been optimized.

Development of Conditions/Catalysts that will Recharge the Spent Fuel

We investigated the regeneration of spent-fuel material 2' using a combination of molecular H₂ and hydride/proton sources. We determined that the spent-fuel material 2' readily takes up two equivalents of molecular H₂ to furnish 3' under mild conditions (Scheme 5). We also established that addition of potassium hydride (KH) to 3' followed by protonation with hydrochloric acid in a single pot gave the desired product 1' in 71% isolated yield. The regeneration route illustrated in Scheme 5 represents a simple and atom economic way to regenerate our spent fuel, with potassium chloride salt being the only byproduct from the regeneration sequence. However, the use of KH needs to be avoided to improve the energy efficiency of the process. The yields described in Scheme 5 have not been optimized.
Preliminary Experimental Thermodynamic Measurements

The availability of 2', 4', and 6' allowed us to experimentally assess the thermodynamic properties of CBN material system (1). Scheme 6 shows the calculated hydrogenation enthalpies [in brackets] versus the experimentally determined values (in parenthesis). These hydrogenations were carried out using a homogeneous catalyst RuCl₂(PPh₃)₃. Thus, calorimetric measurements in general support the computationally determined reaction enthalpy values. We determined that compound 2' can be readily hydrogenated using Pd/C as a catalyst. However, we were unable to measure the hydrogenation enthalpy of this reaction due to the heterogeneous reaction conditions. RuCl₂(PPh₃)₃ did not promote the hydrogen uptake of 2'.

Conclusions and Future Directions

In summary, we developed a versatile synthetic toolbox for the preparation of novel CBN heterocycle H₂ storage materials, including a first-fill synthesis of the charged fuel, the synthesis of the spent fuel, and all proposed partially spent fuel along the desorption pathway. The synthetic availability of CBN heterocycle materials enabled us to 1) determine preliminary thermodynamic data and 2) demonstrate a pathway for regeneration of the spent fuel. In Fiscal Year 2011, we will:

- Optimize our current synthetic toolbox with regard to yields.
- Complete experimental thermodynamic properties for model CBN heterocycles using appropriate homogeneous catalysts.
- Improve energy efficiency for recharging the spent fuel.
- Develop conditions/catalysts for H₂ desorption for CBN materials.
- Formulate the charged fuels as liquids.

End Date: September 30, 2010

Objectives

• Provide demonstrated spent fuel regeneration chemistries and physical properties to enable preliminary cost analyses by Dow.
• Develop and demonstrate heterogeneous catalysts and continuous flow reactor operation.
• Develop liquid ammonia-borane (AB) fuels and increase rate and extent of hydrogen release.
• Identify and demonstrate new materials and strategies for near-thermoneutral hydrogen release (\(\Delta G^\circ\) ideally no less negative than ca. −0.8 kcal/mol).
• Develop analytical methods to quantify gas-phase impurities that may accompany hydrogen release, develop materials and processes to minimize gas-

phase impurities, and demonstrate adequate purity of hydrogen stream.
• Lead most and coordinate all Chemical Hydrogen Storage Center of Excellence efforts and collaborative projects, and communicate recommendations to the Hydrogen Storage Engineering Center of Excellence.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (MYRDDP):
(A) System Weight and Volume
(B) System Cost
(C) Efficiency
(D) Durability/Operability
(E) Charging/Discharging Rates
(K) System Life-Cycle Assessments
(R) Regeneration Processes

Technical Targets

While all of the relevant targets detailed in the DOE MYRDDP will be addressed, our main emphasis focuses on the material requirements. The Center has developed interim technical guidelines to facilitate down selection of promising materials for further development. The Center’s key criteria for down-selection of storage materials include gravimetric and volumetric hydrogen capacities, as well as hydrogen release rate and temperature. The Center’s criteria for materials down-selection, which are mapped to the DOE technical targets for storage systems, are tabulated in Table 1. Gravimetric capacity of materials must exceed 7 wt%, with the potential to exceed 9 wt%. The latter value was determined via an analysis of Millennium Cell’s very aggressive process design for hydrogen release from

Accomplishments

- Completed chemistry and demonstration of a one-pot simplified spent fuel regeneration scheme utilizing hydrazine and liquid ammonia.
- Demonstrated regeneration of spent fuel from ionic liquid AB mixtures indicating that properly designed ionic liquids will not interfere with regeneration chemistries.
- Prepared new storage materials that have lower exo-thermicity, higher rates to higher extents of release at lower temperatures compared to AB, with many compounds exceeding 2010 targets.
- Heterogeneous base metal catalysts for hydrogen release have been prepared and demonstrated to have high rates of release to >9 wt% H₂.
- Worked with University of Pennsylvania (Penn) partners to further develop promising ionic liquid AB fuels that remain liquid throughout the dehydrogenation cycle.
- Worked with Argonne National Laboratory (ANL) and Penn to provide data ANL required to develop preliminary onboard release system analysis of an ionic liquid AB fuel.
- De-selected liquid fuel systems comprised of alkylamineborane–AB because of catalyst lifetime issues.
- Using previously developed hydrogen purity test stand, examined numerous hydrogen release systems, quantifying evolution of impurities vs. time and temperature where impurities were observed.
- Worked with Hydrogen Storage Engineering Center of Excellence to define acceptable impurity mitigation strategies for onboard gas cleanup.

Introduction

Chemical hydrogen storage involves storing hydrogen in molecular chemical bonds where an on-board chemical reaction is used to release hydrogen. Currently, the resulting spent fuel may be regenerated off-board using chemical processing. In addition to the importance of on-board storage capacity and hydrogen release rates, the energy efficiency of the off-board regeneration of spent fuel is a key contributor to the overall energy efficiency of the fuel cycle. Chemical hydrogen storage provides a diversity of options to enable hydrogen for transportation as well as other niche and stationary applications, and could also be used for hydrogen delivery where it offers the opportunity for a liquid or solid fuel infrastructure with the potential for no direct hydrogen handling by the consumer.

Researchers at LANL are advancing a number of integrated projects involving the development of materials, catalysts, catalytic processes, and new concepts for hydrogen release and regeneration of spent fuels, as well as the development of engineering feasibility of the processes. In addition, Los Alamos hydrogen storage research benefits from productive interactions with theory collaborators across the Center at the University of Alabama, the University of California, Davis, the University of Missouri, the University of Pennsylvania, Pennsylvania State University, the University of Washington, Dow, U. S. Borax, and the Pacific Northwest National Laboratory (PNNL). These partners collectively work with LANL on four major areas of research and development (R&D) in chemical hydrogen storage: 1) hydrogen release from AB, 2) regeneration of spent fuel, 3) new materials discovery, and 4) engineering supporting R&D. Additionally, the Center is also working on 'first-fill' R&D to assess processes to provide the first load of a boron-containing fuel derived from mineral borates, and with U. S. Borax in assessing domestic and foreign borate resources and reserves. LANL participates in all of these activities either by contributions to laboratory research, or in coordinating the R&D efforts among the partners, and in providing Center-wide communications among the various areas of R&D to keep all partners apprised of progress and issues.

Approach

LANL contributes to collaborative experimental projects in all areas of the Center’s efforts, primarily through investigations of storage materials chemistry and reactivity, experimental evaluation of the limits of capacity, release rates, and regeneration efficiencies, as well as development of new chemistry and catalytic processes and optimization of promising systems. In work on hydrogen release from AB, LANL’s approach is to develop liquid compositions containing AB.
and to develop mechanistic information to guide heterogeneous catalyst discovery for hydrogen release from AB and AB-like liquid systems. In the area of spent fuel regeneration, LANL’s approach is to optimize the routes to the digestion, reduction, and recycle of reagents to complete a spent fuel regeneration process, and work closely with Dow process engineers to develop preliminary baseline cost and efficiency analyses of spent fuel regeneration. This also involves collaborating closely with Penn and PNNL, who are working on separate approaches to spent fuel regeneration, and also with the University of Alabama that provides theory and modeling, and thermodynamics calculations of spent fuel regeneration chemistries. In the area of new materials discovery, LANL’s role is to work with International Partnership for the Hydrogen Economy (IPHE) partners in synthesizing, characterizing, and testing metal amidoborane compounds for hydrogen release, as well as in assessing other potential new hydrogen storage materials concepts. In the area of engineering supporting R&D, LANL contributes to the Center’s activities by performing experimental work that allows for engineering assessments of chemical hydrogen storage processes to be analyzed. LANL’s engineering effort designs, fabricates, and operates chemical reactor systems for assessing continuous hydrogen release processes, as well as systems that analyze for potential gas impurities that may impact the operation downstream devices such as fuel cells. LANL’s engineering effort also assists the development of criteria for hydrogen storage materials, an activity that informs the materials development and spent fuel regeneration efforts. LANL is a member of the Hydrogen Storage Engineering Center of Excellence lead by Savannah River National Laboratory, and has the task of helping to coordinate input into the design and development of subscale prototypes of chemical hydrogen storage systems.

Results

To enable low-temperature catalytic release of hydrogen over a heterogeneous catalyst, the fuel must be a liquid. Liquid systems are also more readily engineered into a system. Research has continued in working with Penn and ANL to work toward a preliminary onboard hydrogen release system analysis of the liquid fuel system of AB in ionic liquids. Work has continued to develop a complete set of kinetics from which ANL bases their onboard release analysis, and to optimize the liquid properties of the fuel and spent fuel. In addition, LANL has made progress in understanding some of the systematics of impurity formation in hydrogen release materials, and has worked closely with the Engineering Center to develop mitigation strategies to deal with any residual gas-phase impurities.

LANL has discontinued working on what was an initially promising liquid fuel formulation comprised of certain alkylamineboranes mixed with AB. While many of these compositions had useful liquid ranges, an additional requirement is that they must be compatible with catalytic release strategies to obtain the highest rates of hydrogen release possible at the lowest temperatures possible. Our work during this past year indicates that the alkylamineborane mixtures lead to rapid deactivation of the catalyst. The accompanying figure indicates that the rate of hydrogen release from mixtures of sec-butylamineborane/AB are low, and are similar with and without catalyst, indicating that the catalyst is deactivated (Figure 1). In a separate experiment, we observe that sec-butylamineborane by itself is unstable above 50°C, and also decomposes to yield free sec-butylamine, which is a potential catalyst poison (Figure 2). While there may be a solution to these two problems, LANL did not feel it was warranted to expend the effort to continue this line of research in the last year of the project.

2. Regeneration of Spent Fuel

LANL’s prior work in regeneration of spent fuel focused on optimizing the thiocatechol route described previously, and working with Dow (formerly Rohm and Haas) to perform the process modeling necessary to develop a preliminary baseline cost analysis of spent fuel regeneration for AB (see our partner’s annual report from Dow). Upon completion of the cost analysis by Dow, several key features to reduce cost and improve efficiency were apparent. Major improvements were potentially available from reducing the overall mass flow of reagents that was responsible for significant

FIGURE 1. Dehydrogenation of a mixture of sec-butylamineborane and AB at 60°C is invariant in rate with or without a catalyst, indicating that the catalyst is deactivated.
Another potential improvement was to combine steps whenever possible. LANL successfully addressed these opportunities, and discovered and developed a new, simplified spent fuel regeneration scheme that is shown in Figure 3. This scheme involves the use of hydrazine, \(N_2H_4\), a lightweight reducing agent as digestion and reduction agent. During the past year, LANL has demonstrated that by optimizing the conditions, the generation of byproducts can be avoided, and by using liquid ammonia solvent, pure AB may be obtained directly from spent fuel in a single operation of dissolving spent fuel in a hydrazine/ammonia mixture that results in reduction of spent fuel directly to AB. Removing the volatile excess ammonia completes the cycle. Dow has begun a preliminary analysis of this process, and it appears that the process energy is substantially less than the thiocatechol route, and because of the significant reduction in unit operations and separations that the capital costs for the hydrazine route are very favorable. The largest cost appears to be in hydrazine, which is not a surprise to us, as hydrazine is not produced in an efficient process nor on a large scale that makes hydrazine expensive. Future research could be directed at significantly reducing the cost of hydrazine.

### 3. New Materials Discovery

Our previous effort in the discovery of new materials has focused on preparing metal amidoboranes. The driving force behind our research in this area was to explore whether replacing a hydrogen atom of AB with a metal atom would sufficiently alter the reaction pathways and thermodynamics of hydrogen release such that potentially reversible systems would result. We feel that to be practical that these compounds must be reversible, because we have no ideas that will result in an energy efficient regeneration of the resulting spent fuel. It appears to us that any regeneration will require the re-synthesis of the corresponding metal hydride (M-H), and react that with AB to prepare metal amidoborane (M-AB). Of course, if the regeneration requires synthesis of M-H, one might as well use M-H as the storage material, and consider hydrolysis. However, this approach has been determined by DOE to not have a path forward because of the too numerous issues with hydrolysis systems and the regeneration efficiencies involved.

Among the metal amidoborane compounds that LANL has examined to date (\(M = Na, Li, K, Ca, Mg, Al, Ti, Sc, Zn, Sr\)), the thermochemical properties and the hydrogen release temperatures show a good deal of diversity. However, the thermodynamics of hydrogen release for all of the mono metal amidoboranes are still too exothermic to enable direct rehydrogenation using \(H_2\) gas pressure, and so to date, no materials have...
been discovered that can be directly regenerated on board. LANL has discontinued work on mono metal amidoboranes, but we suggest that bimetallic M, M’-amidoboranes still should be surveyed to determined if there are any members of that series that offers the potential of direct rehydrogenation with hydrogen pressure.

4. Engineering Supporting R&D

Engineering supports all of the decision making within the Center to drive R&D towards the most promising near-term solutions. This year our efforts in engineering support have been focused on working with Penn on their ionic liquid (IL)–AB system that is a potential liquid fuel. Two issues that influence engineering design decisions for these potentially liquid systems are 1) impurities that may arise during release, and 2) stability of the materials at 50-60°C. Impurities and stability are monitored using similar approaches. LANL monitored the stability of IL–AB mixtures as a function of time at three temperatures of 50 and 60°C for periods of 5 days. Fourier transform IR spectroscopy of the gas above the IL-AB mixture was monitored to detect potential impurities while the mass of the sample was simultaneously and continuously monitored to detect any weight loss due to decomposition resulting in gas phase products. To monitor impurities at higher temperatures during release, we use both gas-phase IR, TGA, and mass spectroscopy of the evolved gas stream to detect and quantify impurities. Among the impurities that may be detected this way are diborane, ammonia, borazine, and any impurities arising from potential decomposition of the ionic liquid. Figure 4 indicates that at 50°C, there is no detectable mass change, and we find no impurities in the gas phase over a period of 5 days. At 60°C, we detect no mass change after 5 days, but we do observe water in the gas phase. As the particular IL used is known to be hygroscopic, we assume for now that the water arises from water adsorbed on the IL starting material used to prepare the mixture. At 70°C (data not shown) where the onset of hydrogen evolution begins, we observe small quantities of ammonia being evolved initially. A small amount of borazine is also observed, but in quantities much less than from neat AB dehydrogenation.

Conclusions and Future Directions

Research at LANL in collaboration with Penn has demonstrated that the use of heterogeneous catalysts for the release of hydrogen from AB-IL fuels may begin to release hydrogen at high rates at low temperatures, and that these mixtures are quite stable up to at least 60°C. Impurities are released as well, and they include ammonia (an initial small pulse at low temperatures) and a small quantity of borazine at higher temperatures. The quantity of borazine released is relatively smaller than from pure AB. In the area of regeneration, we have discovered and demonstrated an entirely new regeneration scheme that involves digestion and reducing spent fuel to AB in a single process using hydrazine. This hydrazine process successfully regenerates a variety of spent fuel types, including the spent fuel from dehydrogenation of AB-IL mixtures. With our partners at Dow, we have provided laboratory-scale demonstration of spent fuel regeneration and the information necessary to finish a preliminary baseline cost analysis of spent fuel regeneration of ammonia borane using hydrazine.

Objectives

- Quantify borazine release from ammonia borane (AB).
- Develop hydrogen release mechanism for metal amidoboranes.
- Demonstrate high efficiency methods for large-scale synthesis of chemical hydrogen storage materials.
- Develop high-efficiency off-board methods for chemical hydride regeneration to achieve DOE targets (60%):
  - Coordinate with Argonne National Laboratory (ANL) to do preliminary efficiency analysis of regen process.
  - Support collaborators through expertise in chemistry and characterization to determine the kinetics and thermodynamics of hydrogen release and regeneration of H-storage materials:
  - Work with Chemical Hydrogen Storage Center of Excellence (CHSCoE) partners to characterize materials and novel approaches to store and release hydrogen.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume

(B) System Cost
(C) Efficiency
(E) Charging/Discharging Rates
(R) Regeneration Processes
(S) By-Product/Spent Material Removal

Technical Targets

Scheme 1 represents the focus of materials (ammonium borohydride, ammonia borane, diammoniate of diborane, lithium amidoborane and sodium amidoborane) currently under study and provides both the gravimetric and volumetric density of hydrogen. Table 1 presents a summary of the rates of hydrogen release, enthalpies of hydrogen release and impurities measured for various materials, temperatures and reaction conditions.

Accomplishments

- Provided high-purity AB to CHSCoE partners and others from our scaled-up first fill reactor.
- Metal amidoborane (MAB) release mechanism identified as metal assisted hydride transfer
- Quantified H₂ impurities from AB and demonstrated approaches to mitigate and control them.
- AB+ metal hydride mixtures showed different features compared to AB: decreased impurities, less foaming, lower exothermic release.
- Demonstrated >99% boron recovery from digestion of real spent fuels.
- Identified potential new AB synthesis route which may be able to combine first-fill and regeneration lowering costs and increasing efficiency.
- Fully characterized spent AB.

IV.B.1d Chemical Hydrogen Storage Research at PNNL
**Introduction**

Fuel cell vehicles need improved hydrogen storage to meet the DOE driving range targets of 500+ kilometers. To meet this need, the DOE established three Centers of Excellence to develop materials for hydrogen storage. PNNL is part of the CHSCoE which is a partnership between national laboratories, universities and industrial partners. The CHSCoE is tasked with inventing, testing, and recommending chemical hydrides that may meet the DOE targets.

**Approach**

PNNL’s approach is consistent with the philosophy of the CHSCoE. A comprehensive understanding of reaction mechanisms will enable the development of rational approaches to enhance rates of release, increase purity of hydrogen, and provide energy efficient regeneration schemes. In addition to a focus on solid state chemical hydrogen storage, PNNL has responsibilities for theory and simulation and core science and engineering competencies within the CHSCoE. Therefore, PNNL’s work within the CHSCoE is inherently multidisciplinary and highly collaborative with several of the CHSCoE partners.

PNNL has many activities including examination of mechanisms of hydrogen release from solid ABs, experimental work on the regeneration of spent ABs, and addressing the materials handling issues associated with solid fuels. PNNL leads the engineering activities within the CHSCoE, which are now targeted toward off-board regeneration of fuels. This group interfaces on a regular basis with DOE’s Storage System Analysis Working Group.

**Results**

Efforts at PNNL in Fiscal Year (FY) 2010 focused on five major tasks: (i) demonstration of scale up of the “first-fill” synthesis of AB, (ii) examining mixtures of AB and metal hydrides, (iii) International Partnership for the Hydrogen Economy (IPHE) materials including

Summary of rates, enthalpies and purity of hydrogen. theoretical density (measured density). Bz = borazine. ? = not yet measured, will be determined in future work. All compositions tested are not shown. C = Continue, D = Discontinue for on or off board transportation systems, still may be applicable for stationary or portable applications.
identifying the hydrogen release mechanism from MAB, (iv) quantifying the concentration of impurities, NH$_3$, and borazine in the hydrogen released form AB, and (v) regeneration.

**First-Fill:** PNNL demonstrated the bench-scale reactor designed and built in FY 2009. The reactor scaled up PNNL's AB synthesis to 100 g quantities (factor 10x). It is a one-pot synthesis reactor which provides high yield (95-99%) and high purity (>99%) AB. Parametric studies were done using the reactor. The results indicate that a semi-continuous reactor scheme may be viable, and its design is underway. Dow's (formerly Rohm and Haas) analysis of our process indicated that the projected cost was $9.1/kg AB and the high purity and yield make our process superior to the state-of-the-art.

**AB/Metal Hydride Mixtures:** We investigated different combinations of AB mixed with metal hydrides (MH), i.e. MgH$_2$, CaH$_2$, TiH$_2$ and/or ZrH$_2$. We ball milled a series of different combinations of AB+MH powders to obtain tuned materials properties. The composite of ammonia borane+10 mol% TiH$_2$ shows a remarkable drop in impurity levels to <1%, as compared to neat AB, specifically borazine and ammonia which are released simultaneously with hydrogen. The mixture of AB+0.5 MgH$_2$ with addition of 10 mol% TiH$_2$, did not release any detectable amounts of borazine, ammonia or diborane and did not show any foaming. Moreover, the hydrogen release temperature was lowered by ca 20°C.

**IPHE Materials and MAB Hydrogen Release Mechanism:** A new series of substituted metal amidoboranes MNHRBH$_3$ (M = Li,Na,K; R = H, CH$_3$, C(CH$_3$)$_3$-) have been synthesized. A detailed study has indicated that hydrogen release takes place through a metal ion-assisted hydride transfer mechanism and the formation of a metal hydride intermediate. In these compounds the dihydrogen bonding of the parent AB has been replaced by a $M^+$...H$^+$B interaction and this, in agreement with our detailed studies of release from AB, may explain why there is no induction period observed. No ammonia (<10 ppm) was observed for the materials when the material is decomposed in a sealed reactor and the strong dependence of reaction rate on temperature suggests the materials will be unaffected by storage at even high ambient temperatures.

The reactivity trend of hydrogen release from metal amidoboranes is the opposite of the reactivity trend of hydrogen release from metal borohydrides. In the case of the MABs the metal cation performs a hydride transfer (or relay) from the neighboring borane to the protonic hydrogen of the amine. This is interesting from a mechanistic outlook as the formation of the nascent metal hydride is faster for the more stable hydrides, however the more stable the metal hydride the greater the barrier for hydride transfer to the amine – thus the rates for each step are opposite in reactivity the observed rates tend to be moderated. However, as the K > Na > Li the formation of the nascent MH appears to be rate limiting and therefore give the opposite reactivity of the corresponding borohydrides, that is Li > Na > K. As the ionization energy increases, the activation barrier for the M-step decreases, whereas the activation barrier for the H-step increases thereby explaining why the rate trend for release is K > Na > Li [1].

**Impurities from AB:** Hydrogen generated from AB decomposition was analyzed using various analysis tools such as nuclear magnetic resonance (NMR), Fourier transform infrared, and mass spectrometry to determine the ammonia and borazine levels. Quantitative amounts of borazine were found by bubbling AB-generated hydrogen with a sweep gas of 20 ccm nitrogen through a liquid trap (Tetrahydrofuran or glyme) which captured the borazine impurities. We then used solution NMR to measure the amount of borazine produced. Figure 1 contains a summary of the results. It was determined that the ramp rate and temperature impacted the amount of borazine produced, with the temperature being the dominant factor. At temperatures below 150°C, the borazine levels was <1 wt%, but increased by an order of magnitude when the temperature exceeded 150°C. High temperatures combined with fast temperature ramping (>5°C/min) increased the borazine levels to >12 wt%. As far as we can tell the ammonia produced (100-250 ppm) was independent of temperature and ramp rate within our experimental error of measuring ammonia with a Draiger tube. In addition, if the reactor was sealed during hydrogen generation, and the hydrogen released slowly much less ammonia was detected indicating that residence time impacted the ammonia production rate. This is especially true for the MABs. Additives impacted the impurities in different ways. For example, both AB on mesoporous silica scaffolds (1:1) and AB mixed with CoCl$_2$ (<5 wt%) were found to have decreased borazine (<1 wt%) produced even at temperatures >150°C and ramp rates >5°C/min; however, AB on a BN scaffolds resulted in no improvements in regards to borazine.

**FIGURE 1.** Summary of Borazine Release from AB and AB with Additives
production. Since high temperature and ramp rates will be required to generate hydrogen in sufficient quantity to meet the hydrogen generation targets, neat AB research should be discontinued. However, AB with additives such as CoCl₂ showed low borazine release, and CoCl₂ significantly reduced foaming making AB with additives a “Go” decision for future research. Metal amidoboranes did not produce any borazine since the release mechanism is different than that of AB; however, the ammonia release was higher (0.2 wt%) than that of AB.

**Regeneration of Spent Fuel:** Another key aspect of the PNNL project is chemical regeneration. A process was envisioned as shown in Scheme 2; where R is tert.-butanol; PhOH is phenol; M is a transition metal complex. PNNL has found precedent for and demonstrated all the steps individually.

Digestion chemistry had been demonstrated using model spent fuels in previous years: borazine and borazine-derived polyborazylene. However, information is needed to assess regeneration cost and efficiency of real spent fuel. In FY 2010 we worked on digestion of real spent fuels obtained from AB dehydrogenation. Monothiols do not digest spent fuel. We tried to transesterify alkyl borates with thiophenol, but those results were unsuccessful. Digestions with aliphatic alcohols produce borate esters and a white residue, to varying degree depending on the alcohol. We optimized reaction conditions to maximize total conversion and recovery of boron. Approximately 85% of the boron was recovered as B(OEt)₃. This ester as well as other alkyl borates can be transesterified with phenols to produce aryl borates [2]. The boron residue was recovered as boric acid by adding aqueous HCl. Boric acid converts to B(OEt)₃ under same conditions as used for transesterification [2]. Therefore it is envisioned that >99% B can be recovered. Digestion with ammonium tetrafluoroborate was tried since we have been able use BF₄⁻ in reactions analogous to Step 3 using HRh(dmpe)₂. Reacting NH₄BF₄ with spent fuel in effect combines Steps 1 and 4 to accomplish recycling of BF₄⁻ byproduct of Reaction 3.

All the steps of Scheme 2 have been demonstrated using Rh based catalysts. Due to the high cost of Rh, lower cost transition metals (Co and Ni) were examined. In FY 2009 PNNL synthesized complexes with dmpe and other bis phospine ligands and explored their properties and reactivities (for steps 2 and 3). The results show that HCo(dmpe)₂ is not strong enough of a hydride donor to transfer a hydride to B(OPh)₃. However, it readily transfers H⁻ to B(O(CF₂)₃)₃, which has greater H⁻ affinity compared to B(OPh)₃. On the basis of these observations and recent theoretical analyses, PNNL in FY 2010 examined the use of chlorophenols and fluorophenols in place of phenol in the above process with complexes of Co and Ni. We used theory to identify aromatic borate esters with hydride affinities greater than that of B(OPh)₃. Literature reports [3] suggested that halogenated phenyl borates would have greater Lewis acidity than phenyl borate. We calculated hydride affinities for several chloro and fluoro-substituted phenol borates and found indeed that hydride affinities could be significantly increased by halogen substitutions. In collaboration with US Borax scientists (Dave Schubert and Duane Wilson), several compounds were synthesized and characterized by NMR. Their relative Lewis acidities were determined as well based on the adduct with triethylphosphine oxide. We used this index to corroborate calculated hydride affinities and correlate with reactivity toward HRh(dmpe)₂ and HCo(dmpe)₂, and identified the most likely halogenated phenyl borates for Step 3. We found that Co hydrides de-chlorinate chlorophenyl borates. The reactions of HCo(dmpe)₂ with less than fully fluorinated phenyl borates are complex. Evidence for hydride transfer to 2-fluorophenyl borate was not observed, suggesting that esters of mono-fluorophenols do not have high enough hydride affinity. HCo(dmpe)₂ did react with the borate ester of 3,5-difluorophenol and evidence of hydride transfer was observed, but the reaction was complicated by side reactions that consumed B-H containing products and partially decomposed the Co(dmpe)₂⁺ complex.

Reactions of B(SPh)₃ with HCo(dmpe)₂ and HNi(dmpe)₂⁺ were investigated to assess the range of boron compounds that could be reduced with these hydrides. For the Co complex, facile reduction of all B-S bonds to B-H bonds occurs. Reactions run in the presence of triethylamine produced triethylamine borane as the sole boron containing product.

### Scheme 2. Process using Transition Metals Catalysts to Regenerate Spent AB Fuel

1) **Digestion**

\[
\text{BH}_3 + 3 \text{t-BuOH} \rightarrow \frac{9}{2} \text{H}_2 \uparrow + \text{NH}_3 \uparrow + \text{B(O-t-Bu)}_3
\]

\[
\text{B(O-t-Bu)}_3 + 3 \text{PhOH} \rightleftharpoons \frac{3}{2} \text{B(OPh)}_3 + 3 \text{t-BuOH}\uparrow
\]

2) **Transition Metal Hydride Formation**

\[
3 \text{M}^+ + 3 \text{H}_2 \rightarrow 3 \text{MH}^+_3 \ 	ext{[+ 3 base]} \rightarrow 3 \text{MH} + 3 \text{H}^+\text{base}
\]

3) **Hydride Transfer/Ligand Redistribution**

\[
3 \text{MH} + 4 \text{B(OPh)}_3 + \text{Et}_3\text{N} \rightarrow 3 \text{M}^+ + \text{B(OPh)}^-_3 + \text{Et}_3\text{NBH}_3
\]

4) **Recycle**

\[
3 \text{B(OPh)}^-_3 + 3 \text{H}^+\text{base} \rightleftharpoons 3 \text{PhOH}\uparrow + 3 \text{base} + 3 \text{B(OPh)}_3
\]

5) **Ammoniation**

\[
\text{Et}_3\text{NBH}_3 + \text{NH}_3 \rightarrow \text{BH}_3\text{NH}_2\downarrow + \text{Et}_3\text{N}
\]
For the Ni complex, two of the three B-S bonds were readily replaced to give PhSBH₂NEt₃. As mentioned, digestion of spent fuel to B(SPh)₃ has not been demonstrated. Also, these reactions produce metal complexes with SPh ligated to the metal. Digestion to B(SPh)₃ and recycle of these complexes remain to be worked out.

Finally, Dow’s cost analysis of AB synthesis revealed the most significant cost being NaBH₄ production from AlH₃-L (Scheme 3). Adding to the cost is the fact that 25% of the hydrogen in the NaBH₄ is lost in the conversion to AB. After looking at the process production route, we believe that AB could be produced directly from the AlH₃-L improving the hydrogen utilization and eliminating NaCl production potentially resulting lower cost (Scheme 4). A literature search revealed that all the steps of PNNL’s proposed process have been demonstrated except one. We successfully demonstrated that step this year. This process still requires Al³⁺, which is very expensive to produce. We believe there is a way to avoid the smelting process and potentially decrease the cost of AB synthesis. If the smelting process can be avoided, then this new synthesis process would also be applicable to regeneration of spent fuel. Therefore, a single facility could be used for fuel synthesis and spent fuel regeneration decreasing capital costs. This is a recommendation for future work.

Conclusions and Future Directions

Conclusions

- Bench-top scale AB synthesis reactor demonstrated a 10x increase in AB production capability showing

- AB + metal hydride mixtures showed different features compared to AB, with some mixtures showing no borazine production, less foaming, and lower exothermicity.

- Quantified impurities in H₂ from AB and demonstrated approaches to mitigate and control.

- In order to meet the hydrogen generation targets, the ramp rate and temperature needed for AB to generate hydrogen also result in high impurities, it is recommended that neat AB not be further developed for use in on-board hydrogen storage.

- AB with additives such as CoCl₂ can meet the hydrogen generation rates without producing excessively large amounts of borazine, further development of AB with additives is recommended.

- Identified potential new AB synthesis/regeneration route.

- Since the chlorinated phenyl borates undergo dechlorination in reactions with Co hydrides, work to develop AB regeneration via this system is not recommended.
Future Work

This project has ended. Therefore the future work is primarily working with the Engineering Center in the development of systems. Recommendations for future work based on this project include:

- Development of a flow reactor for AB synthesis.
- AB with additives to reduce borazine impurities.
- Investigation of the new AB synthesis/regeneration route.
- Metal amidoborane development to find an endothermic system that is regenerable on-board.
- Develop and assess routes for converting spent fuel to B(SPh)₃ and recycle of Co(dmpe)₂SPh and [Ni(dmpe)₂SPh]⁺.
- Develop better understanding of reactions of fluorinated phenyl borates with Co hydrides to assess feasibility of their use in regeneration scheme.
- Assess reactivity of fluorinated and chlorinated phenyl borates using Ni²⁺ hydrides.

Objectives

The Hydrogen Sorption Center of Excellence (HSCoE) developed high-capacity sorbent materials that operate at cryogenic to ambient temperatures and are efficiently and quickly charged in the tank with minimum energy requirements and minimum penalties to the hydrogen fuel infrastructure. Work was directed at overcoming barriers to DOE system goals and identifying pathways to meet the hydrogen storage system targets. In particular, the HSCoE strove to:

- Develop high specific surface area (SSA) sorbents with optimal H binding energies with the focus to increase binding up to ~25 kJ/mol H₂ for room temperature operation. This enables:
  - High-capacity systems that operate at modest pressures (e.g., less than 100 bar) and below fuel-cell operating temperatures (<70°C).
  - Meeting both gravimetric and volumetric targets simultaneously with rapid kinetics.
  - Efficient and rapid on-board refueling with minimum energy requirements.
- Rapidly correlate capacity, structural, and energetic information to reduce time between discovery, assessment, and down-selection of materials:
  - Integrate experiment and theory seamlessly in both “feedback” (explanation) and “feed-forward” (discovery) modes.
  - Devise facile synthetic routes using low-cost approaches.
- Create a nimble and flexible, yet structured, teaming environment to accelerate discovery, evaluation, and selection of promising development directions:
  - Partners were organized in focused groups to optimize development and avoid duplication of effort, with seamless integration of experiment/theory.
  - Quantitative down-select criteria were used prior to beginning significant development and at go/no-go points.

Technical Barriers

The HSCoE developed novel high SSA sorbents to be used in hydrogen storage systems for advanced fuel cell technologies. During the past year, the HSCoE had 15 active projects at 18 institutions. HSCoE partners conducted a wide range of applied research and engineering studies on currently available sorbents and developed design principles and synthetic methods with the goal of creating next-generation materials that have the potential to meet the critical DOE hydrogen storage system targets. The technical barriers addressed by these projects from the Fuel Cell Technologies (FCT) Program Multi-Year Research, Development and Demonstration Plan included:

General:

(A) System Weight and Volume  
(B) System Cost
IV.C Hydrogen Storage / Hydrogen Sorption CoE

Simpson – National Renewable Energy Laboratory

(C) Efficiency
(D) Durability/Operability
(E) Charging/Discharging Rates
(J) Thermal Management

Reversible On-Board:

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
(Q) Reproducibility of Performance

Technical Targets

The HSCoE developed sorption materials for hydrogen storage systems. In general, sorbents can be used in systems to meet most of the DOE hydrogen storage targets for light-duty vehicles. Thus, the HSCoE focused efforts to address the highest-risk targets for sorbents which are primarily associated with capacity and costs, including:

- Cost: $4/kWh net
- Specific Energy: 1.8 kWh/kg
- Energy Density: 1.3 kWh/L
- Charging/Discharging Rate: 3.3 min.

Accomplishments

The HSCoE partners worked closely together to systematically accelerate the development of advanced hydrogen sorbents. For specific details, please review their individual contributions to this report. A summary of the major accomplishments for the HSCoE overall is listed in the following.

- Designed and developed reversible sorbents via ambient temperature hydrogenation techniques that have over 4 wt% storage capacities with isosteric heats of adsorption of 10-30 kJ/mol.
  - Pioneered the development of spillover that has been validated on numerous materials and that have relatively low chemical binding of hydrogen, potentially allowing efficient reversible on-vehicle refueling. This class of materials enables hydrogen storage system designs with more than 75% of the volumetric and gravimetric capacities of the materials and substantially reduces system costs and complexity.
- Developed new materials that increased the gravimetric (~40%, e.g. from ~5 to >7 wt% at 77 K) and volumetric (~150%, e.g. from ~15 to >35 g/L at 77 K) hydrogen storage by physisorption onto high SSA sorbents by optimizing pore sizes (0.7 to 1.5 nm) to increase specific surface area and packing density.
- It may be possible to meet DOE 2015 on-vehicle refueling hydrogen storage system capacity targets with physisorption-based optimized material at cryogenic temperatures and relatively low pressures (i.e. 10 to 50 bar). The decreased pressures, compared to high pressure 350 to 700 bar storage systems, enabled by relatively inexpensive carbon-based sorbents could substantially reduce tank and balance-of-plant costs.
- Synthesized new high SSA physisorption materials with optimized uniform pore size using a variety of scalable/inexpensive processes.
- Discovered and championed an entire class of viable materials that uses lightweight (e.g. 3d metals) metal centers to enhance H₂ isosteric heats of adsorption and enable multiple H₂ binding on each metal site.
- Initial theoretical work demonstrating multiple molecular hydrogen (H₂) binding to electronically unsaturated 3d metals (50 kJ/mol – H₂) was first performed by the HSCoE. These studies initiated hundreds of subsequent theoretical and experimental studies in the research area of strong/multiple H₂ binding. The original paper [1] has been cited nearly 200 times. This work paves the way to meet DOE’s ultimate storage targets at ambient temperatures.
- Designed and developed substitutional materials with enhanced dihydrogen binding energy to increase capacities at near ambient temperatures, on a per SSA basis.
- Substituted materials enhance hydrogen isosteric heats of adsorption (e.g. ~11 kJ/mol for B substituted carbon, compared to ~5 kJ/mol for pure carbon) sufficiently to increase capacities at near ambient (e.g. ~200 K) temperatures. Substituted materials have the potential to meet DOE’s 2015 hydrogen storage system capacity targets. Increasing storage temperatures to near ambient helps decrease system costs by reducing the amount of insulation, tank, and balance of plant costs.
- Confirmed that standard physisorption-based dihydrogen adsorption scales with SSA. To date, no validated experimental evidence exists that any substantial capacity enhancements occurs due to geometric configurations.
- At the outset of the Center, numerous publications had reported extraordinary results for high SSA materials where the enhanced capacities where potentially a result of novel geometries or structures within the material. In general, heats of adsorption can be increased
with multiple wall interactions in very small pores, but this ultimately reduces capacities. The Center did not validate any single element material or any materials with unexceptional electronic states that have substantially higher hydrogen storage capacities beyond what is expected based on the SSA and specific storage conditions.

- Developed unique measurement capabilities to accurately and reliably characterize hydrogen storage properties.
  - Neutron scattering.
  - High-pressure H₂ nuclear magnetic resonance that performs measurements from 77 K to ambient.
  - Hydrogen storage properties with small laboratory-scale (1-100 mg) samples:
    - Enables high throughput and rapid screening analysis:
      - Accurate hydrogen storage property measurements a major problem in the community for decades.
      - Partly due to only having small quantities of “laboratory-scale materials” to characterize.
      - Developed protocols and measurements capable of accurate results from small amounts of sample:
        - Substantially enhanced throughput by eliminating need to develop larger scale synthetic methods or repeating synthesis processes numerous times to make enough material.

Introduction

To realize the full energy efficiency, energy savings, and environmental improvements that fuel cells can provide, significant improvements over currently available high pressure-based gas storage technologies are required. The storage targets presented in DOE’s FCT Program Multi-year Research, Development and Demonstration Plan state the critical needs and goals. To improve the mass, volume, cost, safety, and efficiency requirements for vehicular or early market storage systems, DOE is investigating solid-state storage options such as metal hydrides, chemical hydrides, and sorbents. Nanostructured high surface area materials containing carbon, metals, oxygen, and other elements show tremendous promise for breakthrough performance in gas storage. Enough progress has been made by the HSCoE that it may be possible to use sorbents to construct a hydrogen storage system that meets DOE’s 2010 targets. The capabilities of these materials can be improved further by developing a better understanding of both the factors governing their performance and the design principles for synthesizing the materials and constructing the required systems.

The HSCoE developed reversible sorbent materials for energy storage within this DOE Fuel Cells Technology Project. The HSCoE developed the science base and technology advances needed to identify and create nanostructured sorbents that have the potential meet DOE goals for on-board storage. A guiding principle in developing the required materials was that a continuum of energies exists for binding to substrates and molecules. On the weak side of the continuum is non-dissociative physisorption due purely to van der Waals (vdW) forces (4 kJ/mol). On the strong side is the full chemical bond in materials such as methane (with an energy of ~400 kJ/mol). Between these two limits, with binding energies between 10 and 40 kJ/mol, are: (i) stronger physisorption (due to modification of the key parameters affecting vdW forces), (ii) dihydrogen binding via the formation of complexes that exhibit bond stretching and joint charge transfer interactions, and (iii) weak, reversible chemical bonding of mono-atomic hydrogen to strained receptor materials (“spillover”). The DOE goals can be met with sorption-based materials if (i) the energy for adsorption can be designed to be in an optimal range (10–40 kJ/mol) [2], and (ii) efficient volumetric arrangement of a sufficient number of suitable binding sites can be achieved with a low-weight material. These goals are difficult to reach in conventional high surface area adsorbents that are limited by low physisorption binding energies, heterogeneity of the adsorbent surfaces and adsorption sites, and excessive macroporosity and poor volumetric packing.

Approach

The HSCoE discovered the limits of performance of high surface area adsorbents and synthesized and tested sorbents with the potential to meet the DOE system targets for reversible storage. This involved the design and synthesis of new materials that bind large amounts of hydrogen on both a per-weight and a per-volume basis as (i) weakly and reversibly bound atoms and/or (ii) strongly bound molecules. The HSCoE focused on determining binding mechanisms and energies, and the manner in which suitable sites could be organized in space to achieve a high-volumetric density using low-weight frameworks. This involved determining the affects of geometry, introduction of defects, adventitious dopants, and catalytic species, as well as elemental substitution. The HSCoE investigated a range of different lightweight nanomaterials and porous frameworks and championed the development of new sorbents for ambient temperature hydrogen storage.
Results

HSCoE members worked closely together to effectively leverage unique partner capabilities in a coordinated set of focused efforts to accelerate storage materials development. These close and actively coordinated interactions resulted in dozens of joint projects in the past year, in which the rapid materials development is illustrated by the more than 20 joint publications. In addition, the HSCoE works with more than 40 groups from around the world and directly with the chemical hydride, metal hydride, and engineering centers of excellence to ensure that our development efforts leverage other research activities for efficient utilization of resources. Finally, the HSCoE also ensures that its development efforts are transparent and provided to the scientific community in a timely manner to again help speed the storage materials’ development progress. This is done through the active organization by HSCoE partners of hydrogen storage materials conferences around the world, and through more than 100 presentations at conferences and more than 50 publications in refereed journals in the past year.

A few highlights of results from the massive amount of development work from throughout the HSCoE are provided in the following.

Optimizing High SSA Materials: In general, storage capacities increase with higher SSAs and higher bulk densities. However, while these are necessary requirements for high storage capacities, enhanced binding energies for the entire capacity range will be required in order for the materials to be used to meet DOE targets. The HSCoE has focused efforts to improve all of these material properties independently and simultaneously. Within the last year, the HSCoE continued to increase specific surface areas and capacities of materials using coordinated framework and porous carbon materials (Figure 1). The HSCoE used a number of different synthetic routes to form optimized geometric materials using processes that include: templating, graphene, aerogel, chemical, vapor, and/or pyrolysis. Even though most of these materials will require cryocompression, they have no significant heat transport issues, can operate at moderate pressures, and may require the least engineering (compared to metal or chemical hydrides) to design and construct a system that could meet the DOE 2010 targets. Material capacities of more than 7 wt% and 40 g/L have been demonstrated at 77 K. These capacities increase by ~30% if the sorbent system stored hydrogen at ~50 K, i.e. >8 wt% and >50 g/L. At this temperature, only ~20 bar pressures would be required and it may be possible to design a storage system that could meet the DOE 2015 hydrogen storage capacity targets. This increase in capacity would be traded against decreases in well-to-fuel cell efficiencies but could improve overall system cost compared to high pressure (i.e. 350 to 700 bar) storage by using much lower pressures (Figure 2).

Improving Site-Specific Dihydrogen Binding Energy: In addition to optimizing geometric structures to improve storage properties, the HSCoE pioneered the use of multiple-element materials to improve dihydrogen binding. In good agreement with theoretical models [3], B substituted with an sp2 structure in carbon enhances hydrogen binding to ~11 kJ/mol [4]. Over the past year, the HSCoE also demonstrated this enhanced hydrogen binding in B substituted carbons through the use of neutron scattering and diffuse reflective infrared fourier transform spectroscopy (DRIFT) (see PSU and NIST contributions to this report). The main issues...
remaining include the need to substantially increase the B concentration while maintaining a high SSA (see PSU and NREL contributions to this report). In this regard, the HSCoE investigated the use of several synthetic techniques to address these issues, including: pyrolysis of BC precursor materials, templating BC₃, and chemical replacement processes.

In addition to B enhancing dihydrogen binding and thus storage capacity at near-ambient temperatures, B and N have also been used to stabilize single-metal centers and metal clusters on high surface area materials. The HSCoE has championed the use of coordinated metal centers to increase dihydrogen binding and to also enable multiple dihydrogen binding at a single adsorption site. Work by TAMU and NIST have demonstrated the enhanced binding of metal centers in metal organic framework materials. Furthermore, the neutron scattering work confirm the theoretical prediction that the binding energy depends on the metal used. Although initial reaction to these materials was skeptical, recent experimental results validate the predictions, and there is good agreement between the predictions and all known 3-d metal center materials. Over the past year, the HSCoE has focused efforts in identifying materials and processes that are more synthetically possible (e.g. Figure 4, [6]) starting from existing materials. These types of materials provide a reasonable path for meeting DOE’s ultimate storage targets (i.e., 7.5 wt% and 70 g/L) with inexpensive sorbents.

**Improving Spillover Material Processing:** While most of the work within the HSCoE is associated with enhancing the storage of molecular hydrogen, we are also developing materials that can reversibly store weakly bound hydrogen atoms. For example, Ralph Yang’s group at the University of Michigan pioneered the use of spillover as a viable high capacity ambient-temperature hydrogen storage process. UM demonstrated that over 4 wt% hydrogen can be reversibly stored on a catalyst containing metal organic framework material, and calculations indicate that 7–8 wt% (50–60 g/L) should be achievable at ambient temperature. Over the past year, the HSCoE continued developing new spillover based materials including demonstrating the spillover is enhanced on pyrolized sucrose; a material often used to bridge between catalysts and high surface are receptors. In addition to improving catalyst processing, receptor materials, reproducibility, and rates, the HSCoE also identified potential mechanisms based on geometrical structures and electronic properties that substantially reduce the barrier to diffusion and thus could significantly increase the kinetic transport rate of atomic hydrogen on the receptor surfaces.

**Conclusions**

- The HSCoE partners worked closely together to systematically accelerate the development of advanced hydrogen sorbent materials. This
Designed/developed substituted materials to enable higher hydrogen binding energies in porous materials. Confirmed the enhanced hydrogen binding of the B substituted materials with neutron scattering and DRIFTS measurements. BC$_x$ materials could increase the storage tank temperature and capacity, thus reducing overall system costs once sufficient B concentration and specific surface area are achieved. Substituted materials also enhance stabilization of metals and potentially improve weak chemisorption processes.

Developed new materials with stronger H$_2$ binding either through interactions with exposed metal centers or electrostatic effects. This work included the experimental validation by neutron scattering that the binding energy depends upon the specific metal used. The Center also identified materials that could be more easily synthesized. This work paves the way to meet DOE’s ultimate storage targets with ambient temperature storage densities greater than liquid H$_2$.

Improved spillover process understanding to help create sorbents with higher capacities and sorption rates that can meet DOE 2015 hydrogen storage targets at ambient temperatures. This included identification of electronic and structural dependencies for atomic hydrogen diffusion on the receptor materials, the thermodynamic processes of the catalysts, and improved spillover rates and capacities with functionalization.

HSCoE works with dozens of groups and provides leadership throughout the world.

resulted in the development of multiple new materials that may be able to be used to meet the 2010 and possibly the 2015 DOE storage system targets including cost and gravimetric/volumetric capacities.

**FIGURE 3.** Some coordinated metal center materials designed by the HSCoE maintain optimum hydrogen binding energies for their entire capacity range. This helps engineering and enhances the material capacity.

**FIGURE 4.** Covalent-organic framework with Ca atoms integrated on carbon linkers. This is an example where known materials where used to form sorbents with a potential for high hydrogen storage capacities.
Future Directions

The HSCoE will focus the remaining effort on completing a comprehensive final report. Provide DOE with a comprehensive review of all significant work done, results, lessons learned, and recommendations for future sorption materials development. Key aspects of this review will include material and/or process recommendations for future consideration in engineering system analysis, design, and demonstration, as well as future research and development efforts, including:

- The Center recommends that development efforts for specific material classes be continued where viable routes exist for synthesizing sorbents that can be used to meet the appropriate set of targets:
  - The specific selection criteria for future efforts should focus on the DOE 2015 and the ultimate full-fleet hydrogen storage targets.
  - Numerous materials recommended for no further development.
- Develop materials for hydrogen storage by weak-chemisorption:
  - Ambient-temperature storage via catalytic hydrogen dissociation and transfer to high SSA receptor materials (e.g., spillover) demonstrate 10 to 30 kJ/mol reversible hydrogen binding energies, which enable ambient-temperature storage.
  - Minimizes thermal management and reduces overall storage system cost.
  - Need to improve understanding of atomic H transport to increase rates/capacities and enhance reproducibility and durability.
  - Weak chemisorption enables ambient temperature storage with systems having more than 75% of the material capacities at moderate (~100 bar) pressures.
- Develop materials for multiple hydrogen storage on designated sites:
  - Maybe only route that enables materials to be developed to meet DOE ultimate system targets; especially for on-vehicle refueling.
  - Inexpensive material systems identified to meet ultimate targets.
  - Meeting DOE’s ultimate targets will enable hydrogen to become a viable energy carrier for transportation and other important renewable energy applications.
- Develop substituted/heterogeneous materials that have demonstrated hydrogen binding energies in the range 10–25 kJ/mol:
  - Enables near-ambient-temperature (150–250 K) hydrogen storage.
  - These heterogeneous materials also demonstrate substantial stabilization of single-metal centers and other absorbed species that improve hydrogen storage.
- Limit development of materials in which the storage mechanism is physisorption to only those with optimized structures:
  - To meet the DOE 2015 targets, the only physisorption materials that should be considered for development are those that can have SSAs greater than ~3,000 m$^2$/g, optimized uniform pore sizes in the range of ~0.7 to ~1.5 nm, and excess material hydrogen storage capacities greater than 50 g/L and 7 wt% at cryogenic temperatures (~80–200 K) and moderate pressures (less than 100 bar).

Remaining Issues:

- Develop robust, reproducible, and scalable synthetic methods that create materials where all the adsorption sites are accessible to the hydrogen.
- Improve computational methods to more accurately predict the ability to synthesize designed materials and the hydrogen storage capacity as a function of temperature and pressure.
- Develop a better understanding of atomic hydrogen transport on receptor materials.
- Develop a better understanding of metal center coordination and it's effect on hydrogen adsorption.
- Develop materials in concert with designs for hydrogen storage systems.
- Develop sorbent material measurements standards and certifications.

Support the Hydrogen Storage Engineering Center of Excellence (HSECoE): Work with the HSECoE to select potential materials and provide their intrinsic hydrogen storage properties needed for system engineering design, analysis, and perhaps demonstration.

Sorbent Materials Approach to DOE 2010 Targets: In general, sorbents meet almost all of the DOE hydrogen storage targets. As discussed above, sorbents may greatly improve volumetric capacities, and the HSCoE has developed several materials that may meet DOE’s 2010 on-board refueling targets.

Objectives

- Design, synthesize, and characterize metal-organic frameworks (MOFs) with active metal centers aligned in porous channels and accessible by H₂ molecules.
- Through optimized, cooperative binding, the MOFs are expected to have enhanced affinity to H₂.
- These MOFs can help to reach the DOE 2010 and ultimately 2015 hydrogen storage goal.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

(Q) Reproducibility of Performance

Technical Targets

- The focus of the proposed research is the use of concepts evident in metalloproteins to guide the synthesis of MOFs with gas-adsorption affinity around 15 to 20 kJ/mol for hydrogen.
- The overall objective is to achieve the DOE 2010 and 2015 system goals, primarily the gravimetric and volumetric storage goals, at or near ambient temperatures and moderate pressure for on-board vehicular hydrogen storage (Table 1).

Accomplishments

- Crystal twins with two isomeric phases have been discovered, and gas sorption studies revealed that compared to the β-phase, the α-phase possesses a larger surface area leading to higher hydrogen capacity. This symmetry-preserving isomerization strategy can be applied to other MOFs.
- A MOF, which is based on a polyyne-coupled di-isophthalate linker formed in situ, was constructed. Compared to phenyl rings, the polyyne chains showed improved hydrogen affinity.
- An isoreticular series of MOFs with dendritic hexacarboxylate ligands tend to have high surface area and stability. PCN-68 has an excess gravimetric H₂ uptake of 7.2 wt% at 77 K and 50 bar.
- Porous organic frameworks (POFs) with high surface area and tunable pore size were designed and synthesized. They exhibit promising H₂ uptake.

Introduction

In the past decade, there has been an escalation of interest in the study of MOFs due to their fascinating structures and intriguing application potential. Their exceptionally high surface areas, uniform yet tunable pore sizes, and well-defined adsorbate-MOF interaction sites make them suitable for hydrogen storage. Various strategies to increase the hydrogen capacity of MOFs, such as using pore size comparable to hydrogen.
molecules, increasing surface area and pore volume, utilizing catenation, and introducing coordinatively unsaturated metal centers (UMCs) have been widely explored to increase the hydrogen uptake of the MOFs. Recently, inelastic neutron scattering and neutron powder diffraction as well as computational studies suggest that the choice of both metal centers and ligands can play an important role in tailoring the gas-framework interactions. Additionally, those ligands containing phenyl rings have been proven favorable for hydrogen desorption. MOFs with hydrogen uptake approaching the DOE 2010 gravimetric storage goal under reasonable pressure but cryo-temperature (typically 77 K) were reported. However, the weak interaction between hydrogen molecules and MOFs has been the major hurdle limiting the hydrogen uptake of MOFs at ambient temperature.

Approach

Our strategy to enhance H₂ uptake was as follows: (1) Prepared the catenation isomer pair to evaluate the contribution from catenation to the hydrogen uptake of a MOF material. Catenation can be utilized to reduce pore sizes in porous MOFs and has also been explored as an efficient method to improve the hydrogen uptake of MOFs. (2) Synthesized porous MOFs with high hydrogen adsorption capacities based on different coordinatively UMCs. The implementation of coordinatively UMCs into porous MOFs has been considered one of the most attractive ways to improve their affinities to hydrogen. (3) Hydrogen storage studies in MOFs containing nanoscopic cages based on double-bond-coupled di-isophthalate linkers. Those ligands containing phenyl rings in MOFs have been proved favorable for hydrogen adsorption. (4) Design and synthesis porous MOFs based on an anthracene derivative which can provide additional hydrogen binding sites to increase the hydrogen uptake. (5) Obtained stable MOFs with high surface areas by the incorporation of mesocavities with microwindows. (6) Constructed MOFs with “close-packing” alignment of open metal sites, which can increase the number of nearest neighboring open metal sites of each H₂-hosting void in a three-dimensional framework so that they can interact directly with the guests (H₂ molecules) inside the void. (7) Built up porous lanthanide MOFs and studied their potential application in gas adsorption. (8) Prepared symmetry-preserving isomer pair of MOFs and studied the impact of isomerization on H₂ storage capacity in MOFs. (9) Incorporated polyyne unit into MOFs, which exhibit H₂ affinity higher than that of MOFs containing phenyl rings. (10) Designed and synthesized POFs with chemical stability higher than that of MOFs.

Results

In the past year, we prepared a series of MOFs and POFs and explored their applications in hydrogen storage. Table 2 shows the comparison of hydrogen uptakes of selected MOFs and POFs. Next we will discuss in detail the results of H₂ uptakes of these materials.

(a) Symmetry-Preserving Isomer Pair

A symmetry-preserving isomer pair (α phase and β phase NbO-type structures) of MOFs crystallized in the same R-3m space group but with different pore sizes have been discovered, allowing the direct study of the impact of pore size on gas storage capacity in MOFs for the first time (Figure 1a). The α phase MOF (PCN-16) is isostructural with previously reported NbO-type MOFs constructed from tetracarboxylate linkers and has two distinct types of cages. The first consists of 12 ebdc ligands connecting six paddlewheel secondary building units (SBUs) to form an octahedral cage, in which each ligand utilizes only two of its four carboxylate functionalities; half of the ligands join adjacent SBUs through carboxylate groups from the same phenyl ring and half use carboxylates at opposite ends of the ligand. The dimensions of the windows into the cage are about 10 × 10 Å and 8 × 8 Å (atom to atom distances). The second type of cages, which is elliptical, is formed from six edbc ligands connecting twelve paddlewheel SBUs. In this type, each ligand uses all of its four carboxylate groups. The dimensions of the windows into the elliptical cage are also 10 × 10 Å and 8 × 8 Å. These two
kinds of cages are connected to each other by sharing three paddlewheel SBUs to result in a three-dimensional framework with the NbO topology. The resulting dimensions of the -3m (in space group R-3m) channels are about 8 × 8 Å along the c-axis consistent with the size of the channels in the previously reported NbO-type MOFs. The solvent accessible volume in the dehydrated structure is 72.5% calculated from PLATON/SOLV. In PCN-16', however, the channels are larger than those in PCN-16, with the dimensions of 11 × 11 Å. The solvent accessible volume in the dehydrated structure is 70.1% calculated from PLATON/SOLV, which is slightly smaller than that of PCN-16.

To check the permanent porosities of the pair of isomers, N2 sorption isotherms at 77 K were collected for the dehydrated samples. As shown in Figure 1b, both PCN-16 and PCN-16' display typical Type-I sorption behavior. PCN-16 has a Brunauer-Emmett-Teller (BET) surface area of 2,273 m²/g (Langmuir surface area, 2,800 m²/g) and a total pore volume of 1.06 cm³/g while PCN-16' possesses a 1,760 m²/g BET surface area (Langmuir surface area, 2,200 m²/g) and a 0.84 cm³/g pore volume.

The differing pore structures as evidenced by the BET surface areas directly impact the adsorption capacities for hydrogen as indicated in Figures 1c. PCN-16 demonstrates significantly higher hydrogen adsorption capacity than PCN-16'. At 77 K and 760 torr, PCN-16 can adsorb 2.6 wt% hydrogen, comparable to the values observed in other α phase NbO-type copper MOFs. In contrast, PCN-16' can only adsorb 1.7 wt% hydrogen, much lower than that in PCN-16. This difference persists at higher pressures where the excess hydrogen uptake of PCN-16 saturates at 5.1 wt%, while the saturation for PCN-16' occurs with the value of only 2.9 wt% (Figure 1c).

Because PCN-16 and PCN-16' are isomers of each other and both crystallize in the same space group and contain similar nanoscopic cages, the superior gas adsorption properties of PCN-16 can mainly be attributed to the pore size, which is smaller than that of PCN-16'. The small pores lead to an increased effective surface area, offering more adsorption sites for hydrogen. Indeed, the saturation uptake of hydrogen at 77 K for each isomer is consistent with the different BET surface areas, as explained in a recent analysis. The results above also suggest that α phase NbO-type copper MOFs should be better for gas storage than their β phase counterparts.

The NbO-type MOFs, which consist of 4-connected di-isophthalate ligands and 4-connected secondary building units, have shown excellent framework stability, porosity, and gas adsorption capacity. On the other hand, their hydrogen adsorption capacity at room temperature is relatively low due to weak framework-hydrogen interactions. In our continuing exploration of MOFs as a hydrogen storage medium, double bonds and aromatic rings were studied as possible framework-hydrogen interacting sites. However, prior to this work, carbon-carbon triple bonds, especially polyyne chains, have not been systematically studied for gas adsorption purposes in MOFs. In this contribution, we report an NbO-type MOF (PCN-46) that is constructed based on a polyyne-coupled di-isophthalate ligand formed in situ (Figure 2). The ensuing MOF has permanent porosity after the removal of guest molecules, with a BET surface area of 2,500 m² g⁻¹ and a uniform pore size around 6.8 Å (Figure 2d). At 77 K and 760 Torr, PCN-46 can reversibly adsorb 1.95 wt% of H₂ (Figure 2e). Under high pressure range, the saturated excess gravimetric H₂ uptake is 5.31 wt% (56.1 mg g⁻¹) at 32 bar. Taking the gaseous H₂ compressed within the void pore at 77 K into consideration, the total gravimetric H₂ uptake can reach as high as 6.88 wt% (73.9 mg g⁻¹) at 97 bar. Calculated from the crystal density of the activated form (0.6185 g cm⁻³), PCN-46 has an excess volumetric...
H₂ uptake of 34.7 g L⁻¹ (32 bar) and a total volumetric uptake of 45.7 g L⁻¹ (97 bar).

Based on a variant of the Clausius-Clapeyron equation, the H₂ isosteric adsorption enthalpy of PCN-46 reaches 7.20 kJ mol⁻¹ at low coverage, and decreased to 4.06 kJ mol⁻¹ at medium coverage. The increased heat of hydrogen adsorption in PCN-46, compared to those of other NbO type MOFs, can be attributed to the interaction between dihydrogen molecules and the exposed and delocalized π electrons in the polyyne unit in bdi⁴⁻, which is evidently stronger than that for the phenyl rings in other ligands in the NbO-type MOFs. In addition, the replacement of phenyl rings by polyyne chain leads to a boost of pore volume and hydrogen uptake. Furthermore, in the absence of a catalyst, the hydrogen addition reaction on the polyyne unit has not been observed even at high pressure as shown by the reversible hydrogen sorption isotherms of PCN-46, validating the stability of the MOF under hydrogen storage conditions.

(c) An Isoreticular Series of MOFs with Dendritic Hexa-Carboxylate Ligands and Exceptionally High H₂ Uptake Capacity

It has been well established that the high-pressure gravimetric hydrogen adsorption capacity of a MOF is directly proportional to its surface area. However, MOFs of high surface areas tend to decompose upon activation. In previous work, we've described an approach toward stable MOFs with high surface areas by incorporating mesocavities with microwindows. To extend this work, herein we present an isoreticular series of (3,24)-connected MOFs made from dendritic hexa-carboxylate ligands (Figure 3). In order to test the framework stability, nitrogen sorption measurements were carried out in fully activated PCN-68 and PCN-610. In PCN-68, a dramatic increase of nitrogen sorption has been observed (Figure 3d). The BET surface area calculated based on the low-pressure region data can reach as high as 5,109 m² g⁻¹, with a Langmuir surface area of 6,033 m² g⁻¹. To the best of our knowledge, PCN-68 possesses the highest surface area reported to date for MOFs based on paddlewheel clusters.
The hydrogen uptake capacities of PCN-6X series are shown in Figure 3e. At a low-pressure region (<1 bar), the hydrogen uptake capacity is mainly controlled by the hydrogen affinity towards the framework, which can be quantified by the isosteric heat of adsorption. PCN-61, which has the smallest pore size, also has the highest heat of adsorption and highest capacity (2.25 wt% at 77 K, 1 bar). PCN-66 and PCN-68 have heats of adsorption and adsorption capacities similar to each other (1.79 wt% in PCN-66 vs. 1.87 wt% in PCN-68). This trend is consistent with the nature of physisorption, in which narrower pores would have stronger interactions with guest gas molecules due to increased interaction between the guests and the opposite potential walls within small pores. Unlike low-pressure hydrogen sorption capacity, which is dominated by hydrogen affinity, the maximum excess hydrogen uptake capacity in MOFs, which typically can only be reached at high pressure range, is controlled mainly by the surface area and pore volume. This is consistent with observations in the PCN-6X series. As can be seen from Figure 3e, PCN-68, which has the highest surface area, also has the highest maximum excess hydrogen uptake capacity (7.2 wt%, Table 2), which makes it one of the best adsorbents with the highest gravimetric hydrogen uptake capacity. It is worth noting that the maximum adsorption pressure increases from PCN-61 (33 bar) to PCN-66 (45 bar) and PCN-68 (50 bar), indicating higher pressure is needed to reach maximum adsorption in sorbents with higher pore volumes.

Using the crystal density data, volumetric hydrogen uptake capacities were also calculated. Unlike the trend in gravimetric capacity, where material with the highest surface area has the highest capacity, volumetric capacity follows the opposite trend, which is dominated by the densities of the sorbents. The gravimetric capacity has been emphasized in the past hydrogen storage research, and rightfully so. However, volumetric capacity is particularly relevant in volume-limited fuel cell applications. Both of these criteria should be emphasized equally in the search for ideal hydrogen storage materials.

(d) POFs

In the last decade, the chemistry of porous materials has witnessed a renaissance in design and synthesis of porous polymers. Compared to MOFs, porous polymers have higher chemical and thermal stability, which is suitable for further decoration. Three POFs have been synthesized by homocoupling reactions (Figure 4). The polymeric frameworks have high stabilities and surface areas of up to 5,523 m² g⁻¹. Their hydrogen uptake capacity at 1 bar is directly proportional to the surface area. This trend is more obvious at higher pressure ranges, with the highest uptake capacity obtained for POF-3 (4.28 wt%, 42 bar), which compares favorably with the highest ones of carbon materials. This trend is the same for other adsorbents, indicating the importance of a high surface area for maximal hydrogen uptake capacity. Based on a variant of the Clausius-Clapeyron equation, the hydrogen isosteric heat of adsorption can be calculated. Compared with POF-2 and POF-3, the heat of adsorption in POF-1 is surprisingly high (7.59 kJ mol⁻¹) and, most importantly, it remains almost constant over the whole gas loading range. This value is higher than those for other porous polymer analogs, such as PAF-1 (4.6 kJ mol⁻¹) and covalent-organic frameworks (6.0-7.0 kJ mol⁻¹). The high heat of adsorption may stem from the narrower pores, which allow stronger overall interactions of the guest gas molecules because of additional interactions with the opposite walls. In addition, the polyyne motifs may help to increase the gas affinity as well. This hydrogen affinity difference is reflected in the hydrogen sorption isotherms at a lower pressure range (less than 0.5 bar), where the hydrogen uptake in POF-1 rises most steeply. In the higher pressure range, where the surface area and pore volume become dominant, POF-3 has the highest uptake capacity.
Conclusions and Future Directions

Conclusions:

• α Phase NbO-type copper MOFs should be better for gas storage than their β phase counterparts.
• Small pores (5 to 10 Å) in MOFs lead to an increased effective surface area, offering more adsorption sites for hydrogen.
• The polyene chains showed improved hydrogen affinity compared to phenyl rings.
• Constructing MOFs containing mesocavities with microwindows is proven as a general approach towards stable MOFs with high surface areas and high hydrogen uptake.
• Porous organic frameworks with tunable pore size and surface area can be prepared with high chemical and thermal stability, which are good candidate for hydrogen storage.

Future Directions:

• Further enhancement of H₂-MOF interaction by doping coordinatively unsaturated metal centers (heat of adsorption 15 kJ/mol). Based on theoretical calculations, main group metals such as Mg and Ca will be tested.
• Working with partners, test H₂ uptake at temperatures higher than 77 K.
• Preparation of MOFs with high surface area and optimized cage size with newly designed ligands based on theoretical calculations.
• Incorporation of entatic-state metals based on theoretical guidance.
• Preparation of POFs containing active metals.

Phone: (303) 275-4954
E-mail: Jesse.Adams@go.doe.gov

Contract Number: DE-FG36-08GO18142

Subcontractor:
Midwest Research Institute, Kansas City, MO

Project Start Date: September 1, 2008
Project End Date: January 31, 2012

Objectives

- Fabricate high-surface-area, multiply surface-functionalized carbon (“substituted materials”) for reversible hydrogen storage with superior storage capacity (strong physisorption).
- Characterize materials and storage performance. Evaluate efficacy of surface functionalization, experimentally and computationally, for fabrication of materials with deep potential wells for hydrogen sorption (high binding energies).
- Optimize gravimetric and volumetric storage capacity by optimizing pore architecture and surface composition (“engineered nanospaces”).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(B) System Cost
(E) Charging/Discharging Rates

(J) Thermal Management
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

This project aims at the development of surface-engineered carbons, made from corn cob or other low-cost raw materials, which simultaneously host high surface areas, created in a multi-step process, and a large fraction of surface sites with high binding energies for hydrogen, created by surface functionalization with boron, iron, and lithium. Targets are surface areas in excess of 4,500 m²/g, average binding energies in excess of 12 kJ/mol, and porosities below 0.8, toward the design of materials that meet the following 2015 DOE hydrogen storage targets:

- Gravimetric storage capacity: 0.055 kg H₂/kg system
- Volumetric storage capacity: 0.040 kg H₂/liter system

Accomplishments

- Validated H₂ performance of University of Missouri carbons (University of Missouri; National Renewable Energy Laboratory; “blind laboratory”) to within ~ 5%.
- Manufactured B-substituted carbon by thermolysis of B₁₀H₁₄, with B:C = 1-7 wt% without compromising high surface areas.
- Observed significant changes of hydrogen adsorption on B-substituted samples subjected to neutron irradiation (fission tracks in carbon matrix from boron neutron capture). Irradiation shifted excess adsorption peak and slope at 80 K to lower pressures, consistent with an increase in binding energy and decrease in density of the saturated film. Irradiation did not change surface area or pore-size distribution. Estimated saturated film densities at 80 K and 50 bar were 3-8 times the density of unadsorbed hydrogen gas.
- Developed method to determine isosteric heats of adsorption at high coverage from Clausius-Clapeyron equation in a thermodynamically consistent way.
- Developed sub-nm pore structure characterization methods based on small-angle X-ray scattering (SAXS) [1], and incoherent inelastic neutron scattering [2].
Built a large “library” of B-substituted and B-free carbon materials, generating a systematic study of the structure and performance of activated carbons under various processing conditions (KOH concentration, activation temperature, pyrolysis of B-carrying polymers). Demonstrates a wide spectrum of different behaviors, with excess adsorption peaks ranging from 20 bar to pressures way above 100 bar, including record excess storage capacity of 1.3wt% at room temperature.

Found evidence from library that B-substitution and irradiation raises average binding energy to 9-11 kJ/mol (B:C = 1.4 wt%) and alters entire shape of adsorption isotherm (B:C = 1.7 wt%). Ab initio calculations of H2-(B,C) interactions and Grand Canonical Monte Carlo (GCMC) simulations gave $E_B = 10-14$ kJ/mol at B:C = 10 wt% [3].

**Introduction**

High-surface-area carbons from corncob, as developed by our team, show considerable promise for reversible onboard storage of hydrogen at high gravimetric and volumetric storage capacity. A current carbon has a gravimetric storage capacity of 0.11 kg H2/kg carbon at 80 K and 50 bar. This project is a systematic effort to achieve comparable results at 300 K, by increasing surface areas from currently ~3,000 m$^2$/g to ~5,000 m$^2$/g, and substituting carbon with boron and other elements that increase the binding energy for hydrogen. Current high surface areas and high binding energies are hosted by sub-nm pores (“nanopores”) created by chemical means. New surface area, created by fission tracks from boron neutron capture, $^{10}$B + n $\rightarrow ^{11}$B $\rightarrow ^7$Li + $^4$He + $\gamma$ + 2.4 MeV, traversing stacks of graphene sheets, will add as much as another 3,000 m$^2$/g. Thus boron serves in two functions: (i) raise the binding energy by electron donation from H$_2$ to electron-deficient B; (ii) provide the platform for creation of additional surface area.

**Approach**

The approach is an integrated fabrication, characterization, and computational effort. Structural characterization includes determination of surface areas, pore-size distributions, and pore shapes. Storage characterization includes measurements of hydrogen sorption isotherms and isosteric heats. Computational work includes adsorption potentials and simulations of adsorbed films for thermodynamic analysis of experimental isotherms. Comparison of computed and experimental isotherms validates theoretical adsorption potentials and experimental structural data.

**Results**

Figure 1 shows results for hydrogen excess adsorption (80 K, 303 K) for a selected group of seven samples with different sorption characteristics: (i) commercial reference sample MSC-30 (Maxsorb, Kansai Coke and Chemicals Co., Ltd); (ii) boron-free biocarbon, 3K-20100217; (iii) boron-doped unirradiated and irradiated biocarbons 3K-H6 (II, A), 3K-H6 (II,
A) Irr., and 3K*-H6 (II, A) Irr; and (iv) polyvinylidene chloride (PVDC)-based carbons HS;0B (0% B:C) and HS;2B (1.7 B:C). Sample 3K-20100217 is a member of a series of carbons, made from corncob, in which the ratio of potassium hydroxide (KOH) to carbon during chemical activation (treatment at 790°C) was varied from 2:1 (“2K”) to 6:1 (“6K”). Samples 3K and 3K* differ in that the two were fabricated in a stainless-steel vessel, resulting in a ~1 wt% Fe and Cr content, and alumina, resulting in ~1 wt% Al. Boron doping was performed by vapor deposition followed by pyrolysis of decaborane (B10H14). Samples reported here were exposed to air. Irradiated samples were produced at the University of Missouri Research Reactor, with irradiation times between 1 minute and 2 hours, and result in the production of fission tracks from boron neutron capture, 10B + n → 7Li + 4He + γ + 2.4 MeV. PVDC-based samples were formed by thermal decomposition of PVDC or PVDC co-polymerized with n-hexyl-orthocarborane (samples were not further activated, all pores result from pyrolysis) [4]. Adsorption isotherm for sample 3K-20100217 at 77 K was validated at the National Renewable Energy Laboratory and a “blind laboratory,” resulting in an agreement in the excess adsorption to within a ~5% average relative error. Pore-size distributions (PSD) determined from N2 adsorption at 77 K (Figure 2) show that samples 3K-20100217 and MSC-30 contain a comparable number of sub-nm pores, but MSC-30 contains a significantly larger number of supra-nm pores. In contrast, PVDC samples, HS;0B and HS;2B, are essentially free of supra-nm pores. PSDs are consistent with SAXS analyses (Table 1, [1]). The existence of very narrow pores in HS;0B and HS;2B result in large binding energies [5] and explains the high room temperature excess adsorption of HS;0B (Figure 1), despite their low surface areas (Table 1). At low pressures HS;2B excess adsorption grows faster than HS;0B, indicating a number of high binding energy sites, as expected from our ab initio calculations of boron-containing carbons [3].

For irradiated samples, no significant differences in surface area or pore-size distribution between irradiated and unirradiated materials were found (Table 1, Figure 2). But significant differences in hydrogen adsorption isotherms at 80 K were observed (Figure 1). Irradiation shifted the maximum in excess adsorption from ~40 bar to ~20 bar, and made the slope at high pressures steeper (Figures 1, 3). The maxima, $p_{\text{max}}(T)$,
and intercepts with the pressure axis, $p_0(T)$ (Figure 3), were related to the average binding energy, $E_{B,av}$, and mass density of the saturated film, $\rho_{film}(T)$ using:

$$
\rho_{film}(T) = m_{H_2} \frac{N_A}{\nu} \frac{h}{(kT)}
$$

($1$)

$$
E_{B,av} = \frac{m_{H_2} N_A k}{\nu} \ln \left[ \frac{p_0(T) - 2 p_{film}(T)}{p_{film}(T)} \right] \left\{ (1 - \frac{2 m_{H_2}}{N_A}) \frac{h}{(kT)} \right\}^2
$$

($2$)

where $m_{H_2}, N_A, k, \nu,$ and $h$ are the mass of a hydrogen molecule, Avogadro’s number, Boltzmann’s constant, the vibrational frequency of an adsorbed hydrogen molecule relative to the substrate, and Planck’s constant, respectively, and we have assumed the ideal gas law, Eq. (1), and Langmuir adsorption, Eq. (2) [5]. Results are shown in Table 2. The increase in binding energy and decrease in film density as a result of irradiation were attributed to the creation of surface defects, perhaps free radicals, created by fission products, and film discontinuities at edges of fission tracks. Film densities at 80 K and 50 bar were 3-8 times the density of unadsorbed hydrogen gas (Table 2). The binding energies for B-substituted carbons inferred in Table 2, brackets, show that B-substitution raises the average binding energy to ~11 kJ/mol (B:C = 1.4 wt%) and alters entire shape of adsorption isotherm (B:C = 1.7 wt%; Figure 1). 

Ab initio calculations of $H_2-(B,C)$ interactions and GCMC simulations gave $E_B = 10–14$ kJ/mol [3].

### Table 2. Experimental density of the saturated $H_2$ film at 80 K and average binding energy from Figures 1 and 3 and Eqs. (1, 2), with $\nu$ for $H_2$-graphite potential and $\nu$ estimated for $H_2$-B/C potential (in brackets).

N/A – not available

The isosteric heat of adsorption, $\Delta H$, equals the heat released when a molecule is adsorbed at constant coverage (number of adsorbed molecules, absolute adsorption), and an according temperature change [6]. It is related to the binding energy through the relation $\Delta H = E_{B,av} +$ zero-point/thermal energies $= E_{B,av} + (3-5$ kJ/mol), depending on the details of how $H_2$ is adsorbed on the surface [7]. The isosteric heat can be computed from two adsorption isotherms via the Clausius-Clapeyron equation,

$$
\Delta H = \frac{RT}{T_2 - T_1} \ln \left( \frac{p_2}{p_1} \right)
$$

($3$)

where $p_1, T_1$ are two pressures and temperatures corresponding to the same absolute adsorption. This requires conversion of experimental excess adsorption isotherm, $G_{ex}$, into absolute adsorption, $G_{abs}$ (both in mass of $H_2$ per mass of adsorbent),

$$
G_{abs} = G_{ex} + \Sigma \cdot t_{film} \cdot \rho_{gas}
$$

($4$)

where $\Sigma, t_{film},$ and $\rho_{gas}$ are the specific surface area of the adsorbent (Table 1), thickness of the adsorbed film,
and density of bulk gas, respectively. In much of the literature, no distinction is made between absolute and excess adsorption, i.e., the conversion (4) is carried out with a film thickness of zero, and Eq. (3) is evaluated at constant excess adsorption instead of constant absolute adsorption. This leads to an incorrect behavior of isosteric heats at high coverage, where the film thickness is far from negligible. Whenever the excess adsorption isotherm has a local maximum in the pressure range analyzed (Figure 4a), the isosteric heat calculated from excess adsorption rises at high coverage (Figure 5a), which is unphysical. No such unphysical behavior occurs when isosteric heats are calculated from the absolute adsorption isotherm, which has no local maximum (Figure 4b). Figure 5a shows isosteric heats calculated for various hypothetical film thicknesses, \( t_{\text{film}} = 0 \) (“\( G_{\text{abs}} = G_{\text{ex}} \)”), \( t_{\text{film}} = 2.3 \) Å (van der Waals diameter), ..., \( t_{\text{film}} = 4.1 \) Å (best estimate from GCMC simulations of adsorbed \( \text{H}_2 \) on carbon surfaces). Significant differences in isosteric heats, due to incorrect values for \( t_{\text{film}} \), are observed already at pressures as low as 2 bar (Figure 5a). The smallest film thickness at which the calculated isosteric heat curve no longer rises is a lower bound for the actual film thickness.

Figure 5b displays the effect of different choices of the pressure interval.

**FIGURE 4.** Determination of isosteric heats of adsorption from excess (a) and absolute (b) adsorption isotherms, from Eq. (4) with \( t_{\text{film}} = 4.1 \) Å. The maximum in the excess adsorption result in an unphysical rise of the isosteric heat (Figure 5).

**FIGURE 5.** Isosteric heats of adsorption calculated from Eqs. (3, 4) for four different film thicknesses. (a) The increase in isosteric heat at high coverage is unphysical because high-energy adsorption sites are expected to fill at low coverage. The isosteric heat curves for \( t_{\text{film}} = 0 \) and \( t_{\text{film}} = 2.3 \) Å end at \( G_{\text{abs}} \approx 50 \) and \( 60 \) g H\(_2\)/kg °C, respectively, because the 80 K “absolute adsorption” isotherm for these film thicknesses has its maximum at \( -50 \) and \( -60 \) g H\(_2\)/kg °C. (b) Effect of different choices of the pressure interval over which absolute adsorption was fitted for interpolation (determination of \( p_1 \) and \( p_2 \) at constant coverage).
pressure interval over which absolute adsorption was fitted for interpolation (determination of $p_1$ and $p_2$ at constant coverage).

For the case study, MSC-30, isosteric heats drop from $-6$ kJ/mol to $-3.5$ kJ/mol as absolute adsorption increases from $-2$ to $-70$ g H$_2$/kg °C. This is consistent with the expectation that sub-nm pores host binding energies as large as 10 kJ/mol, with larger pores hosting binding energies $\sim 5$ kJ/mol. The analysis also shows that isosteric heats from excess instead of absolute adsorption yield reliable values only at pressures below $\sim 1$ bar (Figure 5a). At the same time, isosteric heats at low pressures may differ by as much as 1 kJ/mol, depending on the pressure interval over which adsorption isotherms are fitted for interpolation (Figure 5b). Work is underway to determine isosteric heats on B-doped samples under oxygen-free conditions.

**Conclusions and Future Directions**

- Observed an unexpected increase in binding energy and decrease in adsorbed film density/thickness in neutron-irradiated boron-containing carbons.
- Developed pore characterization methods using SAXS.
- Developed thermodynamically consistent method to determine isosteric heats at high coverage.
- Future work: (i) Construction of decaborane deposition and decomposition instrument to automate production of samples which will allow optimization of boron doping methods (time, temperature, decaborane concentration). (ii) Characterization of boron-free and boron-containing carbons under exclusion of oxygen and humidity. (iii) Etching of fission tracks to increase surface area and comparison of performance of etched/non-etched materials. (iv) Continue to investigate whether hydrogen and nitrogen see the same surface area. (v) Investigate pressure/temperature/pore shape dependence of new variable $\rho_{\text{sat}}(T)$ (density of saturated film) experimentally and by GCMC simulations. (vi) Design materials with high $\rho_{\text{sat}}(T)$, as a concurrent strategy with increased binding energy. (vii) Improve theoretical models for analysis of excess adsorption isotherms ($p_{\text{max}}$, $\rho_{\text{sat}}$, $\partial G_s / \partial p$) in terms of the binding energies and surface areas. (viii) Develop understanding of correlations between hydrogen storage at 80 K and 303 K. (ix) Expand experimental library of high $E_b$ from boron doping (with extreme care to avoid exposure to oxidizing agents). (x) Attempt synthesis of bulk BC$_3$ and test for predicted H$_2$ intercalation.

Project Start Date: October 2005
Project End Date: Project continuation and direction determined annually by DOE

Objectives

- Quantify the amount, location, bonding states and dynamics of hydrogen in hydrogen sorption materials.
- Direct partner synthesis efforts based on the understanding gained through the use of scattering techniques.
- Demonstrate the fundamental characteristics of useful hydrogen storage materials.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

NIST provides important materials metrologies for Hydrogen Sorption Center of Excellence (HSCoE) partners using neutron-scattering measurements to understand and characterize hydrogen-substrate interactions of interest to the Center.

Enhanced Hydrogen Storage using Supported Metal Centers

This project is conducting fundamental studies of how hydrogen binds in metal organic frameworks (MOFs) with exposed metal sites. Insights gained from these studies will be used by Center partners and applied toward the design and synthesis of hydrogen storage materials that meet the following DOE hydrogen storage targets:

- Cost: $4/kWh net
- Specific energy: 1.8 kWh/kg
- Energy density: 1.3 kWh/L

Accomplishments

- Characterized the hydrogen environment upon adsorption in graphite intercalation materials despite lack of periodic crystal structure.
- Characterized the hydrogen diffusion mechanism and geometry.
- Determined multiple binding sites for H₂ in one of an isostructural series of benzene tris-tetrazole (BTT) compounds. Partial understanding of the local adsorption potential is obtained from the current inelastic neutron scattering data.
- For the first time we have observed a significant perturbation of the hydrogen rotational levels in a high surface area B-doped carbon.
- Further understood the surface chemistry and hydrogen adsorption capacities in zeolite-templated carbons loaded with Pt nanoparticles. Failed to observe any spillover in these materials.

Introduction

To obtain the DOE levels of hydrogen storage in a timely manner, it is imperative that trial-and-error testing of materials be avoided. Thus, the focus must be upon the rational design of new systems. From a thorough understanding of the physics and chemistry that governs the hydrogen-substrate interactions, we will be able to make a more concerted effort to push the frontiers of new materials. The key to improving materials is a detailed understanding of the atomic scale locations of the hydrogen and determining how it gets there and how it gets out. Neutron scattering is perhaps the premier technique for studying hydrogen and the NIST Center.
for Neutron Research is currently the leading facility in the U.S. for studying these materials.

**Approach**

NIST provides important materials characterization for Center partners using neutron-scattering measurements to probe the amount, location, bonding states, dynamics, and morphological aspects of hydrogen in carbon-based materials such as polymers, MOFs, and carbonaceous materials such as carbon nanohorns. NIST works directly with Center partners that produce novel hydrogen storage materials to analyze the most promising samples and to help determine and resolve the fundamental issues that need to be addressed.

**Results**

**MOFs**

MOFs have recently come under intense investigation for gas storage and separation applications, owing to their high internal surface areas, convenient modular synthesis, and chemical tenability. Previously, we have reported a number of MOFs in which removal of a solvent molecule from the coordination sphere of the framework metal cations yields strong adsorption sites for H₂. One possibility for improving the isosteric heat of adsorption within this structure type would be through constructing the structure with M²⁺ cations having a smaller radius. The greater charge density of the exposed metal cations on the framework surface should then be more effective at inducing a dipole in H₂, leading to stronger binding.

The synthesis of a new framework structure with open Fe²⁺ coordination sites, Fe-BTT [1], has confirmed that the large isosteric heat of adsorption for H₂ in Fe-BTT is associated with the presence of open Fe²⁺ coordination sites associated with the [FeCl]⁷⁺ clusters of the framework. The initial isosteric heats are larger than those in isostructural Mn²⁺ and Cu²⁺ derivatives (Figure 1) and much greater than the prototypical MOF-5. Combined with neutron diffraction data and inelastic neutron scattering spectroscopy we have shown that these exposed Fe²⁺ sites provide a strong interaction with H₂, drawing it close to the surface. There is a correlation between the higher initial enthalpies in this series and how close the D₂ molecules can approach the metal ion. The relative distance increase from 2.17(5) Å, 2.27 Å and 2.47 Å, for Fe³⁺, Mn²⁺ and Cu²⁺ ions, respectively. Increasing the adsorbed amount of D₂ reveals a progression of site fillings away from the cation with 10 sites identified at saturation (Figure 2).

The H₂ loading characteristics of Fe-BTT have been further probed by inelastic neutron scattering. In the lowest loading data (< 0.5 wt%), there is an absence of a rotational line at 14.7 meV that would correspond to the first rotational transition of free hydrogen. This is indicative of a strong rotational hindering potential of the binding sites occupied at these levels, consistent with the large initial isosteric heat of H₂ adsorption. At this low loading the strongest adsorption sites are populated, giving rise to two transitions observed at ≈13.2 and ≈19.7 meV. These peaks gain intensity upon increasing the loading to 0.5 wt% of H₂, and can be assigned as rotational lines that correspond to a rotational barrier of approximately 15 meV. Upon increasing the loading, weaker sites become occupied and features closer to the expected ‘free hydrogen’ energy are seen.

The low pressure (1 bar) adsorption of 2.3 wt% at 77 K, and 1.6 wt% at 87 K, is completely reversible, and the steep initial portion of each isotherm is also indicative of the presence of strongly-polarizing binding sites with a high affinity for H₂. The strongly polarizing Fe³⁺ affords an enhanced storage capacity at 298 K 1.1 wt% and 8.4 g/L; the total uptake in Fe-BTT at 95 bar constitutes a 16% increase in volumetric density compared to that of pure H₂ gas at the same pressure. This work was performed in collaboration with J.R. Long (University of California, Berkeley) and A. Dailly (General Motors).

**Neutron Imaging of Adsorption**

The development of new tools that may be of potential beneficial to enabling the engineering of storage tanks is presented. Briquettes of compressed activated carbon (Pfeifer, Missouri), were cut into cylindrical slugs and placed in a thick walled aluminum cell with a gas loading apparatus attached via a capillary.
Illuminating the cell, and recording the image on a neutron sensitive charge-coupled device camera, gives an image as shown in Figure 3; darker pixels indicate more neutrons have been scattered away from the camera at that pixel. Subtracting the ‘noise’ through the darkfield image, and normalizing a hydrogen-loaded image to that of the bare material highlights only the adsorbed hydrogen. Images can be captured using this technique at specific loadings and with relative good statistics in under a second (instrumentation limit is much faster); we averaged 5 seconds to generate the images in Figure 3. As expected, this room temperature adsorption showed little time dependence at room temperature within the measurement timescale. A false color image of the hydrogen adsorbed in the system on increasing pressure form 2 bar to 5 bar is shown in the right panel of Figure 3. The shape of the briquettes are easily observable at 5 bar. While this data has not been taken to the point where we can be quantitative about the amount of hydrogen adsorbed, it would be a relatively simple exercise to complete that and compare to traditional adsorption isotherms. Of some note is that this technique could distinguish the amount of gas in the free space away from the briquettes and that in the briquette itself.

Conclusions and Future Directions

We have continued our primary task of performing various neutron characterization measurements in support of other HSCoE members focusing on optimizing our knowledge of hydrogen interactions for current and future materials development. Specifically we achieved the following results this year:

- Characterized the hydrogen environment upon adsorption in graphite intercalation materials despite lack of periodic crystal structure.
- Characterized the hydrogen diffusion mechanism and geometry.
- Determined multiple binding sites for H\textsubscript{2} in one of an isostructural series of BTT compounds. Partial
understanding of the local adsorption potential is obtained from the current inelastic neutron scattering data.

- For the first time we have observed a significant perturbation of the hydrogen rotational levels in a high surface area B-doped carbon.
- Further understood the surface chemistry and hydrogen adsorption capacities in zeolite-templated carbons loaded with Pt nanoparticles. Failed to observe any spillover in these materials.
- Performed preliminary test-bed work on a macroscopic imaging of hydrogen adsorption in a high surface area carbon.

This work can be extended in the future. In particular there are issues pertaining to: limits for the enthalpy of adsorption of hydrogen in MOFs; understanding electrostatic/morphological control of hydrogen diffusion rates; chemistry of the nanoparticle and substrates used to obtain significant amounts of hydrogen spillover; clearly distinguishing physisorbed hydrogen form a spin-off hydrogen; obtaining quantitative interpretation of imaging adsorption in storage beds; and extending imaging facilities to include cryogenic sample environment.

Objectives

NREL’s research in the Hydrogen Sorption Center of Excellence (HSCoE) is targeted at addressing key technical barriers in DOE’s sub-program for on-board hydrogen storage:

Weight and Volume: System capacities approach material capacities as the tank operation moves toward ambient temperatures and pressures with materials that have optimum binding energies. In general, sorbents already meet the vast majority of DOE hydrogen storage targets and have minimal heat transport requirements. NREL development efforts focus on the remaining targets, e.g., cost and capacity.

- Volumetric and gravimetric capacities are closely linked in sorbents.
- Increase material density (i.e., >0.7 g/ml) to decrease storage system size.
- Increase specific surface area and optimize pore sizes to decrease tank weight/size.
- Optimize binding energies to increase capacities and operating temperature.
  - Develop the highest-efficiency storage system by optimizing sorbent materials that operate reversibly on-board with a hydrogen binding energy in the range of 10–50 kJ/mol (for room temperature operation).
  - Decrease heat-transfer requirements to increase on-vehicle refueling times.
  - Sorption materials typically meet DOE refueling and delivery rate targets.
  - Close the gap between the idealized sorption materials that have been predicted and the synthesis of actual materials using low-cost source materials and synthesis processes such that cost target will be achieved.

Cost: Typical high-surface-area, lightweight materials (e.g., activated carbon) are commercially manufactured at ~$1/kg with carbon costs being only a small fraction. Thus, material costs for a system could be ~$15/kg-H₂ (i.e. >$0.5/kWh, assume 7 wt%).

- Develop sorbents using inexpensive materials and processes.

Impact: NREL’s H₂ storage material goals provide DOE with viable solutions that have the potential to meet even the ultimate technical targets. While this requires revolutionary materials, breakthrough technologies are being pursued.

Technical Barriers

This project addressed the following technical barriers from the hydrogen storage technical barriers section of the Fuel Cells Technologies Multi-Year Research, Development and Demonstration Plan:

General:

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (D) Durability/Operability
- (E) Charging/Discharging Rates
- (J) Thermal Management

Reversible On-Board:

- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
- (Q) Reproducibility of Performance
Technical Targets

This project is developing sorbents for hydrogen storage systems. In general, the effort focuses on creating hydrogen adsorption materials with optimized binding energy (10–30 kJ/mol) such that the system may operate at near-ambient temperatures and moderate pressures. The design and synthesis of these hydrogen storage materials is aimed at meeting the following DOE hydrogen storage targets:

- Cost: $4/kWh net
- Specific Energy: 1.8 kWh/kg
- Energy Density: 1.3 kWh/L
- Charging/Discharging Rate: 3.3 min

Accomplishments

- Developed novel scalable synthetic processes (e.g., templating) to form high-surface-area, lightweight materials with optimal pore structure and composition for H₂ storage.
- Developed materials with ~5% sp² coordinated boron substitution in carbon (BCₓ) and demonstrated that this increases capacity and binding energy. Also developed nitrogen (N) substituted in C and demonstrated that BCₓ improves spillover processes.
- Theory and experiment continued to iteratively interact to design and synthesize several new H₂ storage materials. From the outset of the HSCoE, the ability to synthesize, stability, and DOE targets have been selection criteria for the design of new materials. Also, theory always works closely with experiment to find viable synthetic paths.
- Identified new inexpensive hydrogen sorbents with viable synthetic routes. These included materials like titanium (Ti)-graphite oxide that was experimentally synthesized and demonstrated enhanced dihydrogen adsorption.
- Identified that some oxygen groups are needed for spillover. Spillover does not occur when oxygen groups are missing, spillover rates and capacities are substantially increased when the correct oxygen groups are present, and secondary reactions with the H occur when other oxygen groups are present. These results provide development paths to create higher-capacity, higher-rate H storage spillover materials that meet DOE targets.
- Developed new catalyst processing that improved spillover capacity and charging rates. The decreased processing time, scalability, and improved performance helps spillover materials' development.
- Worked with groups around the world to improve measurement capabilities to provide more accurate and unique hydrogen storage materials characterization at high throughput. This included helping to improve measurement calibrations at other laboratories that have clear issues with irreproducibility and data that are not consistent with standard sorption materials.
- Held workshops and Center partner meetings to develop a comprehensive set of accomplishments and recommendations for the HSCoE. In addition, NREL organized numerous conferences/conference sessions on hydrogen storage to ensure optimal dissemination of results that helps accelerate sorbent development.

Introduction

NREL led the HSCoE to develop reversible sorbent materials for hydrogen storage within the U.S. DOE National Fuel Cell Technologies Project focused on vehicular applications. The HSCoE developed the science base and technology advances required to meet DOE storage goals by investigating a range of hydrogen sorbents. NREL performed development within the HSCoE on a variety of nanostructured and high-surface-area materials that may include carbon, metals, oxygen, and other lightweight elements. These materials show promise for breakthrough performance in hydrogen storage.

A guiding principle in developing the required material is that a continuum of energies exists for hydrogen bound to substrates and molecules. On the weak side of the continuum is non-dissociative physisorption due purely to van der Waals forces (4 kJ/mol). On the strong side is the full C-H chemical bond in methane with an energy of ~400 kJ/mol. Between these two limits, with binding energies between 10 and 50 kJ/mol, are the materials of interest for sorbents. The DOE goals can be met with sorbents if (i) the energy for hydrogen adsorption can be designed to be in this optimal range, and (ii) efficient volumetric arrangement of a sufficient number of suitable binding sites can be achieved with a low-weight material. These goals are difficult to reach in conventional high-surface-area adsorbents that are limited by low physisorption binding energies, heterogeneity of the adsorbent surfaces and adsorption sites, and excessive macroporosity and poor volumetric packing.

Approach

To accelerate development of sorption materials, we focused on four main areas:

- **Increase Matrix Binding Energy**: Increase concentration of substitution atoms (e.g., B for C) in lattices to adsorb dihydrogen directly (via donation), stabilize active species (e.g., transition metals) against...
agglomeration, and/or provide anchor points for building more complex sorbents. Provides 11 kJ/mol H₂ binding energy from B-substitution to enable near-room-temperature sorption.

- **Increase Storage Site Access:** Develop stable high-surface-area, sub-microporous (<1 nm), light matrix materials that can either stabilize large quantities of hydrogen directly or provide frameworks for incorporating/stabilizing other components for hydrogen storage. Greater than 2,500 m²/g specific surface area (SSA) with 0.7 to 1.2 nm pore sizes may provide >6 wt% cryocompression.

- **Form Multiple H₂ Binding Sites:** To exceed DOE 2015 and meet DOE ultimate storage targets, fundamentally new approaches must be developed to store >7.5 wt% and >70 g/L hydrogen.
  - Requires >1 H₂ adsorbed at each binding site and material densities >1g/ml.
  - Develop materials with multiple dihydrogen molecules per binding site.
  - Use inexpensive chemical and gas phase syntheses of organometallics.
  - Combine theory and experiment to optimize development effort.
  - Identify new dihydrogen storage materials based on slight modifications to existing materials.

- **Develop Near-Ambient T Hydrogenation:** Develop detailed understanding using lightweight materials to reversibly store hydrogen via weak chemisorption processes. Investigate surface functionalization and catalyst integration to improve storage thermodynamics and kinetics. Improve processes and measurements to make stable reproducible materials.

**Results**

**Increasing Hydrogen Binding Energy with Substituted Elements:** We used templating to make high-SSA materials, but more importantly, we used this technique to make boron substituted carbon materials with higher binding energy sites (experimental demonstration of ~11 kJ/mol agrees well with calculations). This enhanced adsorption capacity will occur at all temperatures and thus enables improved near-ambient temperature (i.e., ~220 to 350 K) hydrogen storage. Apart from using these substituted nanostructures on their own, the boron (and possibly nitrogen-substituted carbon) sites also provide a means for partially coordinating and stabilizing metal atoms to create complexes that more strongly bind dihydrogen or enable multiple dihydrogens to be adsorbed at each metal site [1].

The main challenges for creating highly loaded boron substituted carbon include:

- As the boron composition increases, the SSA tends to decrease.
- The boron must be sp2 coordinated in the carbon structure to enhance binding properties.

NREL developed processes to form B-substituted C materials with high B composition and high specific surface area. For example, the use of vapor phase boron trichloride with benzene at ~1,100 K is a well-known process that forms BCₓ films [2]. By controlling the processing conditions and precursor materials, NREL produced materials with ~15% boron substituted in the carbon lattice. With X-ray photoelectron spectroscopy (XPS) data, we quantitatively determined the amount of B and the binding environment (Figure 1). These XPS data indicate that the B in the BCₓ materials is typically in multiple binding states. However, by changing the processing conditions, we can increase the amount
of B in the appropriate binding state that enhances adsorption. The boron 1s and carbon 1s spectra are useful in determining the exact state of boron binding, Figure 1a shows the high-resolution B1s spectrum and the associated boron binding energies. The four main peaks are attributable to boron carbide, elemental boron, sp2 boron, and boron oxide. Based on the entire four binding energy peaks, a total atomic B composition value was determined to be 12.6% in this sample. The sp2 coordinated boron was ~4.5%. Another indication of the incorporation of boron into the graphitic carbon lattice is in the carbon 1s spectrum shown in Figure 1b. In this spectrum, the carbon base peak is shifted from 284.5 eV, the recognized value for graphitic carbon, to 283 eV with an associated shoulder at 282 eV. The shift to lower binding energies and the shoulder in the spectrum is attributed to the boron-carbon binding sites.

Through the use of temperature-programmed desorption (TPD) measurements, NREL also demonstrated that BCx materials store hydrogen more strongly than, for example, the template material being used, and that changes in processing affect the amount of B in the materials and the amount of hydrogen stored. The effects of enhanced hydrogen binding and perhaps smaller pore structures associated with BCx materials is also observed with TPD (Figure 2). In general, as the B content of the BCx materials is increased, the hydrogen takes a much longer time to desorb under vacuum conditions. This is consistent with a higher binding energy and/or a more tortuous path associated with the potential formation of smaller porous structures. That said, similar effects are not observed with nitrogen substituted templated carbon materials, suggesting that the higher binding energies associated with boron substitution is playing a major role.

FIGURE 2. Representative example of hydrogen TPD for a templated BCx sorbent. The hydrogen desorption from templated BCx materials with higher B concentration is much slower than from materials with less B.

Coordinated Metal Centers to Enhance Hydrogen Sorption: NREL investigated the use of lightweight metals (i.e., first-row transition metals and group I and II elements) to enhance the binding of dihydrogen on matrix materials and, perhaps more importantly, the ability to create sorption sites that can store more than one dihydrogen molecule [3]. Theorists and experimentalists worked closely at NREL to iteratively design and synthesize new materials with coordinated metal centers. We adhered to the criteria of synthesizing stable materials that have the potential to meet DOE hydrogen storage targets. Thus, theorists not only identify new materials, but work with experimentalists to identify thermodynamically viable synthetic paths to form stable materials. The calculations used to identify these novel materials were validated with all known 3d metal-H2 experimental results. There is good agreement for both the binding energy and the number of dihydrogens being stored between the theory and the known experimental results.

While single metal atom decoration of pure element matrices is possible without metal agglomeration, metal atoms are typically stabilized further at dopant sites (e.g., boron in carbon), and/or with H ligands. Thus, while several investigators have attempted to synthesize materials with single metal atoms coordinated on surfaces, most materials synthesized to date may only be marginally stable, and thus positive results have to date been limited. A specific example of this issue was demonstrated by NREL investigating Li integration with carbon materials. While all attempts to date have not observed enhanced hydrogen interaction effects using Li integrated with pure carbon supports, substantial interactions were observed when Li was integrated with BCx materials. This is in good agreement with theoretical calculations [3]. We used a boron-substituted carbon (BCx) and successfully lithiated it in a tetrahydrofuran solution of Li naphthalide. As shown in Figure 3, TPD measurements demonstrate the reversible desorption of hydrogen at <50°C following room temperature hydrogen exposure. Hydrogen desorption temperatures increased from -120°C to ~50°C by the addition of Li. These TPD measurements are consistent with NREL theoretical predictions that boron sites appear to provide well-defined Li metal binding sites. In addition, high-pressure hydrogen adsorption measurements on the lithiated BCx material at 100 bar and 30°C were ~1.5 times greater than the parent BCx material. Interestingly, the Brunauer-Emmett-Teller SSA of the Li-BCx material was only ~5 m²/g. Surprisingly, the H₂ adsorption sites in the lithiated BCx were stable in O₂ and H₂O.

Work by Hamaed et al. [4] demonstrated that Ti dispersed on amorphous-silica internal surfaces are coordinated via strong Ti-silanol bonds (i.e., ~400 kJ/mol). However, each Ti atom still has sufficient reactivity to adsorb multiple dihydrogen
molecules. Once again, the experimental results (2.7 H$_2$ at <22 kJ/mol>) and models (2.4 H$_2$ at <31 kJ/mol) are in good agreement. But more importantly, these experimental results confirm the basic premise of NREL’s original work that an open metal site can store more than two dihydrogen molecules with energies appropriate for reversible hydrogen storage at ambient temperatures. In a similar approach, we identified that graphene oxide (GO) can be a potential substrate to covalently anchor transition metal atoms that are undercoordinated and well-exposed to accommodate multiple H$_2$ [5]. Zhang et al. reported that Ti atoms grafted on GO could bind multiple H$_2$ ligands with the desired binding energies (Figure 4, 14-41 kJ/mol-H$_2$). The gravimetric and volumetric densities for this system are predicted to be 4.9 wt% and 64 g/L, respectively. NREL developed a successful reaction pathway to synthesize Ti-GO by employing the theoretical calculations [5] to guide experimental investigations. The Ti-GO materials were isolated in an inert atmosphere and then exposed to 500 Torr of H$_2$. TPD measurements demonstrated enhanced H$_2$ binding sites with one benzyl fragment removed. Additional work is being performed to remove the other benzyl fragment to enable multiple dihydrogen adsorption.

**Weak Chemisorption of Hydrogen:** The HSCoE developed spillover materials with the potential for ambient-temperature hydrogen storage. We improved material processing, demonstrating enhanced spillover performance with boron substituted materials, and identified specific surface functional groups that affect spillover.

Improved spillover material processing: The objective was to reproducibly make materials with higher kinetics and hydrogen storage capacities. In general, improved catalyst processing increases hydrogen storage rates and capacities. Thus, we developed processes that reproducibly integrated catalysts (e.g., Pt, Pd, Ru) with controlled particle size (e.g. 1 to 2 nm) and structure, uniformly with different types of receptor materials (e.g., activated carbon, BC$_x$).

**Surface Functionalization:** NREL identified potential issues that produce irreversibilities and cause irreproducible hydrogen sorption measurements. In general, surface composition and properties of the receptor material are important for hydrogen diffusion. For example, reactions with oxygen surface moieties can inhibit or promote hydrogen spillover. TPD analysis of desorbed gases from spillover samples indicates that when some oxygen moieties are present, reduction processes occur to form water, CO$_2$, CO, CH$_4$, and other hydrocarbons. This indicates that some functional groups interact with the absorbed hydrogen to create irreversible chemical reactions. This result explains some of the irreversibility and hysteresis observed in some data, and indicates the importance of monitoring the effluent from spillover measurements to ensure that the hydrogen storage capacity results are being accurately determined. From our work, because higher content of some oxygen species in the receptor material results in higher secondary-reaction products such as water, we recommend that careful analysis be performed whenever oxygen is present in the spillover materials. That said, NREL performed experiments using carbon black (a well known commercial product with no oxygen species on the surface) with Ru catalysts and observed no substantial increase in hydrogen uptake. This suggests that the complete absence of oxygen functional groups prevents spillover. In addition, we synthesized Pt/ carbon from pyrolyzed sucrose templated on silica.
sphere templates, which contains substantial oxygen containing functional groups. This is partly due to the fact that to remove the silica template, the powder after pyrolysis was soaked in 6 M potassium hydroxide solution for four days, filtered, washed with deionized water and dried in at 120°C. The resultant material is highly functionalized. As shown in Figure 5, an enhancement of well over 30% is observed from the base material, and on a per specific surface area basis, the material has well over a 100% enhancement. All these results demonstrate that appropriately functionalized receptor materials can dramatically enhance hydrogen storage capacities at ambient temperature. In general, these materials have excellent kinetics (<5 min to saturation), are the first Pt catalyst based carbon substrate with spillover enhancement of hydrogen adsorption that has been observed at NREL, the adsorption of hydrogen was still increasing approximately linearly at 150 bar, and had minimal irreversibility (multiple cycles were conducted with no loss of sorption capacity or water/methane formation).

Calculations predict that the use of boron-substituted materials may enhance spillover. At the very least, boron substitution may help stabilize catalyst particles for use in weak chemisorption hydrogen storage. While SSA and boron concentration issues must be resolved for boron-substituted carbons, initial evaluations indicate that BCx materials with Ru catalyst provide highly reproducible and reversible spillover that is 20 to 30% above the base material (Figure 6). In general, the capacities of even the non-Ru containing materials are substantially higher on a per specific surface area (i.e. 750 m²/g) bases compared to activated carbons. The higher capacity observed with Ru catalysts while modest is well above detection limits, and unlike other materials used for spillover, this Ru/BCx material is extremely durable providing identical repeated performance even after multiple air exposures. The BCx material substantial enhances kinetics. The spillover binding energies for these materials were measured to be ~20 kJ/mol, and the higher-pressure loading improved to ~83% of maximum in ~5 minutes, which is a substantial improvement from <60% for spillover on pure carbon materials.

Overall, NREL demonstrated that substantial increases in hydrogen storage capacity can be achieved at ambient temperatures with weak chemisorption processes like spillover. While a significant amount of work is still required to develop highly reproducible and robust materials that have the high capacities demonstrated by the HSCoE with less durable materials, the clear indication is that weak chemisorption is a viable path for on-vehicle refuelable hydrogen storage.

**NREL Collaborations and Partnerships:** As the HSCoE lead and a leader in H₂ storage materials development and measurements, NREL collaborates with a large number of groups and institutions around the world. This includes working with the HSCoE partners, DOE Basic Energy Sciences projects, and independent projects, and participating directly with the HSECoe and the DOE Storage System Working Analysis Group. These interactions have led to
several joint publications, and NREL performed ~200 sample measurements this year to assist partners and collaborators in characterizing their hydrogen storage materials.

Conclusions

- Developed novel scalable synthetic processes using templating techniques to form high surface area lightweight materials with optimal pore structure and composition for H₂ storage.
- Demonstrated that B substitution in C increases capacity and binding energy when in the correct sp² coordination. The enhanced binding energy is sufficient to store substantial hydrogen within the DOE target temperature range of ~220 to 350 K; in good agreement with theoretical models. NREL demonstrated that only a small amount of B in most of the BCₓ materials is in the correct coordination state with carbon.
- Identified and synthesized coordinated metal center materials for improved ambient storage of hydrogen. Materials with binding energies between 15 and 25 kJ/mol and/or multiple dihydrogen adsorption have been demonstrated. Ultimately, it should be possible to use these sorbents to meet DOE ultimate storage targets.
- Identified processes and surface functionalizations that helped to synthesize more robust, reproducible spillover materials. Improvements in catalysts and receptors including boron substitution and appropriate oxygen species led to enhanced hydrogen storage performance via weak chemisorption (spillover).
- Improved measurement capabilities and worked with Center partners and other groups around the world to provide more accurate H₂ storage materials characterization at high throughput. This included working with DOE to assemble and publish the best practices document on how to perform and interpret hydrogen storage measurements correctly.

Future Direction

- Establish relationships to improve hydrogen storage measurements techniques.
- Establish hydrogen sorbents working group for continued materials development independent of the HSCoE.

Project Start Date:  July 1, 2007
Project End Date:  June 30, 2012

Objectives

- To design, synthesize, and evaluate porous organic polymers (POPs) as hydrogen storage adsorbents for transportation applications.
- To support POP development with in-depth understanding of hydrogen–adsorbent interactions through modeling/simulation and advanced characterization.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cells Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(B) System Cost
(C) Efficiency
(D) Durability/Operability

Technical Targets

The focus of this project is to prepare new POPs as hydrogen adsorbents with improved storage capacity and heat of adsorption through rational design, guided by computational modeling and advanced characterization. It supports DOE’s initiative in developing adsorption-based storage technology with high uptake capacity, reversibility, and stability. The successful outcome of the project will produce a new storage material that meets DOE 2015 targets:

- Gravimetric density: 1.8 kWh/kg
- Volumetric density: 1.3 kWh/L
- Cost: $2/kWh net

Accomplishments

- Successfully designed and synthesized a coproporphyrin-based POP with high Brunauer-Emmett-Teller (BET) specific surface area (SSA) and narrow pore size distribution. Gravimetric capacities of 5.0% at 77 K and 0.6% at ambient temperature were achieved. Iron was successfully exchanged into the new POP which improved hydrogen heat of adsorption.
- A series of aromatic POPs with similar BET SSA but variable pore sizes were prepared through facile ethynyl trimerization reaction. An H$_2$ isosteric heat of adsorption up to ~10 kJ/mol was achieved.
- New synthetic schemes were developed to integrate various non-C elements (B, N, etc.) into POPs while maintaining high surface areas and narrow pore diameters. Preliminary experiments demonstrated improvement in H$_2$ heat of adsorption.

Introduction

The capacity of on-board hydrogen storage is critical to H$_2$-powered fuel cell vehicles. For practical applications, the storage system must meet the gravimetric and volumetric densities as well as the cost target set by DOE. We plan to address these challenges by exploring a new class of hydrogen adsorbent, POPs. Compared with other adsorbents, POPs have excellent thermal stability and tolerance to contaminants such as moisture. POPs also have low skeleton density and high intrinsic porosity generated by covalent bonds, capable of maintaining SSA during high pressure pelletizing for better volumetric density. Furthermore, they can be produced at a commercial scale with the existing industrial infrastructure. Significant progress has been made in the polymeric adsorbent research [1-3]. Our approach focuses on improving hydrogen uptake capacity and the heat of adsorption by enhancing SSA, porosity, and surface-adsorbate interactions through rational design at the molecular level.
**Approach**

Our design principles aim at improving the following POP attributes: (a) high SSA to provide sufficient interface with \( \text{H}_2 \) (b) narrow pore diameter to enhance van der Waals interactions in the confined space, and (c) “metallic” characters, either through \( \pi \)-conjugation or metal doping, to promote electronic orbital interactions with hydrogen. During Fiscal Year (FY) 2010, we focused our effort on improving \( \text{H}_2 \) isosteric heat of adsorption over POPs by controlling adsorbents’ surface chemical and physical properties. Several series of POPs were systematically designed and synthesized. One example is a polyporphyrin POP with relatively high SSA and narrow pore size distribution. The N4 macrocycle within the POP serves as a coordination site where transition metal (TM) ions can be exchanged in the center of the square-planar ring to bind with \( \text{H}_2 \). Another example is a series of aromatic POPs prepared by facile trimerization reaction with nearly identical SSA but variable pore sizes. Such system can be used to investigate the dependence of adsorption enthalpy on the pore dimension. The surface property, hydrogen uptake capacity, and isosteric heat of adsorption were measured through N\(_2\)-BET and Sievert isotherm methods. In addition, \textit{ab initio} and density functional theory calculations were conducted to compare with the experimental results for a better understanding of the hydrogen-POP interaction.

**Results**

Isosteric heat of adsorption, \( \Delta H_{\text{ads}} \), is an important property for hydrogen adsorbents. To anchor \( \text{H}_2 \) at ambient temperature without consuming excessive energy for extraction, the preferred \( \Delta H_{\text{ads}} \) is from 15 to 20 kJ/mol. Unsaturated metal ligated in a high surface area organic support could promote the interaction with molecular hydrogen through \( d-s \) orbital interaction. For example, theory suggested an enhanced \( \text{H}_2 \) adsorption energy over porphyrin when a selective group of TMs are exchanged into N4-macroyclic ring [4]. We designed and prepared a polyporphyrin POP, poly-tetrakis(3,5-dithiophen-2-ylphenyl)-porphyrin (PTTPP) in FY 2010 and studied the improvement in \( \Delta H_{\text{ads}} \) by comparing \( \text{H}_2 \) adsorption over the metal doped and undoped versions. Figure 1 shows a three-dimensional structure of iron-exchanged polyporphyrin Fe(PTTPP), where Fe is coordinated by four nitrogens in the porphyrin ring. The surface properties of PTTPP and Fe(PTTPP) were investigated by N\(_2\) adsorption isotherm and their hydrogen uptake capacities were measured by a Sievert isotherm apparatus. The results are listed in Table 1. We also investigated the \( \text{H}_2 \) adsorption isotherms at 77 K, 87K, 197 K, 273 K and 297 K. From which we extracted \( \Delta H_{\text{ads}} \) at different hydrogen loadings, as are shown in Figure 2. The isosteric heat of adsorptions was indeed increased when Fe was exchanged into the porphyrin center. However, the enhancement is limited and still falls below the targeted value. We plan to use PTTPP system as a new platform for studying the impact of different metals on \( \Delta H_{\text{ads}} \), taking advantage of versatility of metal exchange through ligation chemistry with the porphyrin.

It has been postulated that the adsorbent pore size influences \( \Delta H_{\text{ads}} \) and the preferred dimension should be slightly higher than the adsorbate’s van der Waals diamater in the range of 0.6 nm to 0.9 nm [5]. In FY 2010, we designed and prepared a series of aromatic POPs through trimerization reaction using monomers

substituted with ethynyl groups at different position, shown as M1 to M4 in Figure 3a. The trimerization reaction led to the formation of four POPs (POP-1 to POP-4) with nearly identical SSAs but variable pore diameters ranging from 8 to 9 Å, as shown in Figure 3b. Hydrogen adsorption was subsequently performed at four temperatures from liquid nitrogen to ambient. Isosteric heats of adsorption, together with the uptake capacities, were obtained. Figure 4 shows $\Delta H_{\text{ads}}$ as the functions of hydrogen loading for all four POPs. Interestingly, no direct correlation between pore diameter and the heats of adsorptions was observed. Instead, we found a correlation between $\Delta H_{\text{ads}}$ and $N_p$ where $N_p$ represents the average number of phenyl groups connected to a benzene after trimerization. The $N_p$ values for POP-2 (2.3) and POP-1 (2.5) are considerably lower than those for POP-3 (3) and POP-4 (3.5), leading to lower $\Delta H_{\text{ads}}$ values. We also performed a quantum mechanical calculation on the interaction between hydrogen and monomers in both open and confined configurations and found the results were consistent with our experimental observation.

**Conclusions and Future Directions**

In summary, we investigated several functionalized POP systems during FY 2010 in an effort to increase...
hydrogen adsorption enthalpy. The two examples we included in this report demonstrate that enhancement of $\Delta H_{ads}$ can be achieved through doping TM or altering chemical environment although further improvement is necessary to reach the preferred value. Our future study will focus on the following areas:

- Continue to incorporate metal and non-C elements to POPs for better hydrogen uptake and heat of adsorption.
- Explore non-conventional activation and doping methods for major improvement in storage capacity and temperature.
- Identify new pathway for next generation POP-adsorbent through rational design and advanced characterization.

### Special Recognitions & Awards/Patents Issued

1. The POP-based adsorbent development was cited as one of the highlights of technical accomplishment by FreedomCAR and Fuel Partnership.
2. Member of Hydrogen Sorption Center of Excellence received 2010 DOE Hydrogen Program Team Award.

IV.C.1g Hydrogen Storage by Spillover

Accomplishments

We have developed two metal-doped zeolites that showed 20 and 21 g/L volumetric capacity at 298 K and 100 atm. Unlike metal organic frameworks (MOFs), zeolites are highly stable and low-cost. The Ni-doped zeolites, in particular, are most promising for practical applications after further development [1].

Introduction

Because of the high bulk densities of zeolites which are substantially higher (2-3 times higher) than that of carbons and metal organic frameworks, plus the high densities of cation sites on a variety of zeolites, zeolites are promising sorbents for achieving high volumetric storage capacities.

Approach and Results

Hydrogen adsorption properties of low-silica type-X zeolites (LSX, Si/Al = 1) [1,2] containing alkali or alkali-earth metal cations (Li+, Ca2+, and Mg2+) have been studied in this project. Li-LSX is commercially used for air separation. It was found that the hydrogen adsorption capacities of LSX zeolites at 77 K were determined mainly by the porosity of the zeolite, while at 298 K, the storage capacities depended on both the H2–cation interactions and the porosity. Among the three exchanged zeolites, Li-LSX had the highest H2 capacity of 1.5 wt% at 77 K and 1 atm, and Ca-LSX had the highest capacity of 0.50 wt% at 298 K and 10 MPa.

Hydrogen storage in LSX zeolites via spillover was also investigated [1]. Three methods including bridge building with a catalyst, metal doping via incipient wetness impregnation and metal doping via chemical vapor deposition (CVD) were employed to induce hydrogen spillover and enhance the storage capacities. Thus, the storage capacities were increased to 0.96-1.2 wt% on the Pt-doped zeolites at 298 K and 10 MPa. The differences between the three methods were compared and discussed [1]. Furthermore, 5 and 10 wt% Ni were doped on Ca-LSX zeolite. The 10 wt% Ni-doped Ca-LSX zeolite showed a storage capacity of 1.15 wt% at 100 atm and 298 K. The important volumetric storage capacities of these zeolites were also estimated based on the densities of the densified zeolites. 21 g/L was obtained for Pt-doped Ca-LSX and 20 g/L was obtained for Ni-doped Ca-LSX, both at 298 K and 10 MPa. The high volumetric capacities were obtained because of the high densities of zeolites which are substantially higher (2-3 times higher) than that of carbons and MOFs.
CVD-Pt/Ca-LSX

In the present study, 5 wt% Pt was doped on Ca-LSX zeolite by CVD of the platinum precursor (Trimethyl methylcyclopentadienyl platinum (IV) and subsequent reduction in a hydrogen atmosphere. The transmission electron microscope (TEM) image of CVD-Pt/Ca-LSX showed nanosized Pt (∼1-3 nm) were well dispersed on the particles of LSX. The hydrogen adsorption isotherm at 298 K (Figure 1) showed that CVD-Pt/Ca-LSX had a storage capacity of 1.20 wt% at 10 MPa, enhanced by a factor of 2.4 compared with that of plain Ca-LSX (0.5 wt%). Reversibility was evaluated by measuring the desorption branch down to 1 atm. The desorption branch nearly followed the adsorption branch although there appeared to be a slight hysteresis. The second adsorption isotherm was in agreement with the first adsorption isotherm. These results indicated that hydrogen adsorption in the CVD-Pt/Ca-LSX was reversible at 298 K.

Ni/Ca-LSX

5 wt% Ni was doped on Ca-LSX by incipient wetness impregnation of an aqueous solution of Ni(NO₃)₂·6H₂O and subsequent reduction in a hydrogen atmosphere at 723 K. The TEM image showed that black Ni particles were dispersed on the LSX zeolites with sizes around 4-10 nm. The loading amount of Ni on Ca-LSX was further increased from 5 to 10 wt% to increase the dissociation sites. As shown in Figure 2, the 10 wt% Ni/Ca-LSX had a storage capacity of 1.15 wt%. Although the loading amount of Ni was doubled, the storage capacity was not increased much.

The volumetric storage capacity of Ni/Ca-LSX was estimated to be 20 g/L (Figure 2), based on the pellet density of 1.7 g/cm³. This indicates Ni/Ca-LSX is a promising sorbent for onboard hydrogen storage.

Conclusion

The updated DOE volumetric target for onboard storage is 28 g/L at near ambient temperature and 100 atm. The two metal-doped zeolites reported here showed 20 and 21 g/L. Unlike MOFs, zeolites are highly stable and low-cost. The Ni-doped zeolites, in particular, are most promising for practical applications after further development.

References

Highlights of 2005-2010

- Developed a bridge-building technique for spillover storage, and obtained up to 4 wt% storage with MOFs at 298 K and 100 atm (U.S. and foreign patents pending).
- Achieved 1.2 wt% hydrogen storage on a Pt-doped superactivated carbon (AX-21) at 100 atm and 298K. Capacities of 1.6 wt% was obtained on Ru/carbon, and 1.1 wt% on Ni/carbon.
- The spillover storage process is reversible at 298 K, i.e., full storage capacity is obtained after degassing at 298 K.
- Developed a simple isotherm equation that is applicable to all spillover sorbents.
- For all spillover sorbents, the rates of discharge at 298 K exceeded the DOE target of 0.02 g/s/kW.
- Developed catalysts that could increase the rates of both charge and discharge for spillover storage.
Increased spillover storage capacities on carbon by 10-40% by each of the following techniques: introducing surface oxygen groups, doping nitrogen and/or boron, plasma treatments, and dosing $\text{H}_2$ with hydrocarbon impurities.

Using deuterium isotope tracer, direct evidence for dissociation/spillover and reverse spillover was obtained.

### Objectives

- Demonstrate high-capacity hydrogen storage in high surface area carbon aerogels (CAs).
- Develop carbon-based sorbent materials that can store hydrogen at ambient temperature and reasonable operating pressures.
- Fabricate porous carbons as scaffolds for complex hydride systems to improve the kinetic performance of the hydride.

### Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume  
(B) System Cost  
(C) Efficiency  
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption  
(Q) Reproducibility of Performance

### Technical Targets

This effort is focused on the design of new nanostructured carbon-based materials that meet the former DOE 2010 targets for on-board vehicle hydrogen storage of 6 percent hydrogen by weight and 45 grams of hydrogen per liter.

### Accomplishments

- New monolithic carbon aerogels derived from sugars (i.e. sucrose, glucose) have been synthesized for use as spillover substrates. These materials possess surface areas up to 600 m²/g and can readily be doped with hydrogen dissociation catalysts, such as platinum or nickel.
- Novel CA-carbon nanotube (CNT) scaffolds have been prepared through catalyzed chemical vapor deposition (CVD) growth of CNTs on the inner pore surfaces of high surface area CA substrates. These substrates promote intimate contact between the surfaces of the CNTs and the incorporated complex hydride, thus influencing the kinetics of hydrogen exchange in the hydride.
- LiBH₄ nanocomposites prepared with the CA-CNT scaffolds showed significant decreases in the temperature of hydrogen desorption relative to that of bulk LiBH₄. These scaffolds also appear to outperform CA scaffolds prepared without CNT. Work performed in collaboration with Metal Hydride Center of Excellence (MHCoE) members at HRL Laboratories.

### Introduction

Porous carbon materials are promising candidates for hydrogen sorption due to their lightweight frameworks and high accessible surface areas. The low hydrogen binding energies, however, that are typical of carbonaceous sorbents (~6 kJ/mol H₂), require that cryogenic temperatures (77 K) be utilized for storage of hydrogen in these materials. In general, the amount of surface excess hydrogen adsorbed on porous carbons at 77 K and ~3.5 MPa varies linearly with Brunauer-Emmett-Teller surface area; gravimetric uptake is ~1 wt% H₂ per 500 m²/g of surface area. Our overall goal in this effort is the design of novel carbon nanostructures that exhibit enhanced binding energies for hydrogen and thus allows for reversible hydrogen storage at ambient temperature and reasonable operating pressures.

### Approach

CAs are a unique class of porous materials that possess a number of desirable structural features for the storage of hydrogen, including high surface areas (over 3,000 m²/g), continuous and tunable porosities, and variable densities. In addition, the flexibility associated with CA synthesis allows for the incorporation of
of CA allows for the dispersion of secondary materials into the carbon matrix that can serve as catalysts or destabilizing agents for the metal hydride and potentially influence the transport properties of the scaffold. Our previous efforts were focused on determining the extent to which the different structural aspects of the CA scaffold (pore diameter, interconnectivity, microporosity, surface chemistry) influence the kinetics of hydrogen exchange in LiBH$_4$. This research is a joint effort with HRL Laboratories, a member of the MHCoE. Our efforts were focused on the design of new CA materials that can meet the scaffolding requirements, while metal hydride incorporation into the scaffold and evaluation of the kinetics and cycling performance of these composites was performed at HRL.

Results

Design of New Spillover Receptors Derived from Carbon Aerogels

Over the last review period, our work as part of the Hydrogen Sorption Center of Excellence (HSCoE) has been focused on the design of novel spillover receptor materials that can potentially improve both capacity and uptake kinetics in spillover materials. Specifically, we have synthesized novel CAs derived from sugars as spillover receptors. This approach builds on the concept developed by Yang et al. of using partially carbonized sugars as “bridges” to facilitate hydrogen diffusion from the catalyst to the receptor. Our material, however, is comprised entirely of “bridge” material and, therefore, these materials should provide sufficiently favorable surfaces for hydrogen spillover. The carbonized sugar aerogels are prepared through the sol-gel polymerization of simple sugars, such as glucose or sucrose, affording highly cross-linked sugar gels. These gels are then supercritically dried and subsequently pyrolyzed under an inert atmosphere to afford the sugar-derived carbon aerogels. These materials are monolithic and possess surface areas up to 600 m$^2$/g. In addition, these porous carbon structures can be readily doped with hydrogen dissociation catalysts, such as platinum, ruthenium or nickel, by either solution- or vapor-phase techniques. Room temperature hydrogen uptake in the metal-loaded sugar-derived CAs has not yet been evaluated within the HSCoE.

Carbon Aerogel as Scaffolds for Complex Hydrides

For our work with the MHCoE, we fabricated a new class of CA scaffolds that contain dispersions of CNTs within the scaffold framework. Incorporation of CNTs into the scaffold has the potential to not only improve the thermal conductivity of the scaffold, but may also affect the kinetics of dehydrogenation for...
certain metal hydrides. Recent work by other groups have indicated that the interaction of the hydride with an electronegative surface, such as that of a carbon fullerene or nanotube, can disrupt the bonding structure of the hydride and, as a result, provide lower energy pathways for hydrogen exchange. These novel CA-CNT scaffolds (Figure 1) were been prepared through the growth of CNTs by CVD on the inner porosity of high surface area carbon aerogel substrates. Because the CNTs populate the surfaces of the CA support, these scaffolds promote intimate contact between the surfaces of the CNTs and the incorporated metal hydride. To evaluate the influence of the CNTs on the kinetics of hydrogen exchange in LiBH₄, the hydride was incorporated into the free pore volume of these scaffolds using melt infusion techniques and the temperature of dehydrogenation was determined using thermogravimetric analysis. As shown in Figure 2, LiBH₄ nanocomposites prepared with the CA-CNT scaffolds showed significant decreases in the temperature of hydrogen desorption relative to that for bulk LiBH₄ and also out-perform earlier generation CA scaffolds prepared without CNT. This approach to scaffold design appears promising and we expect further improvements in performance as the structure of these composite scaffolds are optimized.

**Conclusions and Future Directions**

While this project finished at the end of this review period, we believe there are a number of aspects of this work that warrant future investigation based on the promising results from Fiscal Year (FY) 2010, including:

- Evaluation of room temperature hydrogen uptake (both capacity and kinetics) in the metal-loaded sugar-derived CAs. These results should provide guidance for further optimization of the surface chemistry and texture of the spillover receptors.
- Further investigation of the influence of CNTs and other graphitic nanostructures on the kinetics of hydrogen exchange in complex hydride systems. Initial results for our CA-CNT composites indicate improved kinetic performance of LiBH₄ in these scaffolds.
- Incorporation of other destabilizing agents and catalysts, such as Mg, Ni or Ti, into these CA-CNT scaffolds to facilitate the hydriding and dehydriding processes.

E-mail: James.Alkire@go.doe.gov

Contract Number: DE-FG36-05GO15009
Subcontractor: PoroGen, LLC, Boston, MA
Start Date: May 2, 2005
Projected End Date: June 30, 2010 (no-cost extension to December 31, 2010)

Objectives

Develop and demonstrate reversible nanostructured activated carbon hydrogen storage material which has at least a 5.5 wt% materials-based gravimetric capacity and a 40 gH2/L material-based volumetric capacity at 235–358 K, and potential to meet the DOE 2015 system-level targets.

- Prepare and characterize nanostructured polymer derivatives as carbon precursors.
- Initiate the production of nanostructured activated carbon for hydrogen storage.
- Develop methods for sorbent-based doped polymer/carbon.

Technical Barriers

This project addresses the following On-Board Hydrogen Storage Technical Barriers (2007, section 3.3.4) outlined in the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(C) Efficiency
(E) Charging/Discharging Rate

(P) Lack of Understanding of Hydrogen Physiosorption and Chemisorption
(Q) Reproducibility of Performance

Technical Targets

The research and development of novel high surface area nanostructured carbons for hydrogen storage has been conducted in this project. The Hydrogen Program aims to address the critical need that has been recognized by DOE, which has established a national effort to develop new and advanced high-capacity hydrogen storage materials and technologies. This project is applied toward the synthesis of inexpensive carbon-based, high surface area sorbents that can be combined with chemical-interacting organic, and/or inorganic materials, to yield high storage materials. These new materials and concepts have been designed to meet the DOE 2015 goals concerning the production of low-cost, high specific hydrogen binding energy hydrogen storage materials.

Accomplishments

- Demonstrated synthesis of a modified polymer-based carbon with high surface area (up to 4,000 m²/g) and low average pore width (down to 8.5 Å). Accomplished gravimetric storage capacity of ~6.7-7.0 wt%, and volumetric capacity of ~43-45 g/L at 77 K, 5-6 MPa.
- Achieve a high reproducibly on production in laboratory scale.
- Introduction of a carbon alloy with organocyclic-(CNH)n macromolecules rich with unsaturated bonds that should be available for room temperature (RT) application at moderate pressures for H2 storage systems. The melamine derivative carbonized or incorporating to the activated carbon
without the metal predicated at 77 K and 1 bar is 4-5 wt% with surface area ~2,000 m²/g.

- Using theoretical simulations (Monte Carlo computation) to obtain configurations of Melon (and g-C₃N₄) with d-transition metals (Mg, Ti, V, Ni, Fe) indicating that the complex structures with these metals can increase the hydrogen adsorption and with desirable binding energy.

Introduction

The State University of New York-esf and PoroGen, LLC, have initiated a collaborative effort to develop superior high surface area nanostructured carbons for hydrogen storage. Synthesis of the carbon starts with the preparation of a nanoporous semicrystalline oriented polymer precursor having nanosize pores, with a uniform pore size distribution. This semicrystalline nanoporous polymer precursor is subsequently tailored to form high surface area activated carbons with slit-like micro porous structure (pore width ~7-20 Å). The high surface area of the polymeric precursor aids in preparation of this unique carbon (S_{BET}>3,000 m²/g) and enables doping initial material with chemical agents, which, upon carbonization, introduces specific interaction sites that significantly increase the hydrogen storage capacity of the nanostructured carbon material.

Approach

To achieve the project objectives, polymer-based nanostructured carbons have been synthesized by engineering the structure of the polymer precursors to produce carbon with the designed morphology for activation to high surface area and controlled micropores. Thus, polymer precursors (modified poly(phenylene oxide), modified poly(ether ether ketone [PEEK]), polyetherimide [PEI]) are spun at high melt shear rates further to control the morphology and orientation of crystalline regions. High orientation of polymer chains and alignment of crystalline lamellar regions leads to the formation of a porous material from oriented nano-size pores that upon carbonization, with specific activation agents, produce high surface area, high microporosity activated carbon. Consequently, procedures (including parameters such as heating rate, temperature and time) were developed to properly carbonize polymer precursors. In the activation (pore creation) step, the activation kinetics, including the reactivity size of activation agents, and the homogeneity of activation system, were addressed to control the carbons texture. Interaction of carbon with hydrogen is relatively low and may reach up to 6-7 kJ/mol. Since organocyclic-CNHN macromolecules with unsaturated bonds that exhibit rigid planar configuration and are abound in electronegative nitrogen atoms, can complex metal-salt and are enabled for RT application for H₂ storage systems at moderate pressure. Thus the synthetic methods are expanded to incorporate reactive sites into the carbon nanostructures by doping polymerized unsaturated functionalized polycyclic complexes (Melem, F-Melem, Ni-Melem). Also, melamine derivatives have been synthesized and carbonized for adsorption of hydrogen. Alloying activated carbon with unsaturated functionalized polycyclic complex(ed) with Melem, F-Melem, and/or traces of Ni, Ti, Fe-Melem have been accomplished. Finding the proper compositions, and the ratio of carbon/alloy and other components, is needed. Also, surface modifications of the nanostructures of polymer based carbons (by blending different polymer precursors) and control of hydrogen’s binding energy with the carbon/alloys have been part of this study. Extensive physisorption and chemisorption (H₂ adsorption) characterizations have been performed to verify the synthetic effort.

Results

In Fiscal Year (FY) 2010, the main focus still remained exploration of new materials and synthetic routes by tailoring the morphology of polymer precursor to produce high surface area, higher microporosity and small pore size nanostructured carbons. The hydrogen storage measurement has been tested at several laboratories. Figure 1 shows hydrogen uptake isotherms (excessive uptake) of polymer-based carbons measured gravimetrically (pressure up to 20 bar), and volumetrically high throughput (instrument pressure up to 60 bar) (measurement by Hiden Isochema Co. U.K).

The hydrogen uptake reaches 6.6 wt% for APKI-S6 at 50 bar, and for carbon 5.5 wt% 20 bar (as measured with both techniques). The APKI polymer-carbons are PEEK/PEI, and poly(2,6-dimethyl-1,4-phonylene oxide)-based carbon (APPO) is derivative of phenyl phosphine oxide. Surface areas for APKI6S2-N4, APPO-R8, APKI-S6 and APKI6S2-N20 are recorded as 3,070, 2,550, 3,034, 5,160 m²/g, respectively.

Figure 2 shows excessive hydrogen uptake of polymer-based carbons (PEEK, PEEK/PEI and APPO) at higher pressures evaluated at different testing laboratories.

The hydrogen binding energy for all carbons shown here are ~5-6 kJ/mol. A strategy for increasing hydrogen binding energy has been executed by introducing a large number of certain metal sites to polymer framework. In the past year, a set of Melon configurations, and Melon with Mg, Fe, Ti, V, Ni single metal atoms were first modeled by Monte Carlo computational method at 300 K. These models indicate that Ti and Mg do not only interact with the melon units but also “open” the spacing for hydrogen (up to four for Ti and two for Mg) which were situated here at the local
minimum potential (energy) configuration; where in the case of Ni the metal was found to be competing on the position and “close” the space for hydrogen molecules, which were found the minimum out of the melon units. Metal clusters M(n) (not shown here) are used to model “real” possible events. The Melon with different metal catalysts was carbonized at 700°C from C-N nano tubing with diameter ~12 nm traces of large cluster aggregation of Fe (Figure 3A). Figure 3B shows lattice structure formed on wall of this carbon. The electro diffraction gives a distance of 3.4 Å hydrogen adsorption of carbonized Melon carbon nano-tubing before complex with metal at 87 K and 1 bar is shown in Figure 4. All the samples have surface areas below 650 m²/g. The hydrogen adsorption increases linearly with the surface area. (Uptake about ~3 wt% hydrogen can be obtained by extrapolating to the surface area ~1,000 m²/g).

**Conclusion**

- Accomplished synthesis of a modified polymer based carbons with high surface area (up to 4,000 m²/g) and low average pore width (down to 8.5 Å). The gravimetric storage capacity of these carbons achieved ~6.7-7.0 wt%, and volumetric capacity of ~43-45 g/L at 77 K, 5-6 MPa!!
- Achieve a high reproducibly on production of these carbons in laboratory scale!!
- Organocyclic-(CNH)_n macromolecules rich with unsaturated bonds that should be available for RT
application at moderate pressures for H₂ storage systems has been established. The hydrogen storage of the melamine derivative carbonized or incorporating to the activated carbon without the metal predicated at 77 K and 1 bar is 4-5 wt% with surface area ~2,000 m²/g.

- Using theoretical simulations (Monte Carlo computation) to obtain configurations of Melon (and g-C3N4) with d-transition metals (Mg, Ti, V, Ni, Fe) indicating that the complex structures with these metals can increase the hydrogen adsorption and with desirable binding energy.

IV.C.3  Electron Charged Graphite-Based Hydrogen Storage Material

Technical Targets

This project involves conducting research on graphite-based materials for hydrogen storage with external electronic charges to increase hydrogen storage capacities and charge/discharge rates that meet the following DOE 2010 hydrogen storage targets:

- System Gravimetric Capacity: 0.045 kg H₂/kg system
- System Volumetric Capacity: 0.028 kg H₂/L system
- Durability/Operability: 1,000 cycles
- Cost: $4/kWh net

*GTI metal hydride-based material (3 wt% hydrogen storage) with tank at 1,000 psi

Accomplishments

- Tested a water cooling/heating system for hydrogen storage and release.
- Repeated the electron charge effect experiments on the hydrogen storage capacity of materials under water cooling and heating.
- Tested the in situ regeneration of borane-nitride materials.

Introduction

Hydrogen adsorption/desorption of metal-based materials with storage gravimetric capacity of 3.3 wt% of base material have slow kinetics with chemisorption. For comparison, hydrogen molecules are physisorbed on carbon-based materials at temperatures as low as 77 K. The metal-based materials are polar substrates while the carbon materials are non-polar substrates. The non-polar hydrogen molecules adsorbed on a
non-polar carbon substrate are not dissociated and the force between these two non-polar species is weak van der Waals force. The non-polar hydrogen molecules adsorbed on a polar (metal) substrate generate an electron spillover effect on hydrogen adsorption. Whether the substrate is polar or non-polar, the external electrical force could polarize the substrate surface to change the hydrogen adsorption capacity and kinetics. In the last annual report, it was concluded that positive charge increases hydrogen storage on metal based material and negative charge increases hydrogen storage non-metal hydrogen storage materials. This year, we focus on the substrate and regeneration of hydrogen storage materials.

**Approach**

- Test and evaluate the hydrogen storage system with cooling/heating:
  - Modify the electron charge distribution structure (framework structure) to obtain a 50% hydrogen storage rate increase.
  - Fueling kinetics study: does the electron charge make desorption fast?
  - Theoretical calculation: how much charge is needed to get 6 wt%?
- Build a system with water cooling and heating to enhance hydrogen storage and release rate.
- Scale-up to an 11 liter tank for fueling demonstration to show 50% hydrogen storage increase.

**Results**

A. Hydrogen Storage Tests With/Without Electrostatic Charge

1. System Design

   External electron-charge has been demonstrated to affect hydrogen storage kinetics and capacities. Figure 1 shows the design of our electron-charged hydrogen storage system with cooling/heating feature. In this system, a stainless steel coil with polymer coating as insulation is inserted into the tank. The stainless steel coil conducts electron-charge and cools/heats the hydrogen storage materials. A similar system with 10 ml capacity is used for material screening and hydrogen storage tests.

2. Hydrogen Storage Tests

   The electron-charge hydrogen storage system was checked for any internal short under hydrogen storage pressure. It was determined that even if the voltage goes to 1,000 volts, the leak current is very small and would not affect experimental results. Therefore all the tests using this system show the electro-static non-Faradaic effect on the hydrogen storage due to low Faradaic current.

   Figure 2 is a pressure-composition-isotherm (PCI) curve of a metal-based hydrogen storage material during cooling and heating modes. Hydrogen is adsorbed during cooling and released during heating as expected. The system was verified for use in external charge experimental tests.

   The hydrogen storage system with cooling/heating was connected to an external electrical charge device to determine the effect of external charges on hydrogen storage. Figure 3 shows the PCI curves of the metal-based hydrogen storage material under positive charge (a) and negative charge (b) during cooling and heating. PCI curves with electrical charges shift and shows increased hydrogen storage. However the shift seems to be independent to the charge polarities. It could be due to activation of storage material by external charges. The key is to look for a hydrogen storage material that
3. Regeneration of Borane-Ammonia

The electrochemical activity of BH$_3$NH$_3$ was tested in diglyme because of its high boiling point of 162°C and capability to chelate small cations. For all supporting electrolyte used, when heated near 100°C, the BH$_3$NH$_3$ expanded greatly. This also had an effect on cyclic voltammograms (CVs). Figure 4 shows the CV for BH$_3$NH$_3$ in diglyme.

B. High Surface Carbon for Hydrogen Storage

The hydrogen storage electron-charge system is being developed under cooperation with the State University of New York (SUNY) at Syracuse. GTI tested eight samples provided by SUNY and the results are summarized in Table 3. The best hydrogen storage gravimetric capacity (Sample APKI-S6) is 7.0 wt% at 77 K.

Conclusions and Future Directions

- The electron charge experiments showed that positive charge increases hydrogen storage on metal-based material and negative charge increases hydrogen storage on non-metal hydrogen storage materials.
- The external charge also improves hydrogen charge/discharge kinetics. In situ regeneration of borane-nitride showed 75% increase in rate at 600 psig.

FY 2010 Publications/Presentations

1. A poster presentation on the overall project status was presented at the June 9, 2010 DOE Annual Merit Review Meeting in Washington D.C.

Project Start Date: February 1, 2009
Project End Date: Project continuation and direction determined annually by DOE

Objectives

- Develop system models that will lend insight into overall fuel cycle efficiency.
- Compile all relevant materials data for candidate storage media and define future data requirements.
- Develop engineering and design models to further the understanding of on-board storage energy management requirements.
- Develop innovative on-board system concepts for metal hydride, chemical hydride, and adsorption hydride materials-based storage technologies.
- Design components and experimental test fixtures to evaluate the innovative storage devices and subsystem design concepts, validate model predictions, and improve both component design and predictive capability.
- Design, fabricate, test, and decommission the subscale prototype components and systems of each materials-based technology (adsorbents, metal hydrides, and chemical hydrogen storage materials).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(B) System Cost
(C) Efficiency
(D) Durability/Operability
(E) Charging/Discharging Rates
(G) Materials of Construction
(H) Balance of Plant Components
(J) Thermal Management
(K) System Life Cycle Assessments
(L) High Pressure Conformality
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
(S) By-Product/Spent Material Removal

Technical Targets

This project is directing the modeling, design, build and demonstration of prototype hydrogen storage systems for each metal hydride, chemical hydride and hydrogen sorption materials meeting as many of the DOE technical targets for light-duty vehicular hydrogen storage. The current status of these systems vs. the onboard hydrogen storage system technical targets are given in Table 1.

Introduction

The Hydrogen Storage Engineering Center of Excellence (HSECoE) brings together all of the materials and hydrogen storage technology efforts to address onboard hydrogen storage in light-duty vehicle applications. The effort will begin with a heavy emphasis on modeling and data gathering to determine the state-of-the-art in hydrogen storage systems. This effort will span the design space of vehicle requirements, power plant and balance of plant requirements, storage system components, and materials engineering efforts. These data and models will then be used to design components and sub-scale prototypes of hydrogen storage systems which will be evaluated and tested to
determine the status of potential system against the DOE 2010 and 2015 technical targets for hydrogen storage systems for light-duty vehicles.

**Approach**

A team of leading national laboratories, universities, and industrial laboratories, each with a high degree of hydrogen storage engineering expertise cultivated through prior DOE, international, and privately sponsored programs has been assembled to study and analyze the engineering aspects of condensed phase hydrogen storage as applied to automotive applications. This diverse group will bring creativity and originality to the HSECoE, where innovative concepts must be identified to develop hydrogen storage systems capable of meeting the stringent DOE goals. The technical activities of the HSECoE are divided into three system architectures: adsorbent, chemical hydride and metal hydride matrixed with six technologies areas: Performance Analysis, Integrated Powerplant/Storage System Analysis, Materials Operating Requirements, Transport Phenomena, Enabling Technologies and Subscale Prototype Construction, Testing and Evaluation.

**Results**

The following technical accomplishments were achieved by the partners in the HSECoE during the course of the past year. These accomplishments were the result of intense inter-organizational communication and interfacing through the existing technology area lead organization for the Center. These accomplishments are:

- The positions of system architects were formulated to give prime responsibility to individuals for driving technical solutions to identified technology gaps in storage system development.
- Completed programming of the Hydrogen Storage SIMulator to aid in prediction of impact of technical targets.
- Completed baseline fuel cell power plant models with physical storage fuel sources.
- Completed finite element models on metal hydrides and adsorbent system.
- Completed initial metal hydride hydrogen storage system models with various configurations of pressure vessels, buffer tanks, hybridization schemes, pumps and heat exchangers.

IV.D Hydrogen Storage / Hydrogen Storage Engineering CoE

- Completed initial chemical hydride hydrogen storage system models with various configurations of mass transport mechanisms, spent fuel reservoirs and reactors.
- Completed initial adsorbent hydrogen storage system models with various configurations of heat exchangers, pressure vessels, buffer tanks and pumps.
- Completed coupling of vehicle modeling, fuel cell modeling and storage system modeling in a MATLAB/Comsol/Simulink environment.
- Identified acceptability criteria and UP/DOWN select methodology for metal hydrides, chemical hydrides and adsorbent materials.
- Completed identification of parametric models to be used for metal hydride, chemical hydride and adsorbent system thermal models.

\[
\frac{dC}{dt} = \mathcal{A} \exp\left(-\frac{E}{RT}\right) \left(C - C^0\right)
\]

Chemical Hydrides:

\[
\frac{dC}{dt} = \mathcal{A} \exp\left(-\frac{E}{RT}\right) \left(P - \frac{P}{\alpha}\right) \left(C - C^0\right)
\]

Metal Hydrides:

\[
n_{ex} = n_{max} \exp\left[-\frac{RT}{\alpha + RT}\right] \ln\left(\frac{P}{P_0}\right) - \rho_n V_a
\]

Adsorbents:

- Compiled a data base for each of the materials to be modeled and identified technical data gaps in the data with plans to fill these gaps as shown in Table 2.

- Completed an acceptability envelope for metal hydrides to aid in determination of the critical thermochemical characteristics required for storage system consideration:

\[
\left(\frac{1}{L^2}\right) \left(\frac{k M_{Hyd}}{\Delta H_{overall}} \cdot \frac{\Delta T}{\rho_{Hydride}}\right) = \frac{1}{mM_{H2}} \frac{\Delta m_{H2}}{\Delta t}
\]

- Identified critical technologies for pressure vessels, sensing, insulation, thermal generation and fuel purity required to enable use of various storage system materials.
- Determined the current system technical target status of metal hydrides based on NaAlH4 and technology gaps (gravimetric density, cycle life, safety and toxicity) needing to be addressed to meet the 2010 and 2015 technical targets (see Figure 1).

**FIGURE 1.** Spider chart against DOE 2010 targets for sodium aluminum hydride metal hydride system showing technical gaps in gravimetric density, cycle life, safety and toxicity.
• Determined the current system technical target status of chemical hydrides based on solid NH$_3$BH$_3$ and technology gaps (fuel purity, fill time, minimum full flow rate and loss of useable hydrogen) needing to be addressed to meet the 2010 and 2015 technical targets (see Figure 2).

• Determined the current system technical target status of adsorbents based on super-activated carbon and technology gaps (volumetric density, minimum delivery pressure and loss of useable hydrogen) needing to be addressed to meet the 2010 and 2015 technical targets (see Figure 3).

**FIGURE 2.** Spider chart against DOE 2010 targets for solid ammonia borane chemical hydride system showing technical gaps in fuel purity, fill time, minimum full flow rate and loss of useable hydrogen.

**FIGURE 3.** Spider chart against DOE 2010 targets for super activated carbon (ax-21) adsorbent system showing technical gaps in volumetric density, loss of useable hydrogen and minimum delivery pressure.
Conclusion and Future Directions

For each of the storage system types, many of the technical targets have been fully met with a number more met to at least the 40% level. The technical directions to achieve the Phase 2 Go/No-Go decision are set by the technical gaps noted in the spider charts. Furthermore, the technical targets will be prioritized in the coming year give guidance as to the technical gaps requiring further work.

For metal hydride systems, approaches must be proposed which have been shown minimally through modeling that:

- Gravimetric targets can be met through characterization of LiMgN materials systems.
- Cycle life of materials can be estimated through accelerated testing.
- Acceptable toxicity and safety risk levels can be achieved through mitigation strategies.

For chemical hydride systems, approaches must be proposed which have been shown minimally through modeling that:

- Fuel purity can be achieved through impurity trapping and materials development.
- Fill time can be achieved through solid mass flow concepts and novel system designs.
- Minimum full flow rate can be achieved through solid mass flow and solid reactor designs.
- Loss of useable hydrogen can be minimized through materials characterization.

For adsorbent systems, approaches must be proposed which have been shown minimally through modeling that:

- Volumetric densities can be achieved through compaction methods with minimal loss of gravimetric density.
- Minimum delivery pressures can be achieved through novel thermal designs.
- Loss of useable hydrogen can be minimized through utilization of novel low-cost insulation schemes.

As Phase 2 is entered, experimental validation of modeling will take precedence. Heat and mass flow experiments will be detailed constructed and performed to validate modeled performance. The modeling and empirical validation cycle will be used to obtain enhanced performance.

Contract Number: DE-AC05-76RL01830  
Project Start Date: February 1, 2009  
Project End Date: January 31, 2014

Objectives

The Pacific Northwest National Laboratory (PNNL) objectives address some of the critical engineering challenges that currently limit design optimization and commercialization of on-board hydrogen storage systems. Each of these objectives and corresponding tasks have been established to advance the state-of-the-art in analysis, design and engineering for chemical hydride storage, pressure/containment vessel construction for metal hydride and cryogenic adsorbent systems, and component miniaturization to achieve PNNL, Hydrogen Storage Engineering Center of Excellence (HSECoE), and DOE goals.

- Demonstrate the performance of economical, compact, lightweight vessels for a hybrid pressurized metal-hydride and adsorbent system, and containment vessel for a chemical hydride system.
- Guide design and technology down selection, Go/No-Go decision-making, and address vehicle and market impact through cost modeling and manufacturing tradeoff assessments of the three HSECoE prototype storage systems.

Achieving the objectives will enable PNNL, Savannah River National Laboratory (SRNL), and other HSECoE partners to demonstrate on-board hydrogen storage with the potential to meet 2015 DOE technical targets. This technology and design knowledge will be transferred to the participating automotive original equipment manufacturers, thus advancing the hydrogen market sector and production of future hydrogen-powered vehicles.

Technical Barriers

Specific work scope at PNNL is addressing most of the technical barriers, as described by the Fuel Cell Technologies multi-year program plan, in system weight, volume, cost and efficiency, as well as operational constraints in hydrogen delivery and refueling rates, durability and operating temperatures bounds, and materials of construction. This project addresses the following needs in the Fuel Cell Technologies multi-year program plan:

General to All Storage Approaches:
(A) System Weight and Volume  
(B) System Cost  
(C) Efficiency  
(D) Durability/Operability  
(E) Charging/Discharging Rates  
(G) Materials of Construction  
(I) Dispensing Technology  
(J) Thermal Management  
(K) System Life-Cycle Assessments  
(O) Hydrogen Boil-Off  
(H) Balance of Plant (BOP) Components

Off-board Regenerable Specific:
(S) By-Product/Spent Material Removal
Technical Targets

The Center activities being conducted at PNNL range from process and reactor modeling and component design/engineering to technology application and prototype fabrication for demonstration. The final ultimate goal of the PNNL scope is to demonstrate, with Los Alamos National Laboratory (LANL) partners, a (100-g) scaled chemical hydrogen storage system that meets all the DOE storage performance targets. As a snapshot of progress to date, the spider chart in Figure 1 represents the principal DOE performance targets and status toward achieving those targets as a percentage. The DOE has established an initial in-process review gate of 40% for each of the targets; the dashed line represents this 40% threshold.

Accomplishments

Progress toward meeting formal Fiscal Year (FY) 2010 milestones is on track. Accomplishments achieved to date against these milestones include:

- Initiation of process flow diagram and model development for a solid chemical hydride storage system.
- Established common modeling approaches and platform for use among Center partners.
- Determine functional criteria and design rules based on modeling performance predictions and hydride system needs.
- Complete a conceptual design for a solid chemical hydride reactor that will provide input to the HSECoE’s Phase 1 Go/No-Go decision making process, and insight into the ability of such a system to meet the 2015 volumetric capacity target of 1.5 kWh/L.
- Complete COMSOL modeling of configurations.
- Down-select systems to be modeled for transient response.
- Complete preliminary design for fuel element transfer system (solids handling coupled to reactor).
- Complete test station for monolithic fuel element and hydrogen release measurement.
- Provide Rev.0 cost model, structure details and spreadsheet to Center partners for their evaluation.
- Determine bulk kinetics measurements and impact on performance.
- Complete modeling and establish pressure vessel design rules for use with prototypes.

FIGURE 1. Progress toward achieving DOE performance targets for solid ammonia-borane (AB) hydrogen storage. Seventeen targets are above the 40% threshold set as an initial gate target in March 2011.
• Complete identification of known materials compatibility issues and establish corrective action plan for component designs.

Introduction

To date there has been multiple on-board vehicle-scale hydrogen storage demonstrations, including several studies to examine phenomena and characteristics that impact the engineering of hydrogen storage systems. However, none of these demonstrations have simultaneously met all of the DOE hydrogen storage sub-program goals. Additionally, engineering of new chemical hydride approaches specifically is in its infancy, with ample opportunity to develop novel systems capable of reaching the DOE targets for storage capacity. Toward this goal, PNNL is leading efforts as part of the HSECoE led by SRNL, to design and fabricate a 100 g of hydrogen scaled system based on solid or slurry chemical hydride storage media. This system is intended to be demonstrated at LANL during FY 2014 as the HSECoE concludes.

Approach

The PNNL will actively contribute to the five technology areas established as part of the HSECoE led by SRNL. The goal of this center, and PNNL’s role, is to develop and demonstrate low-cost, high-performing, on-board solid-state hydrogen storage through a fully integrated systems design and engineering approach.

PNNL will target six key objectives to optimize performance characteristics and reduce the size, weight, and cost of a solid-state hydrogen storage system. This will be accomplished through a carefully engineered and integrated design approach, including application of advanced materials (structural and hydrogen storage), use of micro-scale enhancements of heat and mass transfer, better understanding and tailoring of bulk storage media and system kinetics, and assessments of manufacturing and cost impact based on established models/approaches for technology tradeoff or “viability” studies.

PNNL will also serve multiple leadership roles within the HSECoE technology area structure to help facilitate collaboration across the center partnership and to feed technical results back through and disseminate to other center partners. Achieving the objectives will enable PNNL, SRNL, and other HSECoE partners to demonstrate on-board hydrogen storage with the potential to meet 2015 DOE technical targets. This technology and design knowledge will be transferred to the participating automotive original equipment manufacturers, thus advancing the hydrogen market sector and production of future hydrogen-powered vehicles.

Results

During FY 2010 the basis of a solid chemical hydride reactor design model and system construct was created. Further, system flow sheets were established for a solid monolithic system, which provides preliminary insight into component configurations for chemical hydrides. Flow sheets and design information from component and system models were used to identify knowledge gaps that would be addressed in an experimental program later in FY 2010 and FY 2011. This modeling and experimental data will be used as the basis for down-selection of flow sheets at the end of Phase 1.

To date multiple monolithic fuel element conceptual forms have been considered:

• Disks
  – Five-inch disks, 1/8” thick sequentially inserted into 60-120 3/16” slots.
  – Slots loaded every 2-4 seconds.
  – 170°C oil channels between each slot for preheat/cooling.

• Beads
  – Beads loaded into 60-120 1-1/4” diameter, 5-inch long chambers.
  – Chambers loaded every 3-6 seconds.
  – 170°C oil channels surround each chamber.

• Tape
  – Two-inch wide, 1/8” thick tape runs through reactor at 20 ft/min.
  – Eighteen passes in 3 ft long reactor.
  – 170°C oil channels surround each pass.

Models that represent these physical formats have been drafted, and for FY 2010 are being used to analyze hydrogen mass and heat transfer throughout the dehydrogenization reaction zone and within the fuel storage container. Furthermore, a fourth fuel element type is in the process of being added to the physical domain model that describes the fuel element in a gel or slurry form that may have the added advantage of easier loading on- and off-board the vehicle.

Additionally, a series of models that captures the physiochemical nature of a solid chemical hydride system was drafted that will be use to simulate hydrogen release in monolithic fuels in order to guide system design and determination potential for achieving hydrogen release rate target of 1.6 g H₂/s for an 80 kW fuel cell. This model also incorporates the fuel element engineered form models (e.g. disks, beads, tape) and takes into consideration two different reactor designs and processes routes – batch versus continuous.

The model is built upon a three-tier hierarchy, with the lowest level being a kinetics model that describes
the mass/heat phenomena of the systems; second tier describes the reactor function and physical design, while the highest tier is a BOP component model that follows the process flow diagram configuration. Basic inputs to the model are: reaction rate, reactor design, DOE targets (80 kWe), while outputs are: reactor size, fuel usage, hydrogen loss, and impurity level.

This three-tier series of models are built using a combination of COMSOL, MATLAB and Microsoft Excel, which input/output files are readily transferable between other Center partners. The models once refined and validated experimentally, will be used for sensitivity analyses, understanding reaction residence times, determining reactor size and complexity versus extent of reaction (fuel usage). The modeling effort will also focus on defining fuel element void space (e.g. slot gap size, packing density), ultimate reactor operating pressure, hydrogen loss, and level of impurities.

This initial baseline model utilizes AB in an engineered form, known (or predefined) reactor design dimensions, heat transfer, and diffusion resistance. Figure 2 shows this baseline reactor and storage system. The model is currently being adapted to also include provisions to simulate the functions of a gel or slurry fuel.

To address weight and volume constraints design consideration was given to combining function and components into single units, as well as integrating multiple functionality into the reactor and on-board mass transfer components. As an example, the AB thermohydrolysis reaction and control of kinetics exclusively in the auger rather than ballast tank with the baseline design show in Figure 2. Additionally, the fuel element feed and product tanks are combined into a single unit that works by displacing and refilling the tank volume with fresh and spent fuel, hence minimizing overall system volume. As a result, estimated system volume and weight appears to be within achievable
means relative of the DOE 2010 performance targets. Estimates weights and volumes for the primary systems components are given in Table 1.

Beyond process and kinetics modeling, PNNL has established the modeling approach, assumptions, and basic structure to simulate various pressure vessel geometries and layered structures, including model parameters that account for basic cost and performance. This effort and model is being used to conduct assessments of materials and design options between Type I-IV pressure vessels, which include a first-order approximation of cost from a materials-of-construction perspective. It was concluded that carbon fiber-wrapped Type-IV tanks is the closest known option to meet 2015 weight targets. However, the trade-off is higher cost of the carbon fiber, which may be a contrite to implementation at this point in time unless options for lower cost carbon fiber and/or tank designs can be developed. Based on this study further analysis will emphasize options for aluminum tanks and liners, as well as modeling lower cost and strength carbon fibers for use in Type-IV tanks.

Additionally in FY 2010 PNNL developed the selection criteria for storage materials to aid in down selecting materials systems for further focus on system modeling and design. These selection criteria are used as a screening tool for subsequent material considerations, and to identify gaps in the property data which will need to be addressed by HSECoE partners or other independent projects. As part of this effort, materials property data collection from the existing materials centers of excellence has been completed.

**Conclusions and Future Directions**

- A representative systems model of an AB-based bead reactor system was developed and successfully simulated in MATLAB/Simulink environment.
- A COMSOL transport model was developed for a bead and a block system. The heat and mass transfer model used a simple reaction rate expression: (1) Bead reaction can occur within the auger that has been designed assuming a 200°C wall. (2) Heating the outside surface of a block can light off the reaction for the entire block.
- An improved kinetic model has been developed and implemented into the system model.
- Hydrogen loss and impurities assessed for solid AB as material is moved into and out of the pressurized reaction system.
- Materials properties database established for HSECoE partners.
- Screening criteria/questionnaire created.
- Engineering cost model structure established.
- Studies and analysis of pressure vessels performed:
  - Metal hydride hybrid
  - Vessel material of construction sensitivity analysis
  - Liner material assessment
- Materials compatibility and reactivity studies started.

Future planned scope for FY 2011 will predominately include implementation of the new reactor designs in MATLAB/Simulink and corresponding simulation analysis for assessing impact on: improve hydrogen delivery temperature; increase volumetric/gravimetric density; include variable transport properties (ρ, Cp, k, zH₂); and address impurities and hydrogen losses in design. Investigation of alternate materials of chemical hydride options, such as alane, will also occur. Additionally, implementation of the new kinetic model in MATLAB/Simulink and corresponding simulation analysis is planned, including the additional of temperature dependent transport properties into models as they become available. This effort will be supported by experimental efforts to determine needed property and kinetics data for each storage material system, as well as for model validation and calibration purposes.
Objectives

- Collaborate closely with the Hydrogen Storage Engineering Center of Excellence (HSECoE) partners to advance materials-based hydrogen storage system technologies.
- Develop vehicle/power plant/storage system integrated system modeling elements to improve specification of storage system requirements and to predict performance for candidate designs.
- Establish detailed heat and mass transfer modeling and apply to design improved internal heat exchange configurations.
- Design and evaluate compacted/structured hydride powder beds including integration into the heat exchange configurations.
- Assess the viability of on-board purification for various storage material classes and purification approaches.

Technical Barriers

This project is concerned with assessing and developing all aspects associated with viability of storage systems and therefore addresses a broad set of technical barriers from the Storage section (3.3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:
(A) System Weight and Volume
(B) System Cost
(C) Efficiency
(D) Durability/Operability
(E) Charging/Discharging Rates
(G) Materials of Construction
(H) Balance of Plant (BOP) Components
(I) Dispensing Technology
(J) Thermal Management
(K) System Life-Cycle Assessments

Technical Targets

The goals of this project mirror those of the HSECoE which by the end of Phase I (March, 2011) seeks to define systems configurations which can fully meet four of the DOE 2010 numerical system storage targets as outlined in the Multi-Year Research, Development and Demonstration Plan and partially meet the remaining numerical targets to at least 40% of the target or higher.

Accomplishments

Accomplishments of the current project comprise:

- Demonstrated that powder compaction with a uniaxial press can simultaneously increase the density of sodium alanate materials by 63% (39% reduction in volume) and the thermal conductivity by a factor of seven in comparison to the properties of loose powder while maintaining comparable hydrogen absorption and desorption rates.
- Developed a biaxial flexure screening test for determining the strength of compressed pellets and changes in the pellet strength due to hydrogen absorption and desorption cycles.
• Designed and optimized a heat exchanger for a sodium alanate-based hydrogen storage system with a fast refueling time and developed a lumped parameter model of such a system for inclusion in vehicle level modeling.
• Demonstrated viability of an onboard hydrogen purification cartridge for ammonia, which addresses concerns about the presence of ammonia in hydrogen from chemical hydride (e.g. ammonia borane) and metal hydrides (e.g. LiNH2/MgH2 mixtures).
• Designed and implemented an integrated power plant storage system modeling framework in Simulink.

Introduction

Physical storage of hydrogen through compressed gas and cryogenic liquid approaches is well established, but has drawbacks regarding weight, volume, cost and efficiency which motivate the development of alternative, materials-based methods of hydrogen storage. Recent worldwide research efforts for improved storage materials have produced novel candidates and continue in the pursuit of materials with overall viability. While the characteristics of the storage materials are of primary importance, the additional system components required for the materials to function as desired can have a significant impact on the overall performance. Definition, analysis and improvement of such systems components and architectures, both for specific materials and for generalized material classes, are important technical elements to advance in the development of superior methods of hydrogen storage.

Approach

UTRC's approach involves a broad set of tasks which leverage prior experience, coordinate with other UTRC projects and extend to new areas of concept development. A graphical representation of our approach to conduct the research is shown in Figure 1. It shows material-related tasks at the base of the pyramid, component design tasks in the center, and system-related tasks near the top, which all tie in with the overall structure of the HSECoE. The results will be used by the HSECoE to determine the viability of materials-based hydrogen storage systems. The project is divided into three phases with the first covering two years. A Go/No-Go decision at the end of Phase 1 (March 31, 2011) will guide activities and concepts for deeper evaluation in Phase 2.

Results

DOE’s 2010 target for the volumetric capacity of a hydrogen storage system is 28 grams hydrogen per liter on a system basis. At the time of this study sodium alanate was a Tier 1 material in the HSECoE, and it was therefore selected as a model material for evaluating the impact of compaction on the density and thermal conductivity of a prototypical hydrogen storage material. Reaching the targeted volumetric capacity with sodium alanate requires powder compaction. For this purpose UTRC installed a heated platen uniaxial press inside a glovebox with an inert atmosphere. The density of the pressed pellets as a function of the compaction pressure is shown in Figure 2. The thermal conductivity of the compacted material was measured with a Hot Disk® Thermal Constants Analyzer and is shown in Figure 3 as a function of density. The results show that compaction of sodium alanate enables an increase in density of about 63% in comparison to loose powder (59% reduction in volume) which results in a seven fold increase of the thermal conductivity. Compacted sodium alanate appeared to have a slightly slower hydrogen absorption rate and this is subject of future research.

Sodium alanate pellets need to be strong for this automotive application. A biaxial flexure screening test was developed in order to measure the strength and determine any strength change after hydrogen absorption and desorption cycles. Initial results show a small volumetric expansion (~2%) of the pellets due to repeated cycling and the pellets maintained their strength (1.4 kpsi), but experiments will need to be repeated and performed over a larger number of cycles in order to better determine the significance of those results.

DOE’s 2010 target of 4.2 minutes for system fill time (for 5 kg hydrogen) is challenging for a hydrogen storage system based on sodium alanate due to the relative high heat of hydrogen absorption (~40 kJ/mol hydrogen) and kinetic limitations. A COMSOL Multiphysics™
A thermochemical simulation approach was co-developed with Savannah River National Laboratory and used to engineer a sodium alanate-based hydrogen storage system with such a short fill time, while maximizing gravimetric and volumetric capacities. It required an enhancement of the reaction kinetics beyond what is currently observed. The allowable temperature rise in the sodium alanate bed during refueling was restricted to 170°C. This constraint was imposed as a decrease of the hydrogen absorption rate was observed when holding the material at 180°C for an extended period of time (15-75 hrs), which is undesirable. The heat exchanger tubing diameter, aluminum content in the bed and the tube spacing were optimized with this model and the results are shown in Figure 4. It clearly shows the improvement of the volumetric capacity due to compaction and how a relative high volumetric capacity can be achieved even at a short fill time by using tightly spaced small diameter tubing (1/8”) in the heat exchanger and improvement of the reaction rate beyond what is currently observed. However, compaction only reduces the volume of the hydrogen storage material and therefore the gravimetric capacity of the sodium alanate bed still remains low (<18 g H2/kg) in comparison to DOE’s 2010 target (45 g H2/kg system).

UTRC is leading the Integrated Power Plant Storage System Modeling technical area of the HSECoE and with other partners has developed a simulation framework that was implemented in Simulink™. The framework is shown in Figure 5 in a graphical form. The team developed an interface matrix between the different simulation modules under guidance of Ford. The framework created a strong focus for the team members. Each member contributed models such as the lumped parameter model of a sodium alanate system by UTRC, the sodium alanate system with a different design by General Motors (GM), the cryo-adsorption system by GM, the chemical hydride system based on ammonia borane by the Pacific Northwest National Laboratory, the proton exchange membrane (PEM) fuel cell system by Ford and the vehicle level model by the National Renewable Energy Laboratory (NREL). The integrated framework enables a dynamic evaluation of the performance of a vehicle with a materials-based hydrogen storage system and a seamless comparison of various hydrogen storage systems on a common and quantitative basis, which is critical for the Go/No-Go decision in the end of Phase 1.
Hydrogen from the hydrogen storage system needs to have a sufficient purity in order to enable high performance and long life of the PEM fuel cell system. The SAE J2719 guideline [1] was adopted as the hydrogen purity standard. This guideline not only specifies the total hydrogen content but also sets limits on the concentration of specific impurities such as ammonia. Ammonia was shown to be an impurity of concern by Keith Wipke from NREL [2] as part of the Hydrogen Fuel Cell Vehicle and Infrastructure Learning Demonstration project as some of the hydrogen that was tested contained 1 ppm ammonia, which exceeds the SAE guideline of 0.1 ppm. Ammonia is not only introduced on-board the vehicle by the hydrogen filling station but two candidate materials for hydrogen storage (ammonia borane and LiNH₂·Mg H₂ mixtures) have also been reported to release hydrogen that is contaminated with ammonia. Therefore, ammonia abatement was selected as an initial focus for the hydrogen purity task. A chemical adsorption cartridge was selected for an experimental evaluation as it has distinct benefits in terms of cost and low hydrogen loss in comparison to the two alternative purification approaches (palladium membrane and on-board regenerable physical adsorption). An experimental setup was designed and built to determine the dynamic sorption capacity of various sorbents. It uses a photo-acoustic analyzer to monitor the ammonia content in the effluent of the sorbent bed as a function of time. The breakthrough time was defined as the time at which the ammonia content would exceed 0.6 ppm, which is the detection limit of this analyzer. It was determined experimentally that a commercially available sorbent had a dynamic sorption capacity for ammonia of about 2-2.5 wt% as a result of both physical and chemical adsorption under dry conditions (no humidification). A cartridge with about 4 kg of this sorbent would last about 3 months when processing 5 kg of hydrogen per week if the hydrogen would contain 200 ppm ammonia. This appears to be a viable approach and improving the capacity of the sorbent to reduce weight and volume is part of our future work. It is realized that abating hydrogen impurities with purification methods is only one approach and that it would be desirable to have an improved understanding and control over the hydrogen release mechanism to avoid the formation of impurities all together.

Qualitative risk analysis was performed on a chemical hydride system (based on ammonia borane) and on a cryo-adsorption system (based on AX21) and fault trees were developed for both.

**Conclusions and Future Directions**

Conclusions derived from the work in Fiscal Year 2010 are:

- Compaction of hydrogen storage materials, with sodium alanate as an example, is a valuable engineering tool for improving thermal conductivity and volumetric capacity of a hydrogen storage system but there is a trade-off between how much one can compact and when the decrease in permeability starts to become an issue. Also,
verifying that strength and compact integrity is maintained, is important.

- Sodium alanate is a good model material for developing engineering tools (compaction method, multiphysics model) though it is recognized it cannot fulfill the DOE targets.

- Evaluating different hydrogen storage systems on a common basis, by establishing a common simulation framework, is important for down-selecting hydrogen storage systems for Phase 2 consistently across the center.

- On-board hydrogen purification with commercially available sorbents to remove ammonia is feasible as long as the ammonia content is low (e.g. <200 ppm).

Future work will comprise:

- Determine hydrogen permeability of compacted sodium alanate pellets and use results in COMSOL Multiphysics™ model to quantify impact of pressure gradients on hydrogen absorption and desorption rate.

- Develop a small test article of compacted sodium alanate to determine thermal performance with aspects of heat exchanger integration.

- Expand the compaction effort, thermal conductivity and permeability measurements, to other materials that are of interest to the HSECoE.

- Use the Simulink framework to compare performance of various hydrogen storage system designs on a common basis and evaluate against DOE targets in close cooperation with the HSECoE partners.

- Improve ammonia dynamic sorption capacity of sorbent material and expand hydrogen purification approach from ammonia to other impurities of concern.

- Qualitative risk assessment of hydrogen storage systems of interest to the HSECoE.

Start Date:  February 2009
Project End Date:  February 2014

Technical Objectives

- Develop fuel gauge sensors for solid-state hydrogen storage media.
- Mathematically model the aging characteristics (i.e., shelf-life) of candidate hydrogen storage materials.
- Develop rate models for hydrogen release on candidate chemical hydrides.
- Develop novel strategies for start-up and transient operation with candidate chemical hydrides.
- Identify hydrogen impurities and develop novel impurity mitigation strategies.
- Design, build, and demonstrate a subscale prototype reactor that releases hydrogen using chemical hydrides (technology area lead).

Management Objectives

- DOE Program Liaison: Coordinate/collaborate with the Chemical Hydrogen Storage Center of Excellence (CHSCoE).
- Chemical Hydride System Architect: Monitor and guide progress on chemical hydride systems.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (C) Efficiency
- (A) System Weight and Volume
- (D) Durability/Operability

Technical Targets (2015)

- Gravimetric Capacity: 3 kWh/kg
- Volumetric Capacity: 2.7 kWh/L
- H₂ Discharge Rate: minimum full flow rate 0.02 H₂ g/s kW
- H₂ Purity: 99.99 %H₂
- Start-Up Time to Full Flow: 5 s @ 20°C, 15 s @ -20°C
- Loss of Usable H₂: 0.05 g/hr-kg H₂ stored

Accomplishments

- Demonstrated novel acoustic fuel-gauge sensor with metal hydrides:
  - Patent submitted
- Developed and updated testing protocols for accurate shelf-life data acquisition.
- Collected shelf-life data for neat ammonia borane (AB) and liquid AB formulation.
- Screened approximately 20 catalysts for room temperature dehydrogenation of liquid-phase AB.
- Developed dual-catalyst bed reactor model to investigate start-up and transient operation.
- Quantified borazine and diborane impurities generated from neat AB.
- Demonstrated that borazine and diborane can be scrubbed to produce fuel-cell quality hydrogen.
- Developed preliminary system designs for liquid-phase chemical hydrides.

Introduction

This project is a new start (February 2009). Hydrogen storage systems based on chemical hydrides require a chemical reactor to release the hydrogen from the storage media, which is a fundamental difference from the other modes of hydrogen storage, adsorbents and metal hydrides. This hydrogen-release reactor is crucial to the performance of the overall storage system, especially in meeting the DOE targets for hydrogen generation rate, transient operation, and startup times.
The reactor must be designed to achieve these targets while meeting the constraints of the overall system volume and weight targets.

One challenge in developing efficient reactor designs is in addressing the wide range of applicable variables, including reactant and product phases (solid, liquid, and gas are all possible); exothermic, endothermic, or autothermal reaction thermodynamics; catalyst effectiveness; selectivity; space-time; and reactor volume. The first objective of the LANL team is to quantify these variables for candidate chemical hydride materials through rate expressions modeled from tightly controlled, well-defined kinetics experiments free of mass and heat transfer effects. In LANL’s Phase 1 work, these rate expressions will be applied in system-level models. In Phase 2, the rate expressions will be used with computation fluid dynamics codes to develop novel and efficient reactor designs in collaboration with other Hydrogen Storage Engineering Center of Excellence partners.

Kinetics experiments can be used to identify routes to optimize catalyst design, improve reactor efficiency, and reduce weight, volume, and cost. The experiments and the resulting rate models will therefore support achieving the objective of optimizing the reactor for an on-board automotive system. In addition, the engineering team will work with the CHSCoE to optimize the catalysts for candidate chemical hydride systems.

LANL will also address the unique requirements of on-board automotive hydrogen storage systems. For example, these systems require fast startup, operation over a wide dynamic range (10:1 turndown or greater), and fast transient response to meet the demands of a drive cycle. The LANL team will develop novel reactor designs and operation strategies to meet these transient demands. In addition, the shelf life and stability of the hydrogen storage media is crucial for an automotive system, especially pertaining to safety and cost. Starting with the kinetics models, the LANL team will develop mathematical models for the aging characteristics of candidate hydrogen storage media (for example, complex metal hydrides or chemical hydrides) subjected to a range of environmental factors. These models can be incorporated into system-level models of performance and cost and also used for the development of accelerated aging protocols necessary for later testing.

**Technical Tasks**

**Technical Task 1: Design and Develop Fuel Gauge Sensors for Solid-State Hydrogen Storage Media**

Approach: LANL will employ an inexpensive, simple, and robust method of using the natural properties of the hydrogen storage media to develop novel fuel gauge sensors.

**Technical Task 2: Develop Models of the Aging Characteristics of Hydrogen Storage Materials**

Approach: In collaboration with the material Centers of Excellence, aging experiments will be performed as a function of temperature (0°C–60°C), pressure (0 psig–5,000 psig), percent relative humidity (0%–90%), and percent air (0%–100%). Collected data will be regressed into a model for predicting the degradation of stored hydrogen storage media as function of geographic location, diurnal cycles, storage temperature, storage pressure, and storage atmosphere (such as humidity and air).

**Technical Task 3: Develop Rate Models for Hydrogen Release on Candidate Chemical Hydrides**

Approach: LANL’s approach will be to collaborate with the CHSCoE on reactor testing candidate chemical hydrides under tightly controlled experimental conditions (such as temperature and pressure) using LANL’s in-house designed and built reactors. Intrinsic rates will be determined over ranges of temperature (25°C–200°C), composition, pressure (0 psig–100 psig), and space-time (0.01 s–10 s). Reactor tests will also be performed to ensure that mass and heat transfer effects are negligible. The sought-after data will include selectivity, conversion, hydrogen yield, and mass balances of all reactants and products.

**Technical Task 4: Develop Novel Strategies for Start-Up and Transient Operation with Candidate Chemical Hydrides**

Approach: Exothermic reactions offer the greatest opportunities to meet the DOE technical targets of start time to full flow and transient response by taking advantage of the heat generated upon hydrogen release. The heat required to raise the reactor temperature to that of the desired operating temperature can be obtained on-board without external heat sources by designing novel thermal integration strategies coupled with exothermic hydrogen release reactions. Modeling efforts will be conducted to determine which approach has the largest impact on reducing startup time and transient response; additional decision criteria will include reactor mass, reactor volume, and reactor cost.

**Technical Task 5: Identify Hydrogen Impurities and Develop Novel Impurity Mitigation Strategies**

Approach: As materials are down selected and available, we will produce hydrogen from
candidate materials and operate small, 5 cm$^2$ single-cell proton exchange membrane (PEM) fuel cells to evaluate the quality of the hydrogen. This task will produce durability data on PEM fuel cell operation using hydrogen generated from hydrogen storage materials. Impurity identification can be accomplished by performing post-characterization studies on the PEM fuel cell, such as cyclic voltammetry, scanning electron microscopy, transmission electron microscopy, X-ray fluorescence, diffuse reflectance infrared Fourier transform spectroscopy, solid-state nuclear magnetic resonance, and high frequency resistance. LANL has previously demonstrated the catastrophic effects of hydrogen impurities generated from ammonia borane on PEM fuel cells. Prior to the PEM fuel cell test, the impurities generated from AB were unknown.

Results

Fuel Gauge Sensor Development (Task 1)

Experiments were performed to determine the viability of employing acoustic sensor technology on metal hydrides as a fuel gauge sensor. Data were collected on commercial and non-commercial steel cylindrical pressure vessels containing metal hydride storage materials. In each case, the mass of metal hydride was small compared to the total mass of the system. However, large differences in the swept frequency response were evident (Figure 1), thus establishing a proof-of-principle that a hydrogen level sensor based on acoustic principles is feasible.

Figure 2 shows changes in the measured acoustic response spectra of the fully charged, large Solid H™ cylinder as it was removed and replaced. A small amount of water-based gel couplant was added in between each measurement and the exact placement of the cylinder on the transducers (including rotation component) was subject to small variability. While there are differences in the recorded spectra, several resonance peaks (e.g. at 45, 87, 136, 191, 248 kHz, etc.) are present in each scan albeit with slightly different amplitudes.

These data strongly indicated the need for an improved method of controlling the charge state of the hydride without disturbing the position of the hydride cylinder or the acoustic couplant in between measurements. Moreover, the variability introduced into the measurement via the previous method would preclude tracking the acoustic response at intermediate levels of charge or discharge. Demonstration of this ability will be very important for the purposes of level gauge development. Furthermore, during initial reversibility experiments where the hydride was charged and discharged repeated, it found that the properties of the water-based gel couplant would change due to the large exotherms associated with incorporation of H into the crystalline lattice of the metal hydride. The gel became more viscous and overtime eventually became very tacky due to dehydration of the gel. It is known that this stiffening of the couplant would introduce changes

![Acoustic Responses for (a) Fully-Discharged Metal Hydride and (b) Fully-Charged Metal Hydride](image-url)
in the resonance spectra and in particular, change which modes of vibration within the system were excited.

Mathematically Model the Aging Characteristics of Candidate Hydrogen Storage Materials (Task 2)

Shelf-life models were obtained for neat AB under non-isothermal reacting conditions. Differential scanning calorimetry (DSC) heat flow data were used to correlate dehydrogenation activity (or reaction progress) as a function of temperature. Models were generated using the Freidman analysis (or differential isoconversional technique). A shelf-life mode for neat AB was generated and is shown in Figure 3. Figure 3 shows the modeled reaction progress (i.e., extent of dehydrogenation) as a function of time and temperature. According to the model, AB will be stable

FIGURE 2. Four measurements of the Solid-H™ BL-30 storage cylinder, charged state, from 5 to 300 kHz conducted in succession with minor changes in placement of cylinder on top of the transducers, the possibility for slight rotation of cylinder, and variation in amount of water-based gel acoustic couplant.

FIGURE 3. Shelf-Life Model for Neat AB
at 40°C for approximately 15 days before significant dehydrogenation occurs. This model, however, under predicts the shelf-life model of neat AB. Consequently, this model does not agree with experiment and therefore has been down-selected (or given a "no-go"). Disagreement between the experiment results and the current model can be attributed to the movement of the DSC pan upon dehydrogenation, giving rise to inaccurate heat flow results which translated into the model. Additional experiments are being performed that address this issue. Updated models will be generated and compared to the data to ensure agreement between them.

**Develop Rate Models for Hydrogen Release on Candidate Chemical Hydrides (Task 3)**

Rate models for the dehydrogenation of liquid phase AB have been generated using a limited data set. The data set primarily includes hydrogen production as a function of temperature. In addition, the data were collected in a batch reactor with hydrogen being the only measurable quantity. A complete set of kinetics data would include hydrogen production as a function of temperature, concentration, flow rate, and catalyst. In addition, mass balances resulting in selectivities and yields are necessary for an accurate and complete description of the reaction kinetics. We are working with the CHSCoE in obtaining these results for rate model regression.

**Identify Hydrogen Impurities and Develop Novel Impurity Mitigation Strategies (Task 4)**

Observed impurities generated from AB are ammonia, borazine and diborane. Impurities from the thermal decomposition of AB have been shown to be catastrophic to fuel cell operation and durability. We have quantified (via calibrations) borazine and diborane that are generated from neat AB, AB/methyl cellulose and AB dissolved in ionic liquids. The amount of borazine and diborane generated is strongly dependent upon temperature, catalyst, purity, additives, and physical phase (i.e., solid phase or liquid phase). Shown in Figure 4 are the gas phase infrared spectra of (a) neat borazine, (b) gas phase products observed from neat AB thermal decomposition, and (c) neat diborane. In contrast to neat AB, AB dissolved in ionic liquids only generates ammonia as the impurity. Borazine and diborane were successfully scrubbed using activated carbon (as shown in Figure 5) producing fuel cell grade hydrogen.

**Develop Novel Strategies for Start-Up and Transient Operation with Candidate Chemical Hydrides (Task 5)**

Start-up and transient operation are critical features that need to be addressed for all viable on-board hydrogen delivery systems. Our approach is to design and implement novel strategies that address these two DOE targets. We looked at a design where a room temperature dehydrogenation catalyst was homogeneously mixed with a high temperature catalyst (~70°C); refer to Figure 6. The room temperature catalyst provides a means to accommodate both the startup and transient operation of the fuel cell. The short coming of the room temperature catalyst is that it promotes the release of only one equivalent of hydrogen. This is in contrast to the high-temperature catalyst that allows for multiple equivalents of hydrogen to be released. In other words, there are two reaction pathways that are catalyzed by the different catalysts. Competing reaction pathways result in a trade-off scenario between hydrogen production efficiency, heat generation and transient response. The homogeneous dual catalyst bed design results in a hydrogen production efficiency that is below the DOE gravimetric targets.
Consequently, this approach will not work and has been discarded as a viable design. We have also screened approximately 20 different catalysts for room temperature activity. None of the dehydrogenation catalysts proved to be viable room temperature catalysts. Results are shown in Figure 7. Because of the poor room temperature dehydrogenation activity observed with all of the catalysts tested, research on these catalysts has been discontinued.

**Design, Build, and Demonstrate a Subscale Prototype Reactor Using Liquid or Slurry Phase Chemical Hydrides (Task 6)**

In order to address the DOE targets we must first assess the current status via preliminary system designs. Shown in Figure 8 are two preliminary on-board system designs for liquid/slurry-phase AB. The preliminary system designs will be translated into a spider chart that compares the system to the DOE targets as a whole. We have identified areas that need to be addressed. These areas include impurity mitigation, startup and transient operation, and heat management. Preliminary costs and overall system efficiencies will also be calculated from the system designs.

**Summary**

- Level gauge milestones for Fiscal Year (FY) 2010 are on track and will be met by end of the fourth quarter.
- The change in swept acoustic frequency response with metal hydride hydrogenation/dehydrogenation observed in commercially prepared metal hydride
cylinders has been reproduced in simple stainless steel vessels:
- Characteristic response observed for two different metal hydride alloys.
- Ergenics™ 208 and LaNi alloy obtained from Aldrich in different cylinder masses/volumes show same effect.
- Experiments confirm that sound waves are coupling with, and interacting with, the metal hydride within the stainless steel pressure vessels and not due to secondary effects.
- Patent submitted.
- Acoustic sensor may be useful for metal hydride and adsorbent cycling studies.
- Developed and updated testing protocols for accurate shelf-life data acquisition.
- Collected shelf-life data for neat AB:
  - Shelf-life model for neat AB under predicts stability because of foaming issues, resulting in inaccurate data.
  - Preliminary shelf-life data collected for a liquid AB formulation:
    - Liquid-AB formulations stable for 100 hrs @ 60°C; need to measure shelf-life for extended time periods (>1,000 hrs).
  - The homogeneous dual catalyst bed design for handling the startup and transient operation of the fuel cell has been discontinued because the low temperature catalyst is too fast resulting in hydrogen production efficiencies equal to 0.4 (max is 1.0).
  - Screened approximately 20 heterogeneous catalysts for room temperature activity:
    - Reactor tested catalysts cannot meet the startup requirement needed for an on-board hydrogen delivery system.
• Novel reactor designs (without auxiliary heating sources) addressing start-up and transient operation require the development of novel heterogeneous catalysts that are active at room temperature.
• Preliminary system designs for both liquid phase and solid phase chemical hydrides have been generated.

Future Directions

Acoustic Fuel Gauge Sensor
• Investigate the effects hydrogen head pressure on acoustic response.
• Investigate the effects valve positioning and supply lines on acoustic response.
• Perform compaction test to determine if acoustic coupling effects.
• Demonstrate tracking intermediate states of hydrogen charge of the commercial hydride cylinder and look at effects of temperature on the resonance spectra.
• Begin work with other H₂ storage media.

Shelf-Life Modeling
• Collect shelf-life data on solid AB with anti-foaming agent.
• Collect a complete set of shelf-life data on liquid-AB formulations.
• Update experimental setup and protocols as needed to ensure accurate data for model development.
• Verify model accurately predicts shelf-life models for extended time periods.

Reaction Rate Models for Hydrogen Release on Candidate Chemical Hydrides
• Acquire complete set of kinetics data:
  – Low-temperature catalyst route
  – High-temperature catalyst route
• Focus on segregated dual catalyst bed design.

Low Temperature Catalyst Development for Startup and Transient Operation
• Continued efforts will focus on converting the room temperature homogeneous catalysts into heterogeneous form while maintaining room temperature activity.

Hydrogen Impurities and Mitigation
• In collaboration with the CHSCoE, quantify impurities from liquid AB formulations as a function of temperature ramp.
• In collaboration with the CHSCoE, quantify impurities from solid AB formulations as a function of temperature ramp.
• In collaboration with MHSCoE, quantify impurities from candidate metal hydrides formulations as a function of temperature ramp.
• In collaboration with United Technologies Research Center, explore and test possible alternative scrubbing technologies for ammonia, diborane and borazine.

Project End Date: September 30, 2014

Objectives
- Perform vehicle simulations of various systems configurations.
- Provide support in defining the fuel interface and forecourt requirements.
- Lead the storage system energy analysis and provide results.
- Compile and obtain media engineering properties through collaboration with the Hydrogen Storage Material Center of Excellence (HSMCoE).

Technical Barriers
This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program’s Multi-Year Research, Development and Demonstration Plan:
(A) System Weight and Volume
(B) System Cost
(C) Efficiency
(E) Charging/Discharging Rates
(I) Dispensing Technology
(K) Systems Life-Cycle Assessments

Technical Targets
This project is conducting simulation and modeling studies of advanced onboard solid state hydrogen storage technologies. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage vessels that meet the following DOE 2015 hydrogen storage for light-duty vehicles targets:
- Cost: to be determined
- Specific energy: 0.055 kg H₂/kg system
- Energy density: 0.040 kg H₂/L system
- Charging/discharging rates: 3.3 min

Accomplishments
- Developed a vehicle model framework to aid in the development and understanding of hydrogen storage system requirements for light-duty vehicles.
- Devised a methodology to assess onboard hydrogen storage technical target sensitivity in a light-duty vehicle context.
- Obtained preliminary greenhouse gas emissions and well-to-wheels (WTW) efficiency figures for baseline physical storage systems.
- Identified potential materials for analysis and provided storage system design guidance to help meet DOE storage targets with sorption materials.

Introduction
Overcoming challenges associated with onboard hydrogen storage is critical for the widespread adoption of hydrogen-fueled vehicles to occur. The overarching challenge is identifying a means to store enough hydrogen onboard to enable a driving range greater than 300 miles within vehicle-related packaging, cost, safety, and performance constraints. By means of systems analysis and modeling, hydrogen storage system requirements for light-duty vehicles can be assessed. With these findings and through collaboration with our Hydrogen Storage Engineering Center of Excellence (HSECoE) partners pathways for successful hydrogen storage system technology can be identified thus enabling future commercialization of hydrogen-fueled vehicles.

Approach
An array of tools and experience at NREL is being used to meet the objectives of the HSECoE. Specifically, extensive knowledge of multiple vehicle simulation, WTW analysis, and vehicle performance tools are being employed and integrated with fuel cell and material-based hydrogen storage system models developed by our
HSECoE partners. This integrated model framework allows for the evaluation of various hydrogen storage options. Engineering requirements are defined from these studies thus enabling the design of hydrogen storage vessels that could potentially meet DOE performance and cost targets in a vehicle system context.

In the area of media engineering, attaining the objectives of the HSECoE relies on NREL’s leadership in developing custom analytical instrumentation for hydrogen sorption analysis. These tools are used to thoroughly characterize hydrogen storage sorbents so that an optimized storage vessel specific to the sorption material may be efficiently engineered. NREL will use these methods to analyze sorption materials identified by the HSECoE as holding promise for application in commercial on-vehicle refuelable hydrogen storage systems capable of meeting DOE targets.

Results

An approach to evaluate hydrogen storage system characteristic trade-offs across several vehicle configurations was demonstrated. Evaluating trade-offs between storage system characteristics – including gravimetric capacity, transient response time, cost, and full flow rate – and understanding their sensitivity to overall vehicle system viability can assist in prioritizing research areas of onboard hydrogen storage.

Initial analysis involved two parts. In Part 1, a fuel cell vehicle (FCV) configuration was assumed. Each of the four hydrogen storage system characteristics considered was swept in a parametric study and the vehicle viability, a normalized measure of the vehicle cost and performance, was recorded. Holding all other vehicle components – including the fuel cell, motor, and energy storage system (ESS) – constant through this exercise helped identify vehicle viability sensitivity to varying levels of certain hydrogen storage characteristics as shown in Figure 1.

In Part 2 of the analysis, each of the hydrogen storage characteristics was swept while allowing specific vehicle component power and energy levels to vary. These components included the fuel cell, motor, and ESS. By allowing the vehicle components to vary with changes in the hydrogen storage system, the “Most Viable” FCV configuration could be identified for a particular system.

The results in Figure 2 suggest that allowing the fuel cell, motor, and ESS power and energy levels to vary as

![FIGURE 1. Onboard Hydrogen Storage Technical Target Sensitivity in a Light-Duty Vehicle Context - Part 1 Results](image-url)
the transient response of the hydrogen storage system increases assists in maintaining a higher viability index than if the vehicle component sizing remained fixed.

In the area of media engineering, NREL worked with our HSECoE partners to compile engineering properties for selected sorbents. Initially, the commercially viable sorbents AX-21 (i.e. MSC-30) and MOF-5 were selected as model sorbents to provide the basic information needed to construct accurate hydrogen storage system models. However, the materials will probably not be sufficient to meet the HSECoE goals or the DOE 2015 targets. Thus, NREL led the sorption materials team to develop detailed sorbent selection criteria and to identify potential sorbent materials that may improve the hydrogen storage system designs. As part of this work, additional metal-organic framework, high specific surface area carbon, and weak-chemisorption sorbents were identified. With most of these novel sorbents, most of the engineering properties are unknown and thus need to be measured to feed into the storage system designs. As part of this work, the Engineering Center specifically removed from further consideration MOF-177, but identified four other materials to more fully characterize.

With NREL's unique sorption materials perspective, our initial assessment of the state of sorbent materials for hydrogen storage was refined based on recent modeling results from the Storage System Working Analysis Group (SSWAG) led by Argonne National Laboratory (ANL), and TIAx. The initial conclusion by NREL is that while confirmation of many of the specifics still needs to be made, sorbents should meet the vast majority of DOE targets. The main issues are cost, volumetric and gravimetric capacities, and depending upon the hydrogen storage conditions used, the well to fuel cell efficiency. Based on an initial assessment of the SSWAG using MOF-177, an optimized adiabatic storage system filled with liquid hydrogen would operate at ~250 bar and 80 K with a gravimetric capacity of >5 wt% and a volumetric capacity of ~35 g/L. However, this hydrogen storage system will be almost an order of magnitude higher than DOE present 2015 targets. Based on these results, NREL developed several recommendations for improving the hydrogen storage system including increasing the overall capacity of the system to ~13 Kg, decrease the storage maximum pressure to ~40 bar, and enable larger temperature swings to increase the amount of delivered hydrogen. With these changes, it may be possible to meet DOE 2010 capacity targets, and be within a factor of 2 or DOE 2010 cost targets (Figure 3).
NREL also recommended using improved and less expensive optimized pore size sorbents that more than double the volumetric capacities, and that enable lower operating pressures and operating at lower storage temperatures with larger temperature swings. This would enable sorbents to be used to potentially meet the HSECoE Phase II and perhaps the DOE 2015 targets, including cost and capacities. However, recent emphasis by DOE on overall well to fuel cell hydrogen efficiencies still need to be fully evaluated for this scenario.

Conclusions and Future Direction

- FCV viability sensitivity to onboard hydrogen storage system improvements can be estimated.
- Improved volumetric capacity by way of optimized materials is needed as well as the inclusion of system cost and efficiency for sorbent based system analysis.
- In collaboration with our HSECoE partners, sub-system models will be refined and fully integrated into the vehicle model framework.
- Working with our vehicle manufacturer partners, the Hydrogen Storage Simulation model vehicle viability index estimation methodology will be further reviewed and validated and sensitivity analysis repeated as necessary.
- NREL will investigate data and WTW model integration requirements.
- Systematic compaction measurements to determine maximum attainable sorbent material densities while maintaining the inherent capacities will take place.

Project End Date: January 31, 2014

Objectives

Main objectives of this project are:

- To develop system simulation models for on-board hydrogen storage systems using metal hydride and adsorbent materials and to determine system compliance with the DOE technical targets.
- To develop storage media structures with optimized engineering properties for use in storage systems.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development, and Demonstration Plan (MYPP):

- System Weight and Volume
- Efficiency
- Charging/Discharging Rates
- Thermal Management

Technical Targets

This project addresses the design of on-board hydrogen storage systems for two types of storage media - adsorbent materials and metal hydrides. In particular, the system design is to be optimized with emphasis on meeting following DOE 2010 targets.

Approach

As part of the Hydrogen Storage Engineering Center of Excellence (HSECoE) team, the GM team is building system models for on-board hydrogen storage systems using metal hydrides and adsorbent materials, storage media structuring and enhancement studies, and building a cryo-adsorption vessel for validation of cryo-adsorption models.

**System Modeling:** Over the past year, we have concentrated our efforts on both metal hydride and adsorbent system simulation modeling. The system simulation models have been developed in a MATLAB/Simulink framework using lumped parameter representation for these systems. However, the lumped model development has been guided by estimation of necessary heat transfer parameters based on development of two-dimensional (2-D) models that include thermal transport and hydrogen absorption/adsorption kinetics. The HSECoE coordinating council decided to focus the Center efforts on sodium alanate and AX-21 as the representative metal hydride and adsorbent materials respectively. We have employed the system models for hydrogen discharge during the driving cycles and 2-D thermal transport and kinetic models for refueling the hydrogen storage system.

**Storage Media Structuring and Enhancement:**
To enable fast refueling, it is extremely important to employ storage media with good thermal transport properties in conjunction with an optimized heat exchanger system to remove the heat generated by the exothermic process of hydrogen uptake. For metal hydrides, another challenge is the fracture of storage media during cycling. Fracturing decreases the heat...
transfer and enables the increasingly smaller particles to move in the containment vessel and collect at the bottom of the tank with an adverse impact on the system performance. In addition to the potential fracturing of the hydrides, volumetric expansion during hydriding needs to be addressed. One major objective of this project is to develop, test, and optimize metal hydride composites in the form of pellets or other similar shapes to greatly enhance thermal conductivity of the storage material, and to improve cycling stability and durability of the metal hydride materials. Similarly for adsorbent materials, forming mechanically stable composite pellets out of a powderous material is very useful. Pellets or similar-shaped composites of the adsorbent material will be formed using small amounts of binders in combination with thermal enhancing materials. As with metal hydrides, the main objective is to improve thermal conductivity of the storage material and to improve cycling stability and durability of adsorbent materials.

Accomplishments

1. System Modeling of Metal Hydride Systems

   We have developed system simulation models for two metal hydrides - Ti\textsubscript{1.1}CrMn and NaAlH\textsubscript{4}.

   On-board hydrogen storage systems employing high-pressure metal hydrides like TiCrMn promise advantages including high volumetric capacities and cold-start capability. We have developed a simulation model for this system in a MATLAB/Simulink platform. Transient equations for mass balance and energy balance are used and appropriate kinetic expressions are used for the absorption/desorption reactions for the Ti1.1CrMn metal hydride. During refueling, the bed is cooled by passing a coolant through tubes embedded within the bed while during driving, the bed is heated by pumping the radiator fluid through the same set of tubes. The feasibility of using a high-pressure metal hydride storage system for automotive applications is explored. Drive cycle simulations for a fuel cell vehicle are performed and detailed results are presented. A paper discussing this work has been prepared and accepted for publication in the Int. J. Hydrogen Energy (2010).

   The system simulation model for NaAlH\textsubscript{4} is more complicated and employs additional elements. Because of the high enthalpy of hydrogen absorption and desorption, this system requires burning part of the stored hydrogen to heat up the bed for hydrogen desorption. Thus a catalytic heater that burns hydrogen and heats a warming fluid is a necessary part of the NaAlH\textsubscript{4} system. In addition, a buffer volume storing gaseous hydrogen is needed for periods when the bed is unable to meet the fuel cell demand. This occurs when the bed is cold or contains only hex-phase (Na\textsubscript{3}AlH\textsubscript{6}) which has slow hydrogen desorption kinetics. Figure 1 shows a schematic of the sodium alanate-based hydrogen storage system. System simulation results for the US06 drive cycle are shown in Figure 3.

2. System Modeling of Adsorbent System

   A system model for a cryo-adsorber tank employing the activated carbon AX-21 has also been developed. We have selected the lumped parameter model developed earlier at General Motors to develop system simulation models for the processes in the cryo-adsorber tank. A system simulation schematic for the discharge cycle of a cryo-adsorption system is shown in Figure 2. Hydrogen is discharged from the cryo-adsorber tank using pressure and temperature control. It is necessary to both raise the tank temperature and reduce pressure to desorb and use most of the hydrogen stored in the tank. Temperature of the system is increased by supplying heat either through an electric heater or through a heated sidestream of hydrogen. System simulations for the US06 drive cycle for the case of a constant heat input are shown in Figure 4.

   A preliminary evaluation of the system performance for both sodium alanate and AX-21 systems in relation to the DOE performance targets is shown in Table 1.

3. Storage Media Structuring and Enhancement

   Sodium alanate pellets were prepared using a die and pressures up to 50,000 psi. Use of a binder is not necessary for formation of the alanate pellets. We have studied the hydrogen uptake, thermal conductivity as well as kinetics of sodium alanate pellets of various sizes. Some of the results on hydrogen uptake by the pellets and loose powder are shown in Figures 5. We are also working with AX-21 activated carbon as the adsorbent material for media structuring studies. Results were presented at the 2010 DOE AMR Meeting in Washington, D.C.
Future Directions

- Explore the sensitivity of system performance for the cryo-adsorbent system to various storage pressures.
- Compare the impact of cold-hydrogen and liquid hydrogen refueling on cryo-adsorbent system performance.
- Conduct simulation studies for both the refueling and discharge cycles a new metal hydride system.
- Optimize binders for pelletizing activated carbon and metal hydride materials with respect to engineering properties of interest for hydrogen storage.

Objectives

This project will address three of the key technical obstacles associated with development of a viable hydrogen storage system for automobile applications:

- (Task 1) Create accurate system models that account for realistic interactions between the fuel system and the vehicle powerplant.
- (Task 2) Develop robust cost projections for various hydrogen storage system configurations.
- (Task 3) Assess and optimize the effective engineering properties of framework-based hydrogen storage media (such as metal-organic frameworks).

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (B) System Costs
- (C) Efficiency
- (D) Durability/Operability

Technical Targets

This project is conducting vehicle and system level modeling, cost analysis, and materials property assessment/optimization. Insights gained from these studies will be applied towards the engineering of hydrogen storage systems that meet the following DOE 2010 hydrogen storage targets. We will address the following technical targets from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- Specific energy: 1.5 kWh/kg
- Energy density: 0.9 kWh/L
- Durability (cycle life): 1,000 cycles
- Durability (min. delivery pressure from storage system): 5 bar
- Efficiency (well-to-powerplant): 60%

Accomplishments

Below is a list of accomplishments by-task:

- Task 1. Vehicle Parameter Modeling
  - Determined MATLAB/Simulink as the common platform for building fuel cell and storage system simulation models.
  - Provided key vehicle characteristics parameters to develop the next level of the hydrogen storage simulation model.
  - Initial model and analysis of fuel cell waste heat for initial assessment of target enthalpy.
  - Identified universal modeling framework and interaction assumptions between vehicle, powerplant, and hydrogen storage system models.
  - Evaluated and constructed baseline fuel cell model to support the interaction with the vehicle and hydrogen storage system model.

- Task 2. Manufacturing Cost Modeling
  - Established initial phase of the cost analysis through the pursuit of high level equivalent system studies for the development of a hydrogen storage component cost matrix.
- Supported the manufacturing and cost analysis technology team in the evaluation of the initial cost assessments for the hydrogen storage systems.
- Developed the approach using the cost matrix to decompose the key cost drivers for establishing cost sensitivity and trade-offs.

• Task 3. Assessment of Framework-Based Hydrogen Storage Media
- Completed property screening (e.g., hydrogen capacity, surface area, and pore volume) of five prominent framework powders: MOF-5, MOF-177, IRMOF-8, ZIF-8, HKUST-1.
- Collected and compiled all requisite materials engineering data for Basolite Z-100H, the semi-commercial version of MOF-5 synthesized by BASF. These include: Dubinin-Astakov (D-A) isotherm parameters, thermal properties (e.g., thermal conductivity, heat capacity, etc.), and bulk properties (e.g., bulk density, specific surface area, etc.).
- Designed two preliminary sub-scale hydrogen storage modules to be used for framework material assessment and validation of optimized framework concepts.
- Developed an understanding of, and developed a new measurement protocol which minimizes temperature variation during hydrogen storage experiments at cryogenic temperatures. This allows for more reliable hydrogen capacity measurements and, as a consequence, improved parameterization of adsorption models from experimental data.

Introduction

Widespread adoption of hydrogen as a vehicular fuel depends critically on the development of low-cost, on-board hydrogen storage technologies capable of achieving high energy densities and fast kinetics for hydrogen uptake and release. As present-day technologies -- which rely on physical storage methods such as pressurization or liquefaction -- are unlikely to attain established DOE targets, interest in materials-based approaches for storing hydrogen have garnered increasing attention. To hasten development of these ‘hydride’ materials, the DOE has established three Centers of Excellence for materials-based hydrogen storage research as part of a “Grand Challenge” to the scientific community. While the Centers have made substantial progress in developing new storage materials, significant challenges associated with the engineering of the storage system around a candidate storage material remain largely unresolved.

Approach

As a partner in the Hydrogen Storage Engineering Center of Excellence (HSECoE), Ford is conducting a multi-faceted research project that addresses three of the key engineering challenges associated with the development of materials-based hydrogen storage systems.

First (Task 1), drawing on our extensive expertise in the engineering of fuel cell (FC) and H₂-internal combustion engine (ICE) vehicles, we are evaluating and developing system engineering technical elements with a focus on hydrogen storage system operating parameters. This effort will result in a set of dynamic operating parameters and a high-level system model describing the interaction of the fuel storage system with the FC (or H₂-ICE) power plant.

Second (Task 2), we are leveraging the unique capabilities of the “Ford/MIT cost model” to develop and perform hydrogen storage manufacturing cost analyses for various candidate system configurations and operating strategies. This analysis will facilitate a technology roadmap for potential cost reductions and manufacturing optimization, while providing important feedback to Go/No-Go decisions on prototype design and construction.

Third (Task 3), we are evaluating and optimizing the “effective engineering properties” of an important class of sorbent materials (metal organic frameworks [MOFs] and other framework-like materials) in order to devise improved packing and processing strategies for their use in a systems context. Various mechanical processing routes are being examined (ranging from powders to pelletization to extrusion) in an effort to simultaneously maximize packing density, heat and mass transfer, and hydrogen uptake characteristics.

This work is expected to impact the broader goals for the DOE and FreedomCAR, leading to a significant advance in the engineering of materials-based hydrogen storage systems, refinement in our understanding of the performance targets of hydride materials, and ultimately, the development of commercially-viable hydrogen storage systems.

Results

Below is a description of our technical results for each task and how these results relate to achieving the DOE targets.

Task 1. Vehicle Parameter Modeling

The Integrated Power Plant/Storage System Modeling Technology Area modeling approach focused on a MATLAB/Simulink platform with a common structure to assist in the exchangeability and interaction
of models within the Center. A modeling interface matrix was further refined and utilized in constructing the top-level HSECoE Simulink model structure (Figure 1).

In support of the HSECoE modeling structure, a fuel cell model was developed to provide the linkage between the vehicle model and hydrogen storage model. The fuel cell model as indicated by the interface matrix for the translation of the vehicle power demand to the hydrogen storage flow requirement. It is also needed to characterize the waste heat available for the hydrogen storage system to avoid the need for external heating devices. The original FC model in the Hydrogen Storage SIMulator (HSSIM) vehicle model was based on a simple polarization curve from Kartha and Grimes in *Fuel Cells: Energy Conversion For The Next Century*, Physics Today (1994). The desire of the team was to refine the FC model to allow for ambient temperature effects and potentially pressure effects. Therefore, a search was conducted to assess available fuel cell models to be utilized in the Simulink framework. The FC performance equations developed by Stefanopoulou (et al. 2004) in *Control-oriented modeling and analysis for automotive fuel cell systems* had the desired thermal term and appeared appropriate for the initial phase of the model.

**Task 2. Manufacturing Cost Modeling**

The hydrogen storage manufacturing cost analysis is included in the Performance Analysis workstream. In particular, the Manufacturing and Cost Analysis Technology Team is being lead by M. Weimar from the Pacific Northwest National Laboratory. A benchmark study was conducted to assess hydrogen storage cost analysis approaches and progress a tool for decomposing the hydrogen storage system into critical elements. The cost modeling effort has evaluated the assumptions of the HSSIM vehicle modeling and approaches to integrate the cost analysis with the performance modeling, which result in consumer preferences based on both performance and cost. The integration assessment allows the HSECoE team to trade-off vehicle architectures (i.e. hybridization levels) and parameters to optimize the hydrogen storage characteristics.

The initial phase of the cost analysis was established through the pursuit of high-level equivalent system studies that support the development of a hydrogen storage component cost matrix. The draft and the approach of the component cost matrix were presented to the HSECoE partners that reinforced the need for the matrix to serve as a foundation for the system architects. The matrix would include the functions to scale the appropriate components. The team developed the cost strategy to provide the matrix of components and then to decompose the key cost drivers to establish cost sensitivity and trade-offs for the system architects.

**Task 3. Assessment of Framework-Based Hydrogen Storage Media**

As a first step we assessed several key properties a series of benchmark framework materials. This was conducted via a brief property screening study, wherein the hydrogen capacity, surface area, and pore volume data for the following powders were measured in our laboratory using a cryogenic Sievert’s apparatus. The compounds studied included: Basolite Z100H (MOF-5), Basolite Z377 (MOF-177), Basolite Z200 (IRMOF-8), Basolite Z1200 (ZIF-8), Basolite C300 (HKUST-1).

---

**FIGURE 1.** HSECoE High-Level Universal Simulink Model Structure and Interfaces
The data from these measurements are summarized in Figure 2.

The objective for this phase of our work is to gather existing literature data, and, as appropriate, collect new physical, thermal, and isotherm data to facilitate creation of a materials property “data set.” The contents of the data set are important as they serve as inputs for the HSECoE’s modeling activities. The three primary categories of the data set for an adsorbent material include: Dubinin-Astakov isotherm parameters, thermal properties (e.g., thermal conductivity, heat capacity, etc.), and bulk properties (e.g., bulk density, specific surface area, particle diameter, etc.). Subsequently, MOF-5 was selected by the Center as an initial framework material of interest and thus a complete set of its fundamental and engineering material properties is required. Our experiments were conducted using the semi-commercial form of MOF-5 (Basolite Z100H), synthesized by BASF.

Generation of the Dubinin-Astakov parameters for Basolite Z-100H requires collection of isotherms at several different temperatures (e.g., between -196°C and room temperature). Modification of Ford’s existing sorption instrument (Sievert’s apparatus) to include variable-temperature cryogenic capability was necessary. Upon instrument validation, isotherm data for Basolite Z-100H was collected at five different temperatures, -196°, -190°, -178°, -167°, and -151°C, toward determination of the desired Dubinin-Astakov parameters which fully describe an isotherm and can be used for material modeling. These data are shown in Figure 3 as the filled data points.

A modified version of the Dubinin-Astakov equation (Equation 1) [1], was subsequently used as the model for a non-linear regression analysis on the corrected empirical data.

$$n_{ex} = n_{max} \exp\left[\frac{RT}{\alpha + \beta T}\right] \frac{\rho g}{P} - \rho g V_a$$ \hspace{1cm} (1)

In particular, the empirical data from all five isotherms was simultaneously fit to the above model using five fitted parameters from Equation 1: $n_{max}$ (max. uptake), $\alpha$ (enthalpic factor), $\beta$ (entropic factor), $\rho_g$ (gas phase density), and $V_a$ (adsorbed volume). The values for these parameters, which result in a minimization of the error between model and observed data, are given in Table 1.

Based on these values, the standard error between model and experimental data is 0.46 mol/kg or 0.094 wt%. The residual squared value is 0.998. Using these parameters enables one to determine excess uptake at a variety of temperatures and pressures of interest. Additionally, absolute (or total) uptake and heat...
of adsorption behavior can also be calculated. For example, based on the Basolite Z-100H parameters in Table 1 an absolute uptake of approximately 10 wt% is projected at 70 bar and -196°C. This finalized thermal, bulk property, and Dubinin-Astakov data for powder Basolite Z100H were submitted and distributed to the HSECoE. This established process of compiling and generating all relevant data (i.e. “data set”) for a given framework will be extended to future frameworks of interest as well as extension to compacted/processed forms of a given framework of interest.

Lastly, we have initiated and completed the design work for two preliminary hydrogen storage modules which are necessary for anticipated Phase II framework materials testing. The requirements and specifications for both designs were formulated based on a variety of criteria including von Mises yield stresses at the operating temperatures and pressures, material compatibilities, heat transfer, safety, and data acquisition.

Conclusions and Future Directions

- Task 1. Vehicle Parameter Modeling
  - Complete the integration of the FC stack waste heat model and enhance the FC polarization model at sub-zero temperatures with validation of empirical data.
  - Determine the appropriate integration of static parameters (i.e. cost, weight, volume) within the dynamic performance modeling framework.
  - Support the development of the vehicle and storage system modeling, including the implementation of the waste heat interaction, refinement of the weighting coefficients for the viability index, and confirming the vehicle characteristics parameters for current and projected future levels.

- Task 2. Manufacturing Cost Modeling
  - Support the completion of the hydrogen storage system component cost matrix for the system architects to use as a common reference.
  - Evaluate the key components in order to establish their cost functions in relation to the performance model variables.
  - Decompose the key components into their direct and indirect cost elements for the purpose of assessing cost drivers and opportunities.

- Task 3. Framework-Based Hydrogen Storage Media Properties
  - Continue to monitor and experimentally screen the properties of existing and newly discovered powder framework materials which show promise for hydrogen storage.
  - Pursue detailed densification studies of Basolite Z100H (and other framework materials as appropriate) which includes investigation of the impact of the following processing parameters on the resulting hydrogen storage properties: binder (and/or lubricant), compaction conditions, pellet and particle size, ancillary additives.
  - Continue development of lab-scale testing module including the assembly of the test-bench and data acquisition system.

Subcontractor:
Université du Québec à Trois-Rivières (UQTR),
Quebec, Canada

Start Date:  February 1, 2009
Projected End Date: July 31, 2014

Objectives

SRNL and UQTR will:

- Compile property data for sodium aluminum hydride (NaAlH₄), a metal hydride, and AX-21, an adsorbent.
- Collect property data for other select metal hydrides and adsorbents.
  - Compile list of available analytical techniques to support materials property data requirements.
- Develop acceptability envelope for storage media and vessels.
- Develop numerical models to adequately predict storage system behavior for NaAlH₄ and AX-21 based storage systems.
  - Use the models to design optimized storage systems based on NaAlH₄, other metal hydrides, AX-21, and other potential absorbent materials.
- Develop practical and efficient enabling technologies in the areas of hydrogen purification and demonstrate material compatibility for various systems and components for adsorbent and metal hydride storage materials.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section (3.3) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(C) Efficiency
(E) Charging/Discharging Rate

Technical Targets

The goal of the entire Hydrogen Storage Engineering Center of Excellence (HSECoE) is to provide a system model for each material sub-class (metal hydrides, adsorption, chemical storage) which meets the “Technical System Targets: On-Board Hydrogen Storage for Light-Duty Vehicles”, Table 3.3.2 in the DOE Multi-Year Research and Development Plan – April 2009. The end of Phase I, Go/No-Go milestone for the entire HSECoE project states that:

1. Four of the DOE 2010 numerical system storage targets are fully met and that,
2. The status of the remaining numerical targets must be at least 40% of the target or higher.

For SRNL’s specific technical portion of the HSECoE, SRNL will:

- Compile thermochemical data.
- Bound media operating characteristics for metal and adsorption hydride material.
- Develop and apply numerical models that couple mass, momentum and energy balances with chemical kinetics and/or isotherms to simulate hydrogen uptake and discharge.
- Identify technology gaps.
- Identify preliminary system designs to achieve DOE 2015 hydrogen storage goals.

Accomplishments

- Metal hydride modeling accomplishments:
  - Developed and validated baseline models for metal hydride storage systems.
  - Incorporated improved models into optimization routines.
  - Identified principal issues for design of metal hydride-based storage systems.
  - Began investigating novel concepts/system designs.
- Adsorbent modeling accomplishments:
  - Developed and validated baseline models.
Developed an adsorbent unit cell model in Comsol® for optimization.
- Began investigating novel concepts/system designs.

• Acceptability envelope accomplishments:
  - Model developed for metal hydrides.

• Material operating requirements: metal hydrides:
  - Selected NaAlH₄ as initial baseline hydride candidate material for transport phenomena and system modeling development,
  - Databases completed for: NaAlH₄ (with and without catalysts), 2:1 LiNH₂:MgH₂, MgH₂ (without catalysts), TiCrMn, Mg₂Ni.

• System architect analyses: metal hydride:
  - Completed system architect analysis of NaAlH₄ vs. DOE 2010 technical hydrogen storage targets.

Introduction

SRNL and UQTR are involved in several critical aspects of the HSECoE. SRNL is focused primarily modeling, validating, and optimizing hydrogen storage designs for metal hydrides, adsorbents, and, to a lesser extent, chemical hydrides, and system architect analyses of metal hydride systems. SRNL is applying its expertise in modeling dynamic transport phenomena and chemical processes, materials testing, and system modeling to accomplish its objectives in the proposed effort—developing and applying models to identify viable subscale prototype designs, performing design calculations sufficiently accurate for engineering application, and defining the scope and required measurements for experiments with the selected prototypes.

UQTR is developing the governing equations for an adsorbent system that be easily and efficiently implemented by SRNL into a model to accurately predict the adsorption characteristics over a range of temperatures. UQTR is extending its current equations for hydrogen adsorption on activated carbons to any adsorbent used in the storage system design.

Relevance

The ultimate goals of the HSECoE are the design and testing of prototype hydrogen storage vessels, the interpretation of test data, and the implementation for full-scale vessels. Within the HSECoE, the Transport Phenomena Technology area is responsible for the development and application of analyses for storage systems that are necessary to identify and design prototype media and vessel configurations having the best performance relative to the DOE technical targets. Storage vessel models developed by this technology area will be essential to interpret data obtained from prototype testing and to relate it to full-scale systems.

Approach

In Phase I, SRNL and UQTR will:

• Evaluate, interpret, and assimilate data for media and vessel components.
• Develop and apply an “Acceptability Envelope” based on DOE targets.
• Develop, validate and test general models for scoping and detailed evaluation of storage system designs.
• Obtain material operating requirements for metal hydride and AX-21 materials.
• Perform system architect analysis on candidate metal hydride systems for Phase I Go/No-Go decision.

Results

SRNL and UQTR to date have met and or exceeded their Phase I objectives for all of their major technical areas for the HSECoE. These major technical areas include: transport phenomena, material operating requirements and system architecture. Transport phenomena results are shown below and are divided into metal hydride and adsorbent modeling as well as acceptability envelope development and applications. Results for activities under material operating requirements and system architecture are shown for metal hydrides systems.

Transport Phenomena

Metal Hydride modeling accomplishments:

• Developed and validated baseline models for metal hydride storage systems
  - 0-dimensional kinetics models in MathCad® (Figure 1)
  - 1-, 2-, and 3-dimensional models in Comsol®
    - Consolidated all models into Comsol®
• Incorporated improved models into optimization routines
  - Used Nelder-Mead (Downhill Simplex) optimization scheme
    - With given constraints, optimal designs require very small spacing of heat transfer surfaces
Methods can be easily extended to new metal hydride systems
- New hydrides, such as 2:1 and 1:1 LiNH$_2$-MgH$_2$
- New catalysts for existing hydrides
- New tank designs
- Adsorbent systems

- Identified principal issues for design of metal hydride-based storage systems
  - Variations in powder composition and catalyst materials
  - Large impact on the charging and discharging kinetics
  - Large impact on capacity
  - Substantial increase (x50) in NaAlH$_4$ kinetics required to meet 2010 DOE targets for refueling time
    - Heat removal becomes an issue for $\Delta H$ associated with most metal hydrides
  - Short refueling times (e.g., 4.2 min vs. 15 min) for the current NaAlH$_4$ kinetics impact
    - System gravimetric capacities
    - System volumetric capacities

- Began investigating novel concepts/system designs (Figure 2)

Adorsbent modeling accomplishments:
- Model development and validation
  - Numerical models within Comsol®
  - Model validation against experimental data for MaxSorb® (Figure 3)
- Developed baseline scoping models for an adsorbent unit cell in Comsol®

**FIGURE 1.** Fill times calculated from the 0-dimensional Mathcad Kinetics Model for NaAlH$_4$ based on the UTRC Prototype 2 Kinetics.

**FIGURE 2.** Novel concepts for tank designs, such as (a) longitudinal fins or (b) a metallic honeycomb structure.
Began investigating novel concepts/system designs

Acceptability envelope accomplishments (Figure 4):
- Model developed for metal hydrides
  - Based on energy balance
  - Constraints are from DOE technical targets

Model should be used in conjunction with media kinetics
- Can be used to identify range of media and component parameters required to meet operational targets

Application
- Has been applied to NaAlH$_4$ and other metal hydrides

Material Operating Requirements: Metal Hydrides
- Selected NaAlH$_4$ material as initial baseline hydride candidate material for transport phenomena and system modeling development
- Databases completed for:
  - NaAlH$_4$ (with and without catalysts)
  - 2:1 LiNH$_2$:MgH$_2$
  - MgH$_2$ (without catalysts)
  - TiCrMn
  - Mg$_2$Ni

System Architect Analyses: Metal Hydride
- Completed system architect analysis of NaAlH$_4$ vs. DOE 2010 technical hydrogen storage targets
- Completed preliminary analysis on other potential metal hydride candidates (Mg, Mg$_2$Ni, 2:1 LiNH$_2$:MgH$_2$, and 1:1 LiNH$_2$:MgH$_2$)

FIGURE 4. Basic Equation and Concept for the Acceptability Envelope
Conclusions and Future Directions

Proposed future work for metal hydrides:

- All future work will be dependent upon the results from the acceptability envelope
- More detailed models, as needed
  - Consider mass transfer limitations
  - Include hydrogen stored in gas phase
  - Include cooling at tank wall/surface
  - Identify minimum coolant tube thickness
    - Dependent on operating pressure and tube internal diameter
  - Use convection heat transfer coefficient in coolant tubes dependent on internal diameter and coolant flow rate
  - Include pressure vessel mass
    - Important for hydride (high pressure) storage
  - Incorporate limits based on manufacturability constraints
- Model additional metal hydrides suggested by System Architect and Acceptability Envelope calculations
- Evaluate novel concepts and other unique configurations
  - Longitudinal fins
  - Metal honeycomb structures (UQTR)
    - Cell size
    - Addition of cooling channels
  - Hybrid systems – Combination of high pressure tanks and metal hydrides
- For likely viable systems, convert models to form suitable for Simulink system models

Proposed future work for adsorbents:

- Conduct validation experiments that reduce parasitic heat transfer
  - Use N₂ at temperatures closer to ambient
- Compare performance of MOF-5® and MaxSorb®
- Use baseline models in two and three dimensions for design and sensitivity studies
  - Vessel design
  - Structured media
  - Novel concepts

Proposed future work for the acceptability envelope:

- Include balance of plant contributions
  - Mass and volume of storage vessels, fins, tubes, and other structures and fittings
- Complete the application to metal hydrides
  - Include coupled parameter ranges
  - Evaluate candidate metal hydrides (2:1 and 1:1 LiNH₂-MgH₂)
- Develop and apply model for adsorbents

Proposed future work material operating requirements:

- Complete databases for 1:1 LiNH₂-MgH₂ material with and without catalysts
- Determine needed engineering properties for all up selected materials

Proposed future work metal hydride system architect analysis:

- Extend system architect analysis from sodium alanate to other metal hydride systems
- Complete system architect analysis on metal hydride candidate systems for Phase I Go/No-Go Decision

FY 2010 Publications/Presentations

IV.D.1i Key Technologies, Thermal Management, and Prototype Testing for Advanced Solid-State Hydrogen Storage Systems

Objectives

- Develop and apply an understanding of storage system requirements for light-duty vehicles.
- Develop innovative on-board system concepts for materials-based storage technologies.
- Develop and test innovative concepts for storage subsystems and component designs.
- Develop multi-level engineering models to address storage subsystem and fuel cycle.
- Design, fabricate, and test subscale prototypes for each material-based technology.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (referenced to 2015 targets, as revised 2009):

(A) System Weight and Volume: 5.5 % wt$_{sys}$, 55 g H$_2$/kg$_{sys}$, 40 g H$_2$/L$_{sys}$

(C) Efficiency: 90% on-board/60% off-board

(D) Durability/Operability: <1% degradation @ 1,500 cycles, etc.

(G) Materials of Construction

(H) Balance-of-Plant Components

(I) Dispensing Technology

(J) Thermal Management

Technical Targets

Regarding the technical barriers addressed by JPL's activities within the Hydrogen Storage Engineering Center of Excellence (HSECoe), the main areas that would be the focus of technical efforts would be the nature of Thermal Management, Balance-of-Plant components, and Durability/Operability; the last of these will be evaluated directly by a phased effort of testing and analysis at JPL.

Accomplishments

The efforts at JPL during the previous year have centered on a technology development role in the Enabling Technologies area of the Center, specifically the identification, analysis, and characterization of thermal insulating materials for hydrogen storage systems. This effort will extend into Fiscal Year (FY) 2011, featuring the testing of thermal materials in order to inform the modeling/validation effort ongoing within the Center.

JPL has also taken on the role of System Architect for Adsorbent System technology development. In this role, JPL provides oversight and coordination of the various technology areas within the Center that have responsibility for developing credible paths toward satisfying the DOE hydrogen storage targets (2010/2015/ultimate). JPL will also have direct responsibility for a notional “system engineering” role, providing guidance and oversight for conceptual system design.

Specific Accomplishments:

- Initial “insulative materials” database has been developed and deployed within the Center; database contains thermal performance parameters, mass, volume, and cost where possible. Candidate materials continue to be added as they are identified, or as potential vendors/technologies are found.
- Preliminary plans for a low-k material thermal characterization facility are complete; this facility will be used to fully characterize candidate insulative materials across a large temperature range; the potential also exists for this facility to be...
used to analyze the thermal characteristics of bulk hydrogen storage materials, especially cryosorbents. The facility will be hosted in JPL’s Hydrogen Storage Engineering Laboratory.

- **JPL hosted the Center’s Face-to-Face Meeting 4 in Pasadena, CA (March, 2010).** This meeting solidified the System Architect roles and reviewed the first calendar year of Center activity (start date February, 2009). Crucial teaming activities were accomplished between JPL and other Center partners; first high-level system designs shown and preliminary performance numbers reviewed.

Introduction

Activities at JPL under the auspices of DOE’s HSECoE have been designed to contribute to the development of advanced automotive solid-state hydrogen storage systems that meet or exceed the DOE/FreedomCAR technical targets for on-board hydrogen storage. JPL performs in several different roles in the Center; the present effort at JPL is divided into several tasks:

- **Advanced Technology Development.** JPL has a lead role in the Center as a technology area lead in the area of “Enabling Technologies”. This role encompasses the coordination of other partners in the development of technologies for novel thermal devices, fuel sensors, pressure vessels, and gas purity and separation. In addition, JPL has a direct charge under this task of evaluating and developing technologies for passive thermal management for the hydrogen storage system, in both cryogenic and elevated temperature regimes. This role will extend through the entirety of the Center’s duration, and involves collaborations with a majority of the Center’s partners and a responsibility at the center coordinating council level.

- **System Architect/System Engineer.** JPL provides technical guidance and engineering oversight to the Adsorbent System design team in its Center role as System Architect/System Engineer. Additionally, and in coordination with the Center’s conceptual design effort, JPL will provide assistance with overall system design, component selection, and design review for the adsorbent system, especially as it applies to cryogenic system design and operation.

- **Material/Media Evaluation.** JPL is contributing to the evaluation of the engineering properties of candidate hydrogen storage materials. A subcontract with Caltech allows assistance with evaluation of hydrogen sorption materials (cryosorbents).

- **Thermal Modeling & Validation.** JPL will provide modeling support to the Center via parametric and other types of analysis for hydrogen storage systems. This effort includes thermal/thermodynamic/performance modeling of cryogenic storage vessels and associated hardware, both specific to and independent of storage material type. This task is integrated into the overall Center modeling effort. JPL will collaborate with partners Savannah River National Laboratory (SRNL) and United Technologies Research Center (UTRC). This task may involve validation of model results via bench-top testing of novel designs and configurations.

- **Prototype Concept Engineering.** During the development of the prototype storage system(s) for the various material storage concepts, JPL will provide engineering expertise and oversight in various areas, including but not limited to mechanical design, thermal efficiency, system engineering, control and data acquisition, and materials compatibility. This task will be led by Center partner Los Alamos National Laboratory (LANL).

- **Prototype Testing and Evaluation.** JPL will be responsible for the design, construction, and operation of the test stand used for evaluating the subscale prototype storage system based on metal hydride materials, as well as for the final assembly of the prototype itself. JPL will also acquire, reduce, and analyze the data from the prototype and prepare summary reports. This task is the largest portion of JPL’s contribution to the Center, and will be led by LANL.

Via the task breakdown summarized here, JPL will mix management and direct engineering in a three-phase project of roughly 1.5 years per phase. Much of this effort is being accomplished in an “emergent” manner, allowing for changes to scope, approach, and technology basis. The Center’s technology area lead structure is designed to account for this type of operation.

Approach

Within the HSECoE, JPL’s participation covers a wide variety of tasks and activities, spanning technology management and active research and development. In the latter case, JPL relies on in-house expertise in the areas of thermal engineering, cryogenic system design, systems engineering, and hydrogen storage system testing and evaluation. The overall approach involves well-organized and managed communication pathways and closed loops among the other Center partners collaborating with JPL as well as with the Center lead at SRNL. This management approach is built around the technology area concept, wherein key Center partners
IV.D Hydrogen Storage / Hydrogen Storage Engineering CoE

Reiter – Jet Propulsion Laboratory

including JPL – are responsible for sub-management and direction of agile technical teams, each charged with a particular task in the engineering scope. Within this structure, JPL is responsible – via its own work as well as the work of the partner organizations managed within the “Enabling Technologies” technology area – for shepherding the development of key technologies considered necessary for the design and operation of a successful hydrogen storage system.

The Center has also developed the System Architect model for managing the development and configuration of individual storage system designs; as such, there are three Center partners responsible for the guidance and oversight of the design teams assigned to the metal hydride design, the cryo-adsorbent design, and the chemical hydride design, respectively. JPL is the Center partner responsible for the adsorbent system overall design and architecture. The System Architect relationship to the Center is as a matrix organization, utilizing the analytical products of the technology areas in order to reach a system design that credibly satisfies the appropriate DOE Hydrogen Storage targets. This relationship is illustrated schematically in Figure 1.

HSECoE is a widespread effort technically, geographically, and with regard to expertise. JPL maintains a central cognizance within the Center by virtue of its status as an System Architect and technology area lead, working closely with Center partners SRNL, LANL, Pacific Northwest National Laboratory, and UTRC, as well as with Oregon State University, General Motors, Ford, and, via subcontract, Caltech.

Results

Key results of the work during the reporting period are summarized as follows:

- Insulative materials literature/vendor search has resulted in the categorization of potential materials by temperature range (elevated, ambient, and cryogenic) and material type (rigid, blanket, loose-fill). Such materials are considered “physical” or “bulk” insulation, typified by low thermal conductivity and (occasionally) low density. Considering as an example a design for storing a cryogenic (77 K) material, performance of these insulators would be compared to the “standard” approach of using multi-layer vacuum insulation, with regard to cost, mass, and volume. A first-step algorithm for measuring performance in this way has been developed.
  - Key material parameters for solid-aerogel insulation has been obtained internally from JPL where this material is manufactured. These parameters have been included in initial scoping models of tank/storage vessel thermal performance, but data are required for radiative transmissivity and temperature-dependent thermal conductivity data. The means to acquire this information for aerogel and other insulative materials is being developed at JPL in the form of a novel test facility.

Conclusions and Future Directions

The overall HSECoE effort will be continuing through early 2014. At the time of this writing, Center efforts are focused on the near-term goal of demonstrating the performance of several conceptual systems against the 2010 DOE Storage targets; a Center-wide milestone for this achievement is set for the end of the second quarter of FY 2011. With this in mind, there are several broad areas in which JPL plans specific accomplishments:

- Additional physical/bulk insulative materials will be added into the Insulative Materials Database, which continues to be available internally to the Center. It is planned that the database, along with analytical tools, results, and general metrics, will be made publicly available at some point in the future.

- The low-k material thermal characterization facility will be brought on-line and used to validate literature values for several candidate materials in the database. In addition, the facility will allow JPL to acquire temperature-dependent data for these materials, which in many cases is not otherwise available elsewhere. The facility will also be used to directly validate the thermal material properties of storage materials; superactivated carbon and certain candidate metal-organic frameworks are good examples of such materials. Figure 2 shows the current status of the hardware being assembled for this effort.

- Initial scoping models for determining thermal performance of the storage vessel will be integrated into the Center model framework. The models will address issues for cryogenic vessels such as low-temperature dormancy, parasitic heat loads, and passive thermal design approaches. These models will initially be designed for the cryo-adsorbent

[Figure 1: Graphic representation of the System Architect concept, showing the flow-down and cross-reporting paths as well as hierarchical responsibilities within the Center. This concept maintains the goal of aligning notional system design concepts with the overall storage targets as set by DOE.]
system, but will be extensible for the metal hydride and chemical hydride systems as well. Parametric data from the insulative materials search/analysis will feed directly into this effort.

FIGURE 2. In-process photo of the hardware being assembled for the low-k material thermal characterization facility being developed for testing/validation of both insulative materials and low-temperature storage materials. The facility will be a JPL/Center asset capable, for example, of obtaining temperature-dependent data from low-conductivity materials.

Project Start Date: February 1, 2009
Project End Date: January 31, 2014

Objectives

Use microchannel techniques 1) to demonstrate reduction in storage system size and weight, 2) for improvement of charge and discharge rates, and 3) to reduce size and weight and increase performance of thermal balance of plant components.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(E) Charging/Discharging Rates
(H) Balance of Plant (BOP) Components

Technical Targets

This project focuses on optimization of the performance characteristics and reduction in the size, weight, and cost of metal hydride and adsorption hydrogen storage systems. We will achieve these goals through careful design of thermal integration to efficiently harness “waste heat”, and by applying microscale techniques to enhance heat and mass transfer. More efficient heat transfer through microscale combustors, heat exchangers and recuperators allows for substantial reductions in the size and weight of balance-of-plant components. Microchannel-based hydrogen storage systems offer enhanced heat and mass transfer, possibly allowing more rapid charging and startup, quick response to changing driving conditions. In addition, the excellent heat transfer control achievable with microscale components allows for efficient removal of thermal energy generated during charging. These experimental and simulation studies are expected to guide the design of high-efficiency metal hydride and adsorption-based hydrogen storage systems toward meeting the following DOE 2010/2015 targets:

- System gravimetric capacity: 1.5/1.8 kWh/kg
- System volumetric capacity: 0.9/1.3 kWh/L
- Charging/discharging rates: 1.2/1.5 kg/min, 5–15 sec start time to full flow

Accomplishments

- Completed preliminary design of ~1 mm-thick microchannel-based tank insert plate for liquid-cooling and hydrogen distribution. A unit cell in the model in-tank system consists of two of these liquid-cooled distribution plates, separated by adsorbent or metal hydride. (Barriers A and E)
- Completed design and fabrication of a test apparatus that will be used to test the tank insert unit cell. (Barriers A and E)
- Completed simulation tool and a preliminary design of a microchannel combustor/heat exchanger to heat oil used to discharge hydrogen from storage. High-efficiency (>90%) microscale device integrates a flame-proof combustor, oil heat exchanger and thermal recuperator. (Barrier H)
- Completed simulation tools to support the experimental investigations of the tank insert and microchannel combustor/heat exchanger. (Barriers A, E and H)

Introduction

Hydrogen storage involves coupled heat and mass transfer processes that significantly impact the size,
weight, cost, and performance of system components. Micro-technology devices that contain channels of 10 to 500 microns characteristic length offer substantial heat and mass transfer enhancements, by greatly increasing the surface to volume ratio, and reducing the distance that heat or molecules must traverse. These enhancements often result in a reduction in the size of energy and chemical systems by a factor of 5 to 10 over the conventional designs, while attaining substantially higher heat and mass transfer efficiency. In cooperation with the OSU Microproducts Breakthrough Institute and groups at Pacific Northwest National Laboratory, Savannah River National Laboratory (SRNL) and Los Alamos National Laboratory, we are developing: 1) advanced tank inserts for enhanced and mass transfer during charge and discharge of metal hydride and adsorbent hydrogen storage systems; and 2) microchannel-based thermal balance of plant components such as combustors, heat exchangers and chemical reactors.

Approach

Our technical approach to meet the Phase I goals involves: 1) OSU will focus on simulation and experimental investigations to identify and prioritize opportunities for applying microscale heat and mass transfer enhancement techniques; 2) Working with other team members, OSU will identify the highest value applications and conduct experimental investigations and modeling to collect data necessary to support the Go/No-Go decision to proceed to Phase 2.

For each high priority component we plan to use microchannel technology to reduce the relevant barriers to heat and mass transfer. Our approach involves: 1) the optimization of the performance of a single unit cell (i.e. an individual microchannel) and then “number up” using appropriate simulation tools and which are validated by experimental investigations; and 2) developing microlamination methods as a path to “numbering up” by low-cost high-volume manufacturing.

Results

Relative to our Phase 1 technical targets, we identified two high value applications of microchannel technology. The first application is the development of a microchannel tank insert for cooling during charging, heating during discharging and hydrogen distribution. The tank insert can be used with either metal hydride or adsorbing material. The second application is the development of a microchannel combustor/heat exchanger that can be used for on-board oil heating during discharge of a metal hydride hydrogen storage system. Results relative to these two applications are summarized below.

Microchannel-Based Tank Insert - A tank insert that integrates storage media, microchannel heat exchangers and microchannel hydrogen distribution plates may provide improved charging of the storage system, rapid startup, and quicker response to changing driving conditions. Progress to date on the development of the microchannel-based tank insert includes:

- A test apparatus for a tank insert unit cell that includes the storage media, microchannel cooling and microchannel hydrogen distribution has been designed, and is being assembled. This system, expected to be operational in August 2010, will support experiments to determine the kinetics of adsorption and desorption of hydrogen on metal hydrides and carbon-based adsorbents, and also serve as a testbed for developing an optimized hydrogen storage unit cell.
- A microchannel unit cell for metal hydride and adsorbing materials has been designed and the integrated microchannel cooling and hydrogen distribution plates have been fabricated (Figure 1).
- Computational simulation of the unit cell is being performed in parallel with the physical experiments. A multi-phase flow simulation in FLUENT, incorporating full Navier-Stokes equations and sodium alanate reaction kinetics (provided by

![FIGURE 1. Schematic design of ~1 mm-thick high-efficiency microchannel-based storage tank insert, with integrated liquid-cooled heat exchanger (left), and H₂ distribution (right) systems.](image-url)
SRNL), was used to model hydrogen flow in the porous storage medium. The simulation was validated by comparison with published data [1]. The results indicate that particle size is a major factor, and that multi-phase flow components must be included in simulations dealing with small (<2 μm) particles. This and related computational models are also being used to simulate adsorption/desorption processes on single-particle and whole-bed scales, and further validation and optimization studies for the test bed integrated microscale unit cell are currently under way.

**Integrated Microscale Combustor/Heat Exchanger (μCHX)** - The microscale combustor/heat exchanger (μCHX, Figure 2) will be used to safely and efficiently produce heated oil, which is used to discharge hydrogen from the storage bed. Combining the combustion and heat exchanger systems, and the use of microchannels for enhanced heat and mass transfer can drastically reduce the size and weight required for this function, while simultaneously increasing efficiency. A substantial safety benefit of a microscale combustor is that flames cannot be sustained in the sub-millimeter microchannels. Progress to date on the development of the μCHX includes:

- A simulation of the μCHX has been completed, including a detailed model of the kinetics of the combustion reactions. The code has been used to predict the performance of the device and current results suggest the μCHX will be significantly smaller, lighter and more efficient than current compact combustion systems.
- A design of the test apparatus and a μCHX unit cell test article has been completed. Currently, we are assembling the test apparatus and having the μCHX unit cell test article fabricated.

**Conclusions and Future Directions**

- A FLUENT-based two-dimensional computational simulation of hydrogen desorption rates has been completed and used to model the desorption process. A 1 m long, 15 cm radius tank containing 75 kg of sodium alanate bed was modeled, using literature data and accounting for thermal effects on physical properties. The results suggest that two sources of thermal energy one located at each end of the tank, produces acceptable desorption (Figure 3).
- Complete the assembly of the tank insert unit cell test apparatus, assembly of unit cell test articles for metal hydride and adsorbing materials, and validate simulation models and unit cell performance.
- Develop a conceptual design and identify high volume, low cost fabrication approaches for the tank inset.
- Complete the assembly of the μCHX test apparatus and μCHX unit cell test article, and validate simulation model and unit cell performance.
- Provide support for other center partners on applications where microchannel technology can provide significant improvement over existing technology.

**References**

Objectives

- To improve the performance characteristics, including weight, volumetric efficiency, and cost, of composite pressure vessels used to contain hydrogen in media such as metal hydrides, chemical hydrides, or adsorbants.
- To evaluate design, materials, or manufacturing process improvements necessary for containing metal hydrides, chemical hydrides, or adsorbants.
- To demonstrate these improvements in prototype systems through fabrication, testing, and evaluation.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(B) System Cost
(G) Materials of Construction

Technical Targets

This project is conducting fundamental studies for the development of improved composite pressure vessels for hydrogen storage. Insights gained from these studies will be applied toward the design and manufacturing of hydrogen storage vessels that meet the following DOE 2010 hydrogen storage targets:

Introduction

Lincoln Composites is conducting research to meet DOE 2010 and 2015 Hydrogen Storage Goals for a storage system by identifying appropriate materials and design approaches for the composite container. At the same time, continue to maintain durability, operability and safety characteristics that already meet DOE guidelines for 2010 and 2015. There is a continuation of work with Hydrogen Storage Engineering Center of Excellence partners to identify pressure vessel characteristics and opportunities for performance improvement. Lincoln Composites is working to develop high-pressure vessels as are required to enable hybrid tank approaches to meet weight and volume goals and to allow metal hydrides with slow charging kinetics to meet charging goals.

Approach

Lincoln Composites is establishing and documenting a baseline design as a means to compare and evaluate potential improvements in design, materials and process to achieve cylinder performance improvements for weight, volume and cost. Lincoln Composites will then down-select the most promising engineering concepts which will then be evaluated to meet Go/No-Go requirements for moving forward.

The following areas will be researched and documented:

- Evaluation of alternate fiber reinforcement
- Evaluation of boss materials and designs
- Evaluation of resin toughening agents
- Evaluation of alternate liner materials
- Evaluation of damage vs. impact
- Evaluation of stress rupture characteristics
- Evaluation of in situ non-destructive examination (NDE) methods to detect damage
Results

Lincoln Composites has completed the documentation of a baseline design as a means to compare and evaluate potential improvements in design, materials and process to achieve cylinder performance improvements for weight, volume and cost. Baseline characteristics are shown in Table 1.

Lincoln Composites is in the process of conducting testing on alternate fibers relative to fiber strength and impact tolerance. Baseline fiber was selected as Toray T700. Five alternative fibers were selected as part of the study. Vessels were constructed with each of the five fibers using the same parameters on each: mandrel, wind patterns, tooling and processing. Tow count was adjusted, per fiber, to maintain consistent band cross-sectional area. One vessel constructed of each fiber was hydrostatically burst. Stress in the fiber at failure is calculated based on fiber certifications and normalized to Toray T700. Further testing of alternative fibers is being completed. Vessels, that were manufactured along with the burst vessels, are in the process of being impacted (drop testing), cycled and then burst tested. This testing is in process and following the completion of this testing, strength versus cost will be evaluated.

Lincoln Composites is looking into alternative boss materials as part of this project. Specifically, investigation methods are underway to create bosses constructed with Aluminum 7075-T73. Properties, of which, are difficult to acquire through entire thickness. High strength would allow reduction in boss size and allow aluminum use at high temperatures. To date, near net shaped bosses have been machined from 7075-T6 aluminum with the following surface finishes: smooth machining, rough machining, sand blasted and chemical etching. These bosses were then heat treated to a T73 condition. Bosses have been sectioned for review and locations mapped for hardness testing. Results of hardness testing have been received and are in the process of being evaluated. Results to date indicate that heat treating will be sufficient if the parts are rough machined first. Plans are being made for testing of the boss material with respect to stress corrosion cracking.

Investigations into alternate resin compilation are underway to determine effects on the toughening properties of a full-scale vessel. First phase was to research and perform testing on alternate hardeners that could be used with our current baseline resin. Several experiments were run with alternate hardeners with an end result that our current hardener performs best. Next step is to use this hardener to begin looking at different resin formulations. First step is to down-select based on screening of viscosity and $T_g$ results. Further testing is planned to determine mechanical and environmental/chemical properties. Upon completion, a down-select activity will determine what resin formulations will be used to produce coupons for further testing. The last activity will then be to build full-scale vessels with the alternate resin formulations and to perform further testing such as impact.

Studies are ongoing with respect to alternate materials to minimize the permeability of gas through the high density polyethylene (HDPE) liners that Lincoln Composites currently uses. Evaluation of coatings and surface treatments has shown blistering following a hydrogen soak and blow down. Treatments have not been shown to be effective. The first investigation into Nanoclay gave unsuccessful results. The molecular properties of HDPE did not promote dispersion. However, new material found from an alternate vendor has shown some improvements. HDPE with titanium dioxide has resulted in a 25% reduction in permeation. Lincoln Composites has also worked with the addition of ethylene vinyl alcohol (EVOH). We encountered problems with layered materials including the ability to weld. We looked at adding an outside

layer to keep the material away from the weld joint, however, issues with adhesion of the EVOH to the HDPE were experienced. Lincoln Composites is in the process of looking at EVOH that has been modified to increase ductility. The evaluation of nylon as a filler has also been targeted. The cost of nylon, when compared with HDPE, would generate a large cost increase. Liners have been built with the following conditions: HDPE (baseline), HDPE/standard nanoclay, HDPE/development nanoclay, and HDPE/titanium dioxide. These will be wound into full vessels and testing will then move forward on full-scale models. A permeation rate versus cost relative to HDPE is shown in Figure 1. HDPE is the baseline at 1.1. HDPE fillers show 40% reduction with limited cost increase. Alternate materials show promise of significant permeation reduction while others are prohibitively expensive.

Lincoln Composites is looking into an improved database for stress rupture of carbon fiber that may allow for reduced safety factors. This will in turn maintain projected reliability and reduce cost, weight and increase volumetric efficiency with thinner walls. A stress rupture project presented at an industry workshop to gain feedback and support was conducted. This project is currently being refined with some collaborators and funding identified. Additional collaboration and funding is being sought. Stress rupture, fatigue and damage tolerance are all being considered in the study. The evaluation of damage vs. impact is being considered to characterize safety and ability to remain in service after damage. NDE as a means of monitoring the structural integrity is being considered which will allow for thinner laminates and removal from service before rupture.

**Conclusions and Future Directions**

Future work for this project will be to continue progress on evaluating potential improvements. This is work that is being completed in Phase 1 of the project. After completion of Phase 1, Lincoln Composites will down-select most promising engineering concepts and evaluate against DOE 2010 and 2015 Hydrogen Storage Go/No-Go criteria. Phase 2 is continuation of container development in support of system requirements and finally, Phase 3 will be the fabrication of subscale vessels to support assembly of prototype systems for evaluation.

**FY 2010 Publications/Presentations**

Objectives

The overall objective of this effort is to support DOE with independent system level analyses of various H₂ storage approaches, to help to assess and down-select options, and to determine the feasibility of meeting DOE targets. Specific objectives in Fiscal Year (FY) 2010 included:

- Model various developmental hydrogen storage systems.
- Provide results to Centers of Excellence for assessment of performance targets and goals.
- Develop models to “reverse-engineer” particular approaches.
- Identify interface issues, opportunities, and data needs for technology development.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(B) System Cost
(C) Efficiency
(E) Charging/Discharging Rates
(J) Thermal Management
(K) System Life Cycle Assessments

Technical Targets

This project is conducting system level analyses to address the DOE 2010 and 2015 technical targets for on-board hydrogen storage systems:

- System gravimetric capacity: 1.5 kWh/kg in 2010, 1.8 kWh/kg in 2015
- System volumetric capacity: 0.9 kWh/L in 2010, 1.3 kWh/L in 2015
- Minimum H₂ delivery pressure: 4 atm in 2010, 3 atm in 2015
- Refueling rate: 1.2 kg/min in 2010, 1.5 kg/min in 2015
- Minimum full flow rate of H₂: 0.02 g/s/kW (2010 and 2015)

Accomplishments

- Analyzed the gravimetric and volumetric capacities of Type-3 (metal liner) and Type-4 (high density polyethylene [HDPE] liner), 350- and 700-bar compressed hydrogen (cH₂) physical storage systems.
- Updated the analysis of storage capacity and system performance of the cryo-compressed hydrogen (CcH₂) storage systems to include liner fatigue considerations.
- Analyzing the storage capacity of liquid hydrogen storage systems (LH₂) with advanced vapor shields to extend dormancy.
- Revised the on-board and off-board analyses of the metal-organic framework (MOF-177) system with adiabatic LH₂ refueling and cryogenic liner fatigue considerations.
- Initiated system analysis of on-board hydrogen storage systems that use ammonia borane (AB) in ionic liquids (ILs) as the hydrogen storage medium.
- Conducting off-board analysis of AB regeneration using hydrazine.

Introduction

Several different approaches are being pursued to develop on-board hydrogen storage systems with the goal of meeting the DOE targets for light-duty vehicular applications. Each approach has unique characteristics, such as the thermal energy and temperature of charge and discharge, kinetics of the physical and chemical process steps involved, and requirements for the materials and energy interfaces between the storage
system and the fuel supply system on the one hand, and the fuel user on the other. Other storage system design and operating parameters influence the projected system costs as well. We are developing models to understand the characteristics of storage systems based on the various approaches and to evaluate their potential to meet the DOE targets for on-board applications.

**Approach**

Our approach is to develop thermodynamic, kinetic, and engineering models of the various hydrogen storage systems being developed under DOE sponsorship. We then use these models to identify significant component and performance issues, and to assist DOE and its contractors in evaluating alternative system configurations and design and operating parameters. We establish performance criteria that may be used, for example, in developing storage system cost models. We refine and validate the models as data become available from the various developers. We work with the Hydrogen Storage Systems Analysis Working Group to coordinate our research activities with other analysis projects to assure consistency and to avoid duplication. An important aspect of our work is to develop overall systems models that include the interfaces between hydrogen production and delivery, hydrogen storage, and the hydrogen user.

**Results**

Figure 1 summarizes the storage capacities and well-to-engine efficiencies of some storage options that have been analyzed. The results in Figure 1 are only for reference and should not be compared directly since the systems are at different stages of development and have been analyzed to different levels of sophistication. The specific results given here are subject to revision as the models continue to be refined and additional data become available to help validate them.

**Physical Storage**

We modified our physical storage model to include the effects of autofrettage on the fatigue life of metal liners in Type-3 pressure vessels and on the load distribution between the liner and the carbon fiber (CF). We modeled the autofrettage process applied to composite tanks for service at ambient and cryogenic temperatures [1]. For service at ambient temperatures, we determined the induced residual compressive stresses in the metal liner and tensile stresses in the CF. We also modeled the post-autofrettage thermal stresses, the reversal of the residual stresses, and the resulting liner yield at lower loads even though the liner yield and tensile strength are higher at cryogenic temperatures. We used the model to determine the liner and CF thicknesses to meet the target life of 5,500 pressure cycles at 25% over the normal working pressure (SAE J2579). In addition, based on recent data and feedback from tank developers, we reduced the CF strength in our analysis by 10% to account for the variability in CF quality at high-volume manufacturing, and significantly increased the CF translation efficiency from 63% to 82% for 700-bar storage.

The fraction of the tensile load borne by the CF in Type-3 tanks affects the weight and cost of the tank. It is desirable to shift as much of the load to the CF as possible within the constraint of the autofrettage proof pressure. Figure 2 shows the calculated gravimetric and volumetric capacities for the Type-3 and Type-4, ch₂, single-tank systems. We calculate that the CF in a 350-bar, 5.6-kg usable H₂, Type-3 tank system can carry 90% of the total load, the Al liner thickness is 7.4 mm, and the usable storage capacities are 4.2 wt% and 17.4 g/L. The corresponding capacities for the Type-4 tank system (5-mm HDPE liner) are higher, 5.5 wt% and 17.6 g/L. At 700-bar storage pressure, the liner thickness for the Type-3 tank increases to 12.1 mm, the gravimetric capacity decreases to 5.6 wt%, and the volumetric capacity increases to 25 g/L. The storage capacities for the 700 bar, Type-4 tank system are higher.
5.2 wt% and 26.3 g/L. Because the HDPE liner carries negligible load, the liner thickness is unchanged between 350-bar and 700-bar pressures. We conclude that among the various cH2 tank systems analyzed, only the 350-bar, Type-4 system can potentially meet the 2015 gravimetric target of 5.5 wt% for 5.6 kg of recoverable hydrogen. None of the analyzed systems was found capable of meeting the 2015 volumetric target of 40 g/L.

We used the autofrettage model to revise the projected capacities of the Gen-3 CcH2 system with an in-tank heat exchanger and a 276-bar pressure vessel rating [2,3]. We determined that the unloading of the residual stresses during post-autofrettage cooling to cryogenic temperatures limits the maximum CF load share to 85%. The maximum load share is constrained by the proof pressure, which in turn depends on the safety factor (2.25) and the assumed approach to the burst pressure (80%). We estimate that a 9.3-mm liner is needed to withstand 5,500 pressure cycles. The liner thickness would increase if the analysis had considered deep temperature cycling due to refueling with compressed and liquid hydrogen (dual-mode storage). As shown in Figure 2, we project that a 5.6-kg recoverable CcH2 system can achieve capacities of 5.5 wt% and 41.1 g/L, meeting the DOE 2015 targets. Furthermore, with an aluminum outer shell instead of the steel shell, the gravimetric capacity of the 5.6-kg CcH2 system can exceed 9 wt% (but at a higher cost).

### Sorption Storage

We updated and expanded our analysis of on-board hydrogen storage in MOF-177. We investigated the adiabatic refueling option in which the MOF tank is evaporatively cooled by refueling it with LH2. We considered that hydrogen is recirculated through a small ex-tank heat exchanger during discharge to provide the heat of desorption and the temperature swing in the sorbent bed. We conducted fatigue analyses to estimate the required liner and CF thicknesses to meet the target life of 5,500 pressure cycles. We performed life cycle analyses to determine the well-to-tank energy efficiency, greenhouse gas emissions and fuel and ownership costs.

Figure 3 shows the calculated system gravimetric and volumetric capacities and the optimum storage temperature and temperature swing as functions of storage pressure. The optimum storage temperature and temperature swing depend on the storage pressure. The maximum gravimetric capacity of ~5.2 wt% is achieved at 150 atm and 80 K. The maximum volumetric capacity
increases with increasing pressure, reaching \( \sim 35 \text{g-H}_2/\text{L} \) at 350 atm and 100 K.

We estimated that 29% of the weight of the MOF-177 system (250-bar storage pressure, 80-K storage temperature) is in the storage medium, 25% in the liner, 11% in the CF composite, 11% in the aluminum shell, 1% in the multi-layer vacuum superinsulation, and 23% in other miscellaneous components. The corresponding volume distribution is 68% for MOF-177 bed, 6% for the liner, 5% for CF, 3% for the shell, 11% for the multi-layer vacuum superinsulation, and 7% for other miscellaneous components.

Analysis of the refueling dynamics showed that the total cooling load is 7.1 MJ (maximum, from completely empty to completely full). Of this, 62% is to remove the heat of hydrogen adsorption on MOF-177 and 38% is for sensible cooling of the thermal mass and the pressure-volume work of compressing the hydrogen in the tank. During discharge, a constant heat input rate of 1.9 kW is needed to provide \( \text{H}_2 \) continuously at 1.6 g/s full flow rate for an 80-kW fuel cell system. The peak heat input rate increases to 6.3 kW if the heat is supplied only as the tank pressure tends to fall below 4 atm. The system dormancy is a function of the amount of \( \text{H}_2 \) stored in the tank and the tank pressure and temperature at the start of the dormancy period. The minimum dormancy is 16 W-days, or ~3 days with a 5-W heat in-leakage rate.

The effects of varying different parameters on the system gravimetric and volumetric capacities were assessed. The parameter values (base case value in boldface) in the sensitivity study were 100, 250 and 300 atm storage pressure; 3, 4 and 8 atm minimum discharge pressure; and 0.4, 0.6 and 0.8 MOF packing fraction. In addition, the effects of a hypothetical increase in the absolute adsorption capacity by 0%, 20%, and 50% were evaluated. The resultant gravimetric capacities ranged from 4.6 to 5.75 wt% and the volumetric capacities ranged from 24 to 43 g/L. The sensitivity analyses showed that the adsorption capacity was the most significant parameter for the gravimetric capacity, whereas the storage pressure and the adsorption capacity were the two most significant parameters for volumetric capacity. Over the range of parameter values studied, the gravimetric capacity was the least affected by the minimum \( \text{H}_2 \) delivery pressure and the storage pressure, while the volumetric capacity was the least sensitive to the minimum \( \text{H}_2 \) delivery pressure and the MOF packing fraction.

The MOF-177 system, as analyzed, can meet the 2010 storage targets, but a 50% increase in sorption capacity is needed to meet the 2015 targets. With hydrogen obtained by steam-methane reforming and electricity drawn from the Energy Information Agency-projected U.S. grid mix for 2015, our analysis showed that the well-to-tank efficiency is about 41%, which falls well short of the DOE target of 60%. The total greenhouse gas emissions were estimated to be 19.7 kg CO\(_2\) equivalent/kg-H\(_2\), or \( \sim 0.51 \text{kg CO}_2/\text{mile} \) (63-gasoline gallon equivalent fuel economy) which is slightly less than the emissions for a conventional gasoline internal combustion engine vehicle (\( \sim 0.35 \text{kg CO}_2/\text{mile} \) for 50 mpg fuel economy). The ownership cost was $0.15/mile, which is 50% higher than that for conventional gasoline vehicles ($0.10/mile, 30 mpg and $3/gallon gasoline untaxed).

### Chemical Storage

We performed a preliminary on-board analysis for hydrogen storage in a 50:50 liquid mixture by weight of AB and an IL, bmimCl (1-butyl-3-methylimidazolium chloride, C\(_8\)H\(_{15}\)ClN\(_2\)). This AB solution is a stirrable, viscous liquid at room temperature, with a freezing point below \(-10^\circ\text{C}\). However, the solution foams once \( \text{H}_2 \) is released from the AB in the exothermic process; the foam begins to convert to a white solid after releasing 1 \( \text{H}_2 \) equivalent, with the entire mixture becoming solid after releasing 2 \( \text{H}_2 \) equivalents [4]. We fitted the dehydrogenation kinetics data [4] to the Arram-Erofeyev kinetics model with \( n=1.5 \) for the first \( \text{H}_2 \) equivalent released (Step 1) and \( n=2.5 \) for the next 1.55 \( \text{H}_2 \) equivalents released (Step 2). In our model, 100% AB conversion implies the release of 2.35 \( \text{H}_2 \) equivalents from AB. The kinetics model fits the measured data well for temperatures of 75°C, 85°C, 95°C, 105°C, and 110°C. The model could then be used to estimate hydrogen release at higher temperatures. The modeled kinetics showed that a temperature higher than 150°C is needed to release 2 equivalents of \( \text{H}_2 \) in 30 s (average release rate of 67 mEq/s) with a liquid-hourly space velocity (LHSV) of 120 h\(^{-1}\); for comparison, the highest measured release rate is 6 mEq/s at 110°C.

Assuming that an alternate IL (or mixture of ILs) is found such that the solution does not foam or solidify, we developed a conceptual on-board dehydrogenation reactor model using the kinetic data for the AB-bmimCl mixture. The main challenge is to control the peak temperature in this exothermic process, as too high a temperature may lead to undesirable side reactions, as well as issues of solvent stability and AB conversion (complete AB conversion would impede regenerability). The adiabatic temperature rise is in excess of 500°C, which, with an inlet temperature of 150°C, would lead to peak temperatures of 650°C or higher. The reactor temperatures can be controlled by using a heat transfer coolant, product recycle, or a combination of the two, as shown in the system schematic diagram in Figure 4. The reactor model was set up to yield 1.6 g/s of \( \text{H}_2 \) at 100% conversion using ethylene glycol as the coolant with a 10°C temperature rise through the reactor. To limit the maximum temperature to 200°C, the recycle ratio needs to be between 0.90 and 0.95 for an inlet temperature of 150°C and an LHSV of 150 h\(^{-1}\). The
IV.E Hydrogen Storage / Storage Testing, Safety and Analysis

Our analysis of CH₂ storage in Type-3 tanks indicates that the maximum load share in carbon fiber is limited to 90% because of the liner fatigue life requirement and the constraint on proof pressure. We project a gravimetric capacity of 4.2 wt% at 350 bar, decreasing to 3.6 wt% at 700 bar for 5.6 kg recoverable hydrogen. The corresponding volumetric capacity is 17.4 g/L at 350 bar, increasing to 25 g/L at 700 bar. With Type-4 tanks, the gravimetric capacity improves to 5.5 wt% at 350 bar and 5.2 wt% at 700 bar; the volumetric capacity is marginally higher at 350 bar and improves to 26.3 g/L at 700 bar.

- Our analysis of CcH₂ storage in Type-3 tanks indicates that the maximum load share in carbon fiber is limited to 85% because of the unloading of residual stresses at cryogenic conditions. We project a gravimetric capacity of 5.5 wt% and a volumetric capacity of 41.8 g/L for 5.6 kg recoverable hydrogen. The gravimetric capacity can be significantly higher if the steel outer shell is replaced with an aluminum shell.

- We project that an on-board MOF-177 system with adiabatic LH₂ refueling and 5.6 kg recoverable H₂ can achieve 4.8 wt% gravimetric capacity and 34.6 g/L volumetric capacity at 250 bar. The loss-free time and hydrogen loss rate are functions of the amount of hydrogen stored and the pressure and temperature at the start of the dormancy event.

- In FY 2011, we will continue our system analysis of hydrogen storage in liquid ammonia boranes. We will investigate reactor startup, buffer hydrogen storage, fuel stability, and supplemental heat rejection.

- In FY 2011, we will complete our analysis of the single-pot scheme developed by CHCoE for regenerating AB with hydrazine. We will determine the process efficiencies, well-to-tank efficiency and greenhouse gas emissions.

- Also in FY 2011, we will further extend our systems analysis work on physical, sorbent and metal-hydride storage methods.

Conclusions and Future Directions

- Our analysis of CH₂ storage in Type-3 tanks indicates that the maximum load share in carbon fiber is limited to 90% because of the liner fatigue life requirement and the constraint on proof pressure. Objectives

The overall objective for this project is provide independent analysis to help guide the DOE and developers toward promising research and development (R&D) and commercialization pathways by evaluating the various on-board hydrogen storage technologies on a consistent basis. Specific objectives include:

- Compare different on-board hydrogen storage approaches in terms of lifecycle costs, energy efficiency and environmental impact;
- Identify and compare other performance aspects that could result in barriers to successful commercialization (e.g., on-board system weight and volume);
- Examine the effects of system-level cost and performance trade-offs for different storage approaches; and
- Project performance and cost relative to DOE targets.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(B) System Cost
(K) System Life-Cycle Assessments

Technical Targets

This project evaluates the various on-board hydrogen storage technologies being developed by the DOE Hydrogen Storage Centers of Excellence and independent projects. Insights gained from these evaluations will help guide DOE and developers toward promising hydrogen storage materials and system-level designs and approaches that could meet the DOE targets for storage system cost, specific energy, energy density, fuel cost and efficiency.

Accomplishments

We have performed preliminary and/or updated assessments for several hydrogen storage systems. For each system assessment, we projected on-board system performance and high-volume (~500,000 units/year) manufactured cost, as well as determined the critical cost drivers and conducted single- and multi-variable sensitivity analyses to bound cost results. We also reviewed key assumptions and results with developers, DOE, and stakeholders (e.g., material suppliers, national labs, FreedomCAR and Fuel Partnership Tech Teams) and incorporated their feedback into the final results. Finally we compared performance and cost results to other baseline technologies and DOE targets for the on-board storage system. Specific accomplishments include:

- Completed preliminary, high-volume (500,000 units/yr) on-board system factory cost assessments of metal organic framework (MOF) 177 and liquid hydrogen tank systems. The MOF-177 system is projected to cost $16/kWh for a 5.6 kg hydrogen tank and $12/kWh for a 10.4 kg hydrogen tank. The liquid hydrogen system is projected to cost $8/kWh for a 5.6 kg tank and $5.4/kWh for a 10.4 kg tank.
- Revised high-volume on-board system factory cost assessments of cryo-compressed and 350 bar and 700 bar compressed tank systems. For the compressed systems, the analysis was extended to include Type 3 and Type 4 tanks, and single and dual tank systems.
- Supported the Storage Systems Analysis Working Group (SSAWG) evaluation of the well-to-tank energy use and greenhouse gas (GHG) emissions for MOF-177 tanks, cryo-compressed tanks, 350 and 700 bar tanks, and cold gas tanks.
- Completed review of Dow Chemical’s Ammonia Borate 1st fill cost projections.
**Introduction**

DOE is funding the development of a number of hydrogen storage technologies as part of its “Grand Challenge.” This independent analysis project helps guide the DOE and Grand Challenge participants toward promising R&D and commercialization pathways by evaluating the various hydrogen storage technologies on a consistent basis. Using this consistent and complete comparison of various technology options, R&D can be focused and accelerated. Without such an approach, erroneous investment and commercialization decisions could be made, resulting in wasted effort and risk to the development of hydrogen vehicles and a hydrogen infrastructure.

TIAX is conducting system-level evaluations of the on-board storage systems cost and performance for four broad categories of on-board hydrogen storage. The four categories are: reversible on-board (e.g., metal hydrides and alanates), regenerable off-board (e.g., chemical hydrides); and high surface area sorbents (e.g., carbon-based materials), and advanced physical storage (e.g., cryo-compressed hydrogen, liquid hydrogen). Evaluations are based on developers’ on-going research, input from DOE and key stakeholders, and in-house expertise.

**Approach**

This project utilizes an approach that is designed to minimize the risks associated with achieving the project objectives. In coordination with Argonne National Laboratory (ANL), system-level conceptual designs are developed for each on-board storage system and required fueling infrastructure. We work closely with ANL to develop a bill of materials consistent with their performance assessment. Next, system models and cost models are used to develop preliminary performance and cost results. We utilize in-house activities- and product-based cost models to determine high-volume manufactured cost projections for the on-board storage system, and H2A-based discounted cash flow models to estimate hydrogen selling prices based on the required off-board hydrogen infrastructure. Subsequently, these results are vetted with developers and key stakeholders and refined based on their feedback. Coordination with DOE’s Hydrogen SSAWG avoids duplication and ensures consistency. This is an on-going and iterative process so that DOE and its contractors can increasingly focus their efforts on the most promising storage technology options.

**Results**

TIAX developed preliminary cost estimates for a MOF-177 storage system and a liquid hydrogen storage system, and updated previous cost estimates for compressed and cryo-compressed storage systems. Each of the storage system cost projections are estimated based on on-board system designs developed by ANL [1].

The high volume (~500,000 units per year) cost of the MOF-177 system was estimated to be $16/kWh for a 5.6 kg useable hydrogen tank and $12/kWh for a 10.4 kg useable hydrogen tank (Figure 1). The modeled MOF-177 tank consists of a Type 3 carbon fiber pressure vessel surrounded by multi-layer vacuum insulation and an aluminum outer shell. The pressure vessel is filled with a metal organic framework storage media (Figure 2), which stores hydrogen at 250 bar and 100 K. The single biggest contributors to the system cost are the carbon fiber (19%), the aluminum tank liner (14%), and the storage media (14%). It should be noted that the MOF storage media is not yet available at high commercial volumes. As such, our preliminary estimate of the storage media is based on the high volume cost of activated carbon (AX-21); subsequent revisions will revisit this assumption.

The liquid hydrogen storage system was estimated to cost $8/kWh for a 5.6 kg tank and $5.4/kWh for a 10.4 kg tank (Figure 1). The liquid hydrogen tank consists of an aluminum inner shell and steel outer shell.

![FIGURE 1. Preliminary On-board Storage System Cost Comparison Results](image-url)

1 Costs were estimated for both a 5.6 kg useable hydrogen tank and a 10.4 kg useable hydrogen tank for the cryogenic systems. Due to space constraints, only the results for the 5.6 kg tanks are shown. The two different tank sizes reflect two different bases for comparison that were suggested by various stakeholders: the 5.6 kg tank is consistent with other cost analyses performed as part of this project, and reflects the amount of hydrogen needed for a passenger vehicle to achieve 350 mile range. The larger tank is more consistent with the specifications of cryogenic tanks that have been tested to date, which tend to be larger to help mitigate the effects of boil-off.
with multi layer vacuum insulation sandwiched between. The tank is sized to include 7.5% ullage and assumes 40% boil off of hydrogen. The major costs are relatively evenly distributed between the tank (46%, primarily the liner and vacuum insulation), and the balance of plant (54%).

In addition to the new cost analyses described above, TIAX updated previous cost assessments of compressed and cryo-compressed storage systems. The revised cryo-compressed storage system is based on Lawrence Livermore National Laboratory’s Gen 3 tank design [1]. Key changes between the current design and the Gen 2 design used for TIAX’s prior assessment include changes in the liner and vacuum insulation thickness, and a reduction to the system’s nominal pressure (to 272 Bar). The updated estimates for the cryo-compressed system project a system cost of $12/kWh for a 5.6 kg tank and $8.4/kWh for a 10.4 kg tank (Figure 1). The tank, primarily due to the cost of carbon fiber and the aluminum liner, accounts for 55% of the total cost, while the balance of plant accounts for an additional 34% of the total.

The revised compressed hydrogen system cost estimates project that a 350 bar Type 4 tank will cost $15/kWh and a 700 bar Type 4 tank will cost $19/kWh (Figure 1). Both tanks were sized to store 5.6 kg of useable hydrogen. These calculations include a number of revised assumptions compared to TIAX’s prior analysis, the net effect of which was a 10% decrease in the cost of the 350 bar system and a 30% decrease in the cost of the 700 bar system. The revised calculations continue to show that the cost of carbon fiber is the dominant cost component for both the 350 and 700 bar systems, accounting for 75 to 80% of the system cost; the balance of plant accounts for an additional 18%.

In addition to the Type 4, single tank compressed hydrogen storage system, TIAX estimated the system costs for Type 3 tanks and for multi-tank systems. In total, eight different compressed hydrogen tanks were evaluated (i.e., each combination of 350 and 700 bar, Type 3 and Type 4, and single and multi-tank systems). The cost results of this analysis are shown in Figure 3. As shown, the multi-tank systems lead to a minor cost increase in system costs (approximately $0.5/kWh). Although the two tank system has additional surface area compared to a single tank, the carbon fiber thickness may be decreased due to the smaller dimensions. As such, the single and dual tank systems use a very similar quantity of carbon fiber. Moreover, it was assumed that the two tank system uses the same balance of plant as the one tank system. The Type 3 tanks are projected to lead to a modest cost increase compared to the Type 4 baseline: for the 350 bar tank, the system cost increases by $1.3/kWh, while the 700 bar tank cost increases by $2.2/kWh compared to a Type 4 tank. This difference reflects a large increase in the cost of the aluminum Type 3 liner compared to the HDPE Type 4 liner, coupled with a minor decrease in the carbon fiber required.

All of the results reported above should be considered in the context of meeting both on-board and off-board cost targets as well as other DOE targets, including on-board system weight, volume, durability/operability, charging/discharging rates; and off-board primary energy use/GHG emissions and fuel purity. While this project focuses on the onboard hydrogen storage system cost, the results of TIAX’s onboard cost assessments were used as inputs to well-to-wheel lifecycle analysis of system performance cost conducted by the SSAWG (Table 1).

\[\text{i.e., none of the balance of plant components are duplicated.}\]

\[\text{The aluminum liner is able to support a portion of the carbon fiber’s pressure load.}\]

Conclusions and Future Directions

The cost assessments conducted this year allow direct comparison with prior cost assessments and DOE targets. Our models allow us to identify critical cost components, which enables focused discussion with tank developers and manufacturers.

- None of the systems assessed meet the Department of Energy’s 2010 cost target of $4/Wh. The cost of the 5.6 kg 350 bar, 700 bar, cryo-compressed, liquid, and MOF-177 storage systems range from 2 to 5 times the cost of the DOE target. Key factors influencing system costs are the carbon fiber material cost, the cost of aluminum, and in the case of the MOF system, the storage media.
- The MOF-177 system cost is 3 and 4 times the 2010 DOE target of $4/kWh for the 10.4 and 5.6 kg systems, respectively. Achieving the DOE cost targets will require large reductions in the cost of the storage media and the tank materials (aluminum and carbon fiber).
- The onboard liquid hydrogen system cost is 1.3 and 2 times the 2010 DOE target for the 10.4 and 5.6 kg systems, respectively. While the liquid system has amongst the lowest onboard storage system cost, it has low volumetric efficiency, well-to-tank efficiency, and high fuel costs. These shortcomings are a function of fuel boil-off and the high energy requirement associated with liquefaction.
- The cryo-compressed system is 2 and 3 times the 2010 DOE target for the 10.4 and 5.6 kg systems, but meets the 2010 volumetric and gravimetric targets. The base case 350 bar and 700 bar systems are 4 and 5 times higher than the 2010 DOE targets for the 350 bar Type 4 and 700 bar Type 4 systems, respectively, and both systems fall short of the 2010 volumetric capacity targets. Additional analysis of 350 and 700 bar dual tank systems showed minor cost increases of less than 5%; 350 and 700 bar Type 3 systems showed moderate cost increases on the order of 10%. The major cost driver for the compressed system is carbon fiber, while the cryo-compressed system cost is driven by carbon fiber, aluminum liner, and balance of plant component costs.

The rest of this fiscal year, we plan to continue to work with developers and stakeholders to improve the accuracy of the analyzed on-board and off-board system models and finalize our analysis of storage technology options. Specifically, we plan to:

- Incorporate feedback and finalize on-board cost assessments and reports (with ANL) for MOF177 and liquefied hydrogen options. In parallel, we will update previously completed final reports for 350 bar, 700 bar and cryo-compressed systems.
- Complete updated assessments and final reports (with ANL) for previously evaluated technologies, including liquid hydrogen carrier and Gen 4 cryo-compressed systems.
- Complete new assessments and final reports (with ANL) for activated carbon systems.
- Complete off-board cost review for ammonia borane and other technologies as requested by DOE and integrate with overall performance and on-board cost results.
- Continue to work with DOE, SSAWG, Centers of Excellence, other analysis projects, developers, Tech Teams and other stakeholders (as necessary) to revise and improve system models.

Project Start Date: October 1, 2007
Project End Date: September 30, 2010

Objectives

- Develop internationally recognized standard testing techniques to quantitatively evaluate both materials and systems risks.
- Determine the fundamental thermodynamics and chemical kinetics of the environmental reactivity of hydrogen storage materials.
- Build a predictive capability to determine probable outcomes of hypothetical accident events.
- Develop amelioration methods and systems to mitigate the risks of using these systems to acceptable levels.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan in descending order of impact:

(F) Codes and Standards
(P) Understanding of Hydrogen Physisorption and Chemisorption
(Q) Reproducibility of Performance

Technical Targets

This project is conducting fundamental studies of the air and water exposure of numerous solid-state hydride materials in order to assess their risks. Insights gained from these studies will be applied toward the design of risk mitigation methodologies that meet the following DOE 2010 and 2015 hydrogen storage target:

- Environmental Health and Safety: Meets or Exceeds Applicable Standards

Accomplishments

- Standardized United Nations (U.N.) hazard analysis tests completed for all promised hydrides except alane.
- Modeling has been used to determine a critical radius for pelletization of 2LiBH₄-MgH₂.
- Calorimetric characterization of NH₃BH₃ is completed and the accompanying modeling work is nearly completed.
- A modified burn rate test has been developed and verified using less than one-half the material required for the standard U.N. burn rate test.
- The U.N. self-heating test has been modified to a cylindrical geometry to more thoroughly support the modeling effort.
- Environmental exposure risk mitigation strategy invention disclosure filed.
- Four mitigation strategies have been evaluated preliminarily and several have been promising enough to be evaluated under cyclic sorption conditions.
- Initial thermal and chemical kinetic model completed having predictive capabilities for environmental exposure and reactivity scenarios.

Introduction

This report gives a summary of standardized U.N. tests for material packing and shipping, along with calorimetric experiments performed in order to quantify both the rate and the amount of the energy released for hydrogen storage materials. A mathematical modeling effort has been started to predict hydride behavior for hypothesized accidental exposure of the storage materials to an ambient environment, which facilitates an assessment of the risk associated with the utilization of a particular hydrogen storage material. An idealized finite volume model was developed to represent the behavior of dispersed hydride from a breached storage tank or container. Thermodynamic calculations and substantiating calorimetric experiments were performed in order to quantify the energy released, the energy release rates and the reaction products resulting from
water and air exposure of ammonia borane. This thermodynamic data will be used in the computational fluid dynamics model to predict both the hydrogen generation rates and concentration profiles along with localized temperature distributions. The results of these numerical simulations will be used in future work to predict safety windows and to assist in the design of environmental exposure mitigation strategies.

**Approach**

In order for the information generated by this project to be widely accepted and globally distributed, an international program was established linking laboratories in North America, Europe and Asia to perform specialized tasks specific to their organizations capabilities. A set of materials testing procedures, based on internationally accepted standards drawn from U.N. testing procedures has been defined. These tests include exposure to air, humidity, water, and could be modified to include proposed cooling fluids. Numerous potential hydrogen storage materials such as activated carbon, NaAlH$_4$, NH$_3$BH$_3$, Mg(NH$_2$+LiH, AlH$_3$, and 2LiBH$_4$+MgH$_2$ have been tested identically under these conditions to quantitatively determine their reactivity under normally occurring environmental conditions. Independent studies have been performed to understand the chemical kinetics of these reactions with air, oxygen and water as both liquid and vapor as a function of temperature. Calorimetric studies are continuing to investigate the time-dependent reaction rates of the materials. Mathematical simulations are being developed to predict the behavior of these hydrogen storage materials upon accidental environmental exposure.

**Results**

**U.N. Tests**

The standard materials testing procedures employed are based on existing U.N. testing protocols that are used to determine the material classification and ensure safe transport and handling [1]. Six standardized tests were performed including (1) water immersion, (2) water surface contact, (3) water drop testing, (4) pyrophoricity, (5) burn rate, and (6) dangerous self heating. The U.N. tests were modified to include visual recording of the testing event, and the addition of thermocouples in those experiments where this was possible. Table 1 shows the U.N. test results for ammonia borane, alane, lithium borohydride-magnesium hydride (2:1 ratio), and the lithium hydride and magnesium hydride (8:3 ratio) hydrogen storage systems. The 8LiH·3MgH$_2$ system is the only material that failed the pyrophoricity test. All materials, with the exception of ammonia borane, showed reactivity towards water.

**Risk Mitigation**

Four risk mitigation strategies have been identify to mitigate the risks associates with air and water reactivity in this type of materials. Currently, invention disclosures

* Reported values from the Japanese National Institute of Advanced Industrial Science and Technology (JNAIST) (Kuriyama).
are being prepared addressing the use of these strategies for these purposes. The $\text{8LiH} \cdot 3\text{Mg(NH}_2\text{)}_2$ system, supplied by JNAIST was used for testing these strategies. Experiments performed at JNAIST and SRNL show that the systems exhibits high reactivity to both air and water. Figure 1 shows the water drop test for this system as well as a modified sample utilizing one of the strategies pursued. As it can be observed, the original sample ignites upon in contact with the first drop of water. In contrast, the modified sample shows significant charring but did not undergo an ignition event even after being in contact with five drops of water.

**Calorimeter Experiments**

Alane calorimetric measurements (refer to Figure 2) were conducted under dry air as well as 30% relative humidity and 40°C. While the dry air environmental displayed a typical exothermic behavior, the presence of 30% water vapor caused a distinct behavior change in the alane. An exothermic peak is initially observed upon exposure humid air attributed the interaction of moisture with the material. Subsequently, a competing effect is then observed between the dehydrogenation of alane (endothermic peaks) and the oxidation of aluminum metal (exothermic peak). In situ X-ray diffraction studies are underway to further understand changes in crystal structure upon exposure to humid air condition.

**Numerical Simulations**

The numerical simulation examined an environmental exposure of storage material, where the hydride has been released from its containment vessel and is falling through the ambient air. The governing equations solved for each analysis include mass, momentum, and energy balances, plus additional kinetics equations based on isothermal calorimetry data at 70°C for porous $2\text{LiBH}_4\cdot\text{MgH}_2$ exposed to water. FLUENT, a general purpose computational fluid dynamics package, was used to solve the equations using the finite volume approximation method [2]. Further details of the mathematical model are available in the publications list below.

Two sets of initial conditions were used to evaluate the different release scenarios. For the first set of scenarios, the hydride is initialized with ambient air filling the porous media. This assumes the hydride has been out of the container for a short amount of time prior to a reaction occurring, which allows all of the hydrogen gas within the hydride to dissipate (replaced by ambient air) prior to the reaction. Typical results from these simulations are shown in Figure 3 and summarized in Table 2. The smallest diameter hydride spheres (0.05 inch and 0.25 inch radius models) never reach the lower flammability limit (LFL = 0.04) for hydrogen concentration, which means no ignition event occurs. For the larger spheres (0.50 inch and higher radius models), the LFL and/or the auto-ignition temperature (500°C or 571°C depending on the $\text{H}_2$ concentration)
of hydrogen is reached and an ignition event occurs. Figure 3 highlights the species concentrations before and after the hydrogen ignition event occurs for the 0.50 inch hydride sphere model. The $H_2$ concentration (26.6% mole fraction, $m_f$) is well above the LFL prior to the ignition event and then drops off rapidly after the event (~1.5% $m_f$). Note that as the $H_2$ and $O_2$ burn away, water vapor ($H_2O$) increases in their place. Similar results are seen for the larger spheres (1 inch and greater models), but are not shown for brevity.

For the second set of scenarios, the hydride is initialized with hydrogen gas filling the porous media. These scenarios assume that the reaction occurs immediately after the hydride is released from its container, which means the porous space within the hydride is still full of 100% hydrogen gas at the start of the numerical simulation. However, due to the high dissipation rate of $H_2$ into the ambient, most or all of the hydrogen has been expelled from the hydride prior to the start of the chemical reaction (mass/heat generation) within the simulation. Thus, the hydrogen-initialized hydride models have similar results to the air-initialized hydride models and are not shown for brevity. As is shown from the preceding results, small amounts of hydride have a lower chance of ignition compared to the larger amounts of hydride.
Conclusions and Future Directions

Conclusions

• Calorimetric measurements for alane show a competing effect between the dehydrogenation of alane and the oxidation of aluminum.
• NH₃BH₃ poses significantly less risk of ignition than the other materials tested for environmental exposure.
• Four risk mitigation strategies have been identified. Preliminary results on the 8LiH 3Mg(NH₂)₂ showed significantly reduced reactivity upon exposure to water.
• The mathematical modeling is an effective method of determining heat and hydrogen concentrations developed during simulated accident scenarios.

Future Directions

• Conclude standardized testing of AlH₃ as decided in consultation with the centers of excellence.
• Continue the thermodynamic and kinetic testing with AlH₃ and 8LiH 3Mg(NH₂)₂ to feed information into the numerical simulations.
• Continue modeling effort to include actual chemical kinetics to render predictive capabilities
• Evaluate proposed mitigation strategies utilizing calorimetry and modified U.N. tests.

Special Recognitions, Awards/Patents Issued

This project has been recognized by the International Partnership for the Hydrogen Economy. Partners in the project include National Institute for Advanced Industrial Science and Technology in Japan, Forschungszentrum Karlsruhe in Germany, Université du Québec à Trois-Rivières in Canada, United Technologies and Sandia National Laboratories in the U.S.

This project has been recognized by the International Energy Agency-Hydrogen Implementation Agreement with award of the Annual Project Prize for 2010 for “Fundamental research characterized by technical excellence and harmony in international cooperation that contributes to the understanding and advancement of basic and applied hydrogen science.”

Project Start Date: June 1, 2007
Project End Date: May 31, 2011

Objectives

Provide improved definition of the DOE Environmental Health and Safety (EH&S) target and its link to material reactivity to guide research of storage materials. Detailed objectives include:

- Develop qualitative and quantitative analysis tools to evaluate risks for materials-based hydrogen storage systems before and after mitigation methods.
- Perform dust characterization tests for metal hydride, chemical hydride and adsorbent materials.
- Characterize chemical reactions for material exposures associated with both risk events and mitigation approaches using time resolved X-ray diffraction (XRD), liquid reactivity and other specialized testing.
- Assess the trade-offs between residual risk after mitigation and the system weight and volume as well as reaction rates.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

- Qualitative risk analysis (QLRA): identified potential safety-significant failure modes that challenge the integrity of the storage vessel in an on-board reversible system.
- Quantitative risk analysis (QRA):
  - Used the fault tree methodology to perform system-level failure analysis of a baseline design of an on-board reversible storage system.
  - Defined a probabilistic importance measure to estimate contributions of system components to the total failure probability of the on-board system.
  - Developed and quantified a fault tree model to assess the consequences of accidental air intrusion into a hydride-based storage vessel.
  - Developed and applied a stochastic approach using interactive simulation in conjunction with Monte Carlo sampling to manage uncertain inputs in quantitative risk analysis.
  - Defined a probabilistic risk reduction importance measure to quantify the magnitude of safety improvement that can be achieved by reducing the probability of occurrence of undesired events and failure of components credited in the risk model.
- Risk mitigation: experimentally evaluated hydride powder compaction as a potential risk mitigation method.
Introduction

Safety is one of the most significant issues affecting consumer acceptance and adoption of hydrogen-fueled vehicles. Through DOE efforts to understand general public opinions, people have indicated that when selecting a fuel supply, safety is the most important factor. The current project, in close coordination with efforts at Savannah River National Laboratory (SRNL) and Sandia National Laboratories (SNL), will provide quantitative insights to this target and support the development of future risk-informed codes and standards. The results from these collaborative efforts will also have nearer term impact in guiding storage materials research and the development of materials/systems risk mitigation methods.

Approach

The current project has five distinct elements as follows:

- Risk analysis (QLRA and QRA).
- Materials reactivity testing.
- Chemical reaction kinetics testing and modeling.
- Risk mitigation.
- Limited scope prototype testing.

Figure 1 outlines the risk analysis framework of this project.

Results

1. QLRA

Identified safety-significant failure modes associated with the on-board reversible storage vessel (Figure 2). These failure modes include catastrophic vessel rupture due to a vehicular collision and vessel burst due to an external fire in conjunction with failure to vent the vessel. Other failure modes include accidental intrusion of air or water into the storage vessel and the potential for stored hydrogen diffusion/permeation through the vessel walls.

2. QRA

2.1 Developed a system-level fault tree (FT) model for a baseline design of an on-board vehicle reversible hydrogen storage system (Figures 3 and 4). The hydride storage vessels and associated pressure relief devices are among the key components credited in

2.2 Developed a fault tree model which quantifies the consequences of accidental air intrusion into a hydride storage vessel. In this model, air leakage into the vessel was the initiating event and vessel burst was conditional on failure of the safety relief device to open and vent the vessel.

3. Risk Mitigation – Experimental Studies

3.1 A series of scoping tests were conducted to evaluate the hydride material reactivity under selected environmental conditions that could be encountered during a vehicular accident. Catalyzed sodium alanate (NaAlH$_4$+4mole% TiCl$_3$) was used in these experiments.

3.1.1 In immersion tests, loose powder as well as powder compacts (wafers) were immersed in different liquids at room temperature. The liquids selected were water, windshield washing fluid, engine coolant (antifreeze), engine oil and NaCl solution (brine), respectively. These tests were repeated using powder compacts.

3.1.2. In the droplet tests, water, windshield washing fluid, engine coolant (antifreeze), engine oil and brine, respectively, were dropped on loose powder and powder compacts (wafers).

Test results demonstrated that powder compaction has the potential to reduce risk by suppressing material reactivity (in the liquids tested) and preventing consequential ignition of the evolved reaction gases. Additional validation tests are in progress.

3.2 The scope of our risk mitigation scoping tests was extended to include the following high-temperature tests:

3.2.1 Sodium alanate wafers (1-gram each) were immersed in 50-ml hot water at 80°C and in 50-ml thermo-oil at 100°C, respectively. In both cases, only a benign reaction at the wafer’s surface was observed and the evolved reaction gases did not ignite.

3.2.2 The consequences of contacting powder compacts with hot surfaces in the presence of air were investigated; a condition that could be encountered during postulated accident scenarios. In this test, the hydride wafer was placed on an electrically-heated surface. Thermocouples were used to measure the wafer’s temperature. When the temperature of the wafer reached ≈85°C, it ignited and the evolved gases burned but the wafer did not disintegrate. The insights gained from this test will drive the development of additional risk mitigation to prevent the observed hydride fires.

3.3 Experimentally investigated the impact of extended immersion time of catalyzed sodium alanate wafers in different liquids. In these tests, hydride wafers (1-gram each) were immersed for 8 hours (soaking time) in water and in windshield washing fluid, respectively. The experimental observations showed very mild hydride/liquid reactions and the emitted reaction gases did not ignite.

3.4 Performed fast blowdown tests using our project’s specially designed and fabricated test rig that mimics hydride storage vessel rupture. The pressure profile during each blowdown test was recorded and the results showed that depressurization from 100 bars to 20 bars was completed in ≈40 msec. Results of tests with NaAlH$_4$ powder showed that ≈16% of the initial powder mass (30 grams) was entrained to the collection vessel of the rig as a result of the blowdown. Future tests will be conducted using powder compacts instead of the loose powder which was used for establishing a baseline for comparison purposes.
Conclusions and Future Directions

The work conducted in this year included QLRA, QRA and risk mitigation tests. The QLRA identified key safety significant failure modes of the hydride storage vessel (which represents a single point failure in the on-board system). The QRA covered: a) fault tree modeling and quantification of consequences of accidental air intrusion into the storage vessel, b) system-level failure analysis of a baseline design of a hydrogen storage system and c) developing a stochastic approach for managing uncertainties in risk quantification. The experimental work focused on risk mitigation tests to evaluate the hydride material reactivity (both loose powder and powder compacts) under wide ranges of environmental conditions and postulated accident scenarios.

Future work will focus on:

- **Risk Analysis**
  - Continue accident sequences development and quantification for the remaining risk-dominant initiating events.
  - Complete risk analysis framework (both QLRA and QRA) incorporating results from dust cloud tests, experimental and modeling activities at SNL and SRNL.
  - Evaluate candidate risk mitigation methods (material reactivity based and system-based).

- **Economic Consequence Analysis**
  - Perform economic consequence analysis for the identified most probable and worst-case scenarios and assign monetary safety benefits of selected risk mitigation methods.

- **Experimental Studies (including those planned and coordinated with SNL material reactivity project)**
  - Complete dust explosion tests for at least one mitigated material structure.
  - Complete X-ray diffraction characterization test for at least one mitigated material structure.
  - Perform material reactivity tests for selected mitigated and unmitigated material structures. Conduct fast depressurization tests on selected unmitigated and mitigated material structures.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-AC04-94AL85000.

Objectives

- Develop generalized methods and procedures required to quantify the effects of hydrogen storage material contamination in a systems environment:
  - Quantify chemical processes and hazards associated with high- and low-level contamination of hydrogen storage materials.
  - Predict processes during accident scenarios of systems containing hydrogen storage materials.
  - Identify and demonstrate ex situ and in situ hazard mitigation strategies.

- Provide technical basis for codes and standards efforts when appropriate technology maturity has been attained to enable the design, handling and operation of effective hydrogen storage systems for consumer and industrial applications.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume

(D) Durability/Operability
(F) Codes and Standards
(Q) Reproducibility of Standards
(K) System Life-Cycle Assessments

Technical Targets

Technical targets addressed mainly focus on environmental health and safety. This project is enabling the satisfaction of these targets by providing the technical basis for future codes and standards efforts, thus enabling the design, handling and operation of effective hydrogen storage systems.

Environmental Health and Safety

<table>
<thead>
<tr>
<th>Toxicity</th>
<th>Meets or exceeds applicable standards</th>
</tr>
</thead>
<tbody>
<tr>
<td>Safety</td>
<td>Meets or exceeds applicable standards</td>
</tr>
</tbody>
</table>

In addition to the above target, other storage technical targets are impacted by this effort as follows:

- Gravimetric and Volumetric Capacity - This parameter may be influenced by added weight and volume of developed safety systems and mitigation strategies; for example, contamination permeation barriers etc.).
- Storage System Cost - System cost may be impacted by engineering controls that are developed.
- Fuel Purity - Current draft fuel purity standards are based on proton exchange membrane fuel cell requirements. Hydrogen storage materials may have more stringent hydrogen purity requirements.

Accomplishments

- We have found that the hazard presented by the breach-in-tank scenario is significantly minimized when loss of hydrogen was considered.
- We have determined that over-pressures and over-temperatures are probable during a pool fire scenario involving an un-mitigated metal hydride bed.
- We have polymerized both catalyzed and uncatalyzed complex metal hydrides, sodium alanates with vinyl monomers at 10 and 20 wt% (mitigated samples produced).
- We have demonstrated that mitigated samples show a nearly a 70% reduction in energy released during oxidation.
• We have successfully hydrogen cycled polymerized and mitigated samples nearly 160 times.
• We have quantified the impact of cross-linking density on the structural properties of mitigated materials.
• We have scaled up synthesis of mitigated materials to 10 g to enable larger scale testing and analysis.

Introduction

This project is focused on developing generalized methods and procedures required to quantify the reactivity properties of hydrogen storage materials to enable the design, handling and operation of solid-state hydrogen storage systems for consumer and industrial applications. We are performing the experimental and theoretical efforts that are required to understand processes during high-level contamination events including accidents, and low-level contamination events experienced during the life cycle of the storage system. This effort provides the technical basis of the identification of hazard mitigation strategies, and eventually development of appropriate codes and standards. A successful effort in quantifying the reactivity properties of hydrogen storage materials will enable the safe design, production, handling, operation, and disposal of consumer and industrial hydrogen storage systems and provide the technical basis for eventual standards developed for safe hydrogen storage systems.

Approach

We take a science-based approach to understanding, predicting, and controlling contamination processes of hydrogen storage materials. By first understanding the fundamental contamination reaction processes using combination of established and newly developed experimental techniques, we are able to build robust and useful chemical kinetic models. These chemical kinetic models are then coupled with heat and mass transfer characteristics to assemble validated models of contamination scenarios. These validated models are then exercised to develop an understanding of the engineering and administrative controls required to mitigate the hazards caused by the contamination processes in the context of systems.

Results

Prediction of processes during accident scenarios and the development of mitigation technologies for solid state hydrogen storage systems were the focus of efforts in Fiscal Year (FY) 2010.

Efforts to predict processes during accident scenarios investigated the impact of hydrogen evolution on the breach-in-tank contamination scenario, and the fire impingement scenario. In brief, we have determined that the evolution of hydrogen from the bed reduces the extent of the oxidation reaction during a breach-in-tank scenario. We have also determined that a pool fire scenario can lead to a system over-temperature and over-pressure event within a short time of exposure. As a result of this analysis we have identified to mitigation strategies for further development (1) additives that limit the extent and rate of oxidation and, (2) thermal shielding design to limit the reduce the rate of temperature rise within the system during a fire.

Breach-In-Tank Scenario Modeling – We have considered the case in which an accident results in air exposure of alane contained within a tank. We have built our models using desorption kinetics of alane combined with our model parameters developed for permeability and oxidation kinetics. We considered the realistic case for the alane bed breach-in-tank where heat losses to the environment at 5 W/m²-K cool the bed after the initiating event. Considering a one inch diameter, one foot long cylinder (characteristic geometry utilized in the simulations) filled with alane at 0.33 g/cc, calculations indicate that the oxidation reaction is significantly inhibited by the evolution of hydrogen. The loss of hydrogen from the system initially cools the bed to ~85°C prior to any inclusion of air into the bed (Figure 1). These results indicate that an alane breach-in-tank event may present a minimal hazard during an accident. Of course, this analysis is specific to this formulation of alane and the characteristic tank geometry.

Other materials may be much more reactive compared to the alane system. Catalyzed sodium alanates, for example, are materials that represent a prototypical alkali-metal containing complex metal hydride. Our experimental measurements utilizing our contamination flow-through reactor show that catalyzed sodium alanates and their decomposition products are significantly more reactive. Exotherms in excess of 100°C are sustained for nearly 250 s upon exposing a 300 mg sample of hydrogen-depleted material to dry air. Analysis of the products indicates the formation of sodium hydroxide (NaOH) at these temperatures. Mitigation technologies to reduce the extent and rate of reaction during the breach-in-tank scenario are considered below.

Fire Impingement Scenario Modeling - Exposure to a pool fire is one of the potential scenarios associated with solid-state hydride storage systems that might result from a vehicle accident.

The sodium alanate containing system provides an opportunity to observe the processes of a complex hydride during exposure to a pool or impinging fire. For
this system, it is assumed that the formation of sodium metal due to overheating is the outcome requiring management. Using measured heat transfer, mass transfer, and chemical kinetics, an axisymmetric model was assembled for analysis (Figure 2). The results show that a thin desorption front develops in the sodium alanate starting at the outer tube wall, which is heated directly by the fire, and then propagates radially inward. The calculations account for the rapid desorption of the sodium alanate resulting from the fire. Assuming that sodium metal would begin to form at near 350°C, the unshielded case achieves this temperature very quickly, after 180 s. A small amount of shielding (a thin air gap formed by a metal plate) extends this over-temperature event to 300 s – providing good management of the over-temperature hazard. Similar analysis can be performed for a variety to materials, such as alane or interstitial hydrides, to manage the resulting over-temperature or over-pressure hazard. The pool fire scenario may be one of the more important safety design considerations for metal hydride containing systems. This effort scopes details such as pressure relief device and insulation design characteristics required to allow for an adequate delay in loss-of-containment during an accident scenario.

**Mitigation Technology Development** – Towards the goal of mitigating and managing the hazards presented by solid state storage systems, we have demonstrated the ability to polymerize vinyl monomers in the presence of complex metal hydrides, sodium alanates and produce composite materials.

Composite materials were made with 10–20 wt% polymer. Characterization of the composite polymer/metal hydride material was done by scanning electron microscopy and thermal methods. Figure 1 and the accompanying energy dispersive spectrum (EDS) analyses show that the polymer is intimately mixed with the metal hydride particle. The inorganic portion was identified by the strong Na, Al and O signals in the accompanying EDS. The polymer surrounding the inorganic material was identified by the absence of Na and Al signals and the shoulder at low energy for carbon, C. Thermal analysis of composite materials compared to free sodium alanate suggests slower kinetics for mass-transport properties of the melted metal hydride above 150°C.

To test the mitigating properties of the polymer supported material, 360 mg of the polymerized material were analyzed using flow-through calorimetry. The
exotherm resulting from dry gas exposure at 200°C and 0.1 SLPM air was compared to the un-mitigated “neat” material results (Figure 3). It was observed that the energy release was reduced by nearly 70%, indicating that a significant portion of the sample was excluded from oxidation. This was confirmed by product analysis indicating very little formation of NaOH in the mitigated sample compared to the un-mitigated sample. In parallel, catalyzed and supported samples of sodium alanate were hydrogen cycled. Initial results indicate that hydrogen uptake/release is not significantly hindered and even at high cycles (in excess of 30 hydrogen sorption cycles executed). The cycled material was then analyzed by thermal gravimetric analysis (TGA). Results show that the cycled material has an 11% weight loss upon heating, similar to the uncycled material. Our conclusion from this study is that the polymer matrix withstands at least 30 cycles of charging with no indication in loss of polymer matrix.

To optimize the structural properties of the material, the cross-linking density of the added polymer has been varied to determine the effect on mechanical properties. Monomer/cross-linker ratios of 10:1 to 1:1 have been explored. Our results show that with higher cross-linker ratios, the composite materials are more brittle and are easily crushed into a powder. In contrast, the composite materials with a lower cross-linker ratio (10:1 monomer/cross-linker) give very hard solids that are not easily crushed into powders. Little change in decomposition behavior is observed despite large structural properties changes. TGA of the composite materials in argon shows polymer decomposition occurring above 220°C with approximately 11–12 wt% loss (Figure 4). This mass loss is expected since significant char formation occurs in cross-linked polymer networks upon thermal decomposition.

Conclusions and Future Directions

- This project has developed the tools and understanding for eventual codes and standards development and market penetration of metal hydride systems.
- Over-temperature and over-pressure events caused by exposure to air or fire are hazards that need to be managed to enable the widespread utilization of advance hydrogen storage materials.
- Mitigation technologies are being developed that are able to:
  - Contribute a small weight penalty
  - Withstand hydrogen cycling
  - Mitigate unfavorable reactions
  - Structurally support fine reactive solids
- Future work will focus on:
  - Optimization of composite materials
  - Validation at full-scale
  - Enabling design-for-safety of advanced storage systems

E-mail: Carole.Read@ee.doe.gov

Project Start Date: February 7, 2007
Project End Date: Project continuation and direction determined annually by DOE

Objectives

• To prepare a reference document detailing best practices and limitations in measuring hydrogen storage properties of materials.
• The document will be reviewed by experts in the field (International Energy Agency/International Partnership for the Hydrogen Economy, etc.).
• The final document will be made available to researchers at all levels in the DOE hydrogen storage program.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(C) Efficiency
(D) Durability/Operability
(E) Charging/Discharging Rates
(J) Thermal Management
(Q) Reproducibility of Performance

Technical Targets

The goal of this project is to prepare a reference document detailing the recommended best practices and limitations in making critical performance measurements on hydrogen storage materials. This reference document will provide a resource to improve the accuracy and efficiency of critical measurements to aid the projects and ultimately the entire program to achieve or exceed the technical storage targets.

In particular this project is focused on the following target-related performance measurements:

• Kinetics (Targets: system fill time for 5-kg hydrogen, minimum full-flow rate and start time to full-flow).
• Capacity (Targets: gravimetric and volumetric capacity).
• Thermodynamic Stability (Targets: maximum/minimum delivery pressure of H₂ from tank and impact on capacity and kinetic related targets).
• Cycle-Life Properties (Targets: cycle life and cycle life variation).

Accomplishments

• Established new collaborations with: Université Paris-Sud, Texas A&M University, Los Alamos National Laboratory, VU University Amsterdam/Delft University of Technology and University of Nevada, Reno.
• Compiled example measurements from the literature, to illustrate key issues associated with the four tasks outlined above.
• Performed example measurements to illustrate key issues associated kinetics and other measurements.
• Contributions to this project from world experts have been received including written materials, examples, presentation or editorial review of draft documents.
• Final Introduction section 100% complete.
• Final Kinetics section 100% complete.
• Final Capacity section 100% complete.
• Draft Thermodynamic section in progress 85% complete.
IV.E Hydrogen Storage / Storage Testing, Safety and Analysis

- Draft Cycle-Life Properties section in progress 50% complete.

Introduction

The Hydrogen Storage sub-program goal is the development of hydrogen storage materials that meet or exceed the DOE’s targets for the onboard hydrogen storage in a hydrogen-powered vehicle. The growth of research efforts in this field and new approaches to solving storage issues has brought the talents of a wide-range of researchers to bear in solving the grand challenge of hydrogen storage. There is a need to have common metrics and best practices for measuring the practical hydrogen storage properties of new materials that are being developed within the Hydrogen Storage sub-program as well as at an international level. H2 Technology Consulting is tasked with creating a clear and comprehensive resource that will provide detailed knowledge and recommendations for best practices in the measurements of these properties.

Approach

This project is a combined approach of documenting the experience the principal investigator and other experts in the field have with these measurement, incorporating examples from the literature, performing experimental measurements to demonstrate important issues, and finally, condensing key information into a concise reference guide. Each section covers such topics as the overall purpose of the measurements, some basic theory, experimental consideration, methods of measurement, and many details on both material properties and experimental factors that may strongly influence the final results and conclusions. Participation from other experts in the field is being sought out for input, relevant examples, and critical review at all levels.

In Fiscal Year (FY) 2010 sections of the document were reviewed by many experts from around the world. We greatly appreciate the collaborative efforts of all of the reviewers: Dr. Thomas Gennett of the National Renewable Energy Laboratory, Dr. Gary Sandrock and Dr. George Thomas, consultants to the U.S. Department of Energy, Dr. Michael Miller of Southwest Research Institute®, Dr. Anne Dailly and Dr. Frederick Pinkerton of General Motors R&D Center, Dr. Ole Martin Løvvik of the Institute for Energy Technology in Kjeller, Norway, Dr. Eric Poirier of NRC Canadian Neutron Beam Centre Chalk River Laboratories, Professor Channing Ahn of the California Institute of Technology, Dr. Kevin Ott, Dr. Anthony Burrell, and Dr. Troy Semelsberger of Los Alamos National Laboratory, Professor Richard Chahine, Université du Québec à Trois-Rivières, Professor Klaus Yvon, University of Geneva, Professor Sam Mao of the University of California, Berkeley, and Dr. Nobuhiro Kuriyama and Dr. Tetsu Kiyobayashi of the National Institute of Advanced Industrial Science and Technology in Osaka, Japan. In addition, the work has been coordinated and has received important scientific input through our contract monitor Dr. Phil Parilla at the National Renewable Energy Laboratory.

Results

The second task in this project focused on creating a best practices document for capacity measurements. This has been completed reviewed and public commentary has be received and addressed. The final version including a preface, introduction, kinetics and capacity measurement sections is now posted on the DOE Web site.

In addition, this year’s work covered the Thermodynamics and Cycle-Life measurements sections of the “Best Practices” document. For this work collaborations were established with the following contributing authors: Pierre Dantzer, Université Paris-Sud, Shengqian Ma and Hong-Cai Zhou, Texas A&M University, Kevin Ott, Tony Burrell and Troy Semesbgerger, Los Alamos National Laboratory, Yevheniy Pivak and Bernard Dam, VU University Amsterdam and Delft University of Technology and Dahnesh Chandra of the University of Nevada, Reno. Through these collaborations the document has added perspectives of critical measurement issues from the three main materials research areas: on-board rechargeable hydrides, off-board regenerable hydrides, and hydrogen physisorption storage materials.

Examples are included below of important considerations when making thermodynamic measurements. Figures 1 shows the classic conversion of pressure-concentration-temperature (PCT) isotherms of a reversible hydride to a van’t Hoff plot for the determination of the enthalpy and entropy of hydride formation.

This simplified example does not take into consideration, irreversibilities that lead to hysteresis between absorption and desorption measurements. It also depicts the thermodynamic behavior a highly ordered crystalline material as opposed to real materials which range from some structural defects, may also include multiple partial substitutions, to fully amorphous materials. As an example of this, Figure 2 shows...
The heat of reaction in storing hydrogen in a hydride consists of the heats of hydrogen solution as well as hydride formation. In this respect the total heat produced (as measured by calorimetry) will not necessarily be the same as the enthalpy of hydride formation (as measured by the van’t Hoff method). Figure 3 depicts the complete hydrogen absorption of a material where hydrogen is absorbed first in solution, then forms a hydride and finally further dissolution of hydrogen into the hydride. In this sense, the Van’t Hoff measurements based on plateau pressures only are useful in comparing the stability differences between hydrogenated compounds, however they may not fully represent the heat produced (or required) in real hydrogen storage applications.

With physisorption storage materials, the determination of isosteric heat of adsorption for hydrogen is an important aspect of characterizing the potential of porous materials for on-board hydrogen storage applications. By drawing the In pressure vs. 1/temperature plot of H₂ at various hydrogen concentrations, the isosteric heat of adsorption can be determined (Figure 4).

Conclusions and Future Directions

In FY 2010 we were able to establish important collaborations and technical assistance from experts in the field. We were able to complete the final version of the Capacity section in a timely manner. We are currently working on the Thermodynamic and Cycle-Life measurement sections. We expect to complete the draft version these sections in this fiscal year.

Objectives

- Synergistic work between Yaghi (UCLA) and Goddard (California Institute of Technology [Caltech]).
- Build high-throughput preparation setups for covalent-organic framework (COF) synthesis (high temperature and pressure).
- Develop chemistry to realize stable frameworks.
- Introduce potential metal binding sites through the COF synthesis.
- Determine atomistic connectivity of COFs using an ab initio charge-flipping method using powder X-ray diffraction (PXRD) data.
- Predict adsorption enthalpy of H₂ on various metal sites.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(C) Efficiency
(E) Charging/Discharging Rates

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

This project consists of conducting fundamental studies of COFs. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2015 hydrogen storage targets:

- Volumetric density: 40 g L⁻¹
- Gravimetric density: 5.5 wt%

Accomplishments

- Build high-throughput preparation setups.
- Develop structural determination technique using ab initio charge-flipping method.
- Synthesis of new COFs through hydrazone condensation.
- Began modeling study for optimal binding energy.

Introduction

Storage of hydrogen in porous materials is a promising approach to achieve the DOE system requirements for use of hydrogen as a transportation fuel. Since the first report of successful hydrogen storage in metal-organic frameworks (MOFs), we and others have succeeded in incrementally increasing the gravimetric and volumetric capacities to reach the highest hydrogen uptake capacity, albeit at 77 K. However, for on-board vehicular hydrogen storage it is necessary to improve the adsorption enthalpy of porous materials to achieve significant capacities at room temperature. We are therefore undertaking efforts to discover highly porous materials with strong affinity for hydrogen.

Approach

To meet the DOE 2010 targets by physisorption, adsorbents must have high surface area (>3,500 m² g⁻¹) and relatively high density (>0.75 g cm⁻³). We have already demonstrated how to design high surface area MOFs and COFs; however, in many cases, these materials do not show steep H₂ uptake in the low pressure region indicative of the weak interaction with
Hydrogen Storage / New Materials-Independent Projects

Yaghi – University of California, Los Angeles

It is predicted that the impregnation of COFs with metals should enhance the adsorption enthalpy; therefore, we explore methods for the preparation of metalated COFs using high-throughput techniques. In this fiscal year, we developed a new class of COFs for metal impregnation and applied an ab initio charge-flipping method for structural analysis.

Results

Metal impregnation is one of the most promising strategies to improve the adsorption enthalpy of COFs. However, before the metal impregnation experiments, it is necessary to prepare stable COFs, and it is preferable to introduce metal binding sites in the framework through the condensation reaction. To this end, we designed and prepared new COFs having hydrazone and imine moieties. In addition, we applied a new technique to the structural analysis of COFs, which can be useful in determining the structure from low-resolution PXRD data. With regard to the simulation calculations, we demonstrated a method based on accurate quantum mechanics that allows us to screen different metal complexes to determine the enthalpy of adsorption at 298 K and 1 atm. We proposed a way to tune the $H_{ads}$ based on the degree of metalation of our linkers.

1. Synthesis of Crystalline Hydrazone COF (UCLA)

We have developed the synthesis of new COFs constructed from the dehydration of aromatic carbohydrazides and aldehydes to form carbohydrazones (Figure 1A). This functional group shows interesting features such as the presence of both of amides and imines, resulting in materials with high thermal and chemical stability as well as dynamic reversibility forming libraries of polymers that exchange monomers in solution; moreover, hydrazones possess both carbonyls and nitrogen atoms that can be available for metal coordination/impregnation. An additional advantage for the synthesis of hydrazide-based materials is the easy synthesis of the hydrazide building blocks, which are prepared from the condensation of hydrazine and a carboxylic acid ester in refluxing alcohols with high yields.

A new COF, termed COF-41 was crystallized by reacting terephthalohydrazide with 1,3,5-tris(4-formyl-phenyl)-benzene through solvothermal conditions in mesitylene/dioxane/acetic acid/water mixtures (Figure 1A). The formation of the hydrazone linkages was determined by solid state Fourier transform infrared (FTIR) and $^{13}$C nuclear magnetic resonance (NMR) of synthesized COF-41, starting materials, and model compound $N'$-benzylidene-benzohydrazide. The FTIR spectrum of COF-41 shows the characteristic C=N vibrational modes at 1,558 and 1,273 cm$^{-1}$ (1,550 and 1,288 cm$^{-1}$ in model compound). The solid-state $^{13}$C NMR spectrum shows a chemical shift for the C=N of 149.2 ppm, compared to shifts of 150.2 ppm for the model compound and 192.5 ppm for the aldehyde in the starting material. The crystallinity of COF-41 was confirmed by PXRD from which the diffraction peaks were indexed into a primitive hexagonal unit cell ($a = 43.52$ Å, $c = 3.62$ Å) and compared to simulated patterns from crystal models of hexagonal layers packing in bnn (eclipsed) and gra (staggered) topologies.

In order to ascertain the correct structure, we performed porosity studies in which information such as surface area and pore size distribution will confirm one structural model or another. Preliminary porosity measurements on COF-41 (Figure 1B) give the Brunauer-Emmett-Teller (BET) surface area of 110 m$^2$ g$^{-1}$ with a Type IV isotherm, characteristic of a mesoporous material. It seems that the obtained surface area was smaller than that of ideal value; therefore, we plan to optimize the synthetic and sample activation conditions.

2. Synthesis of Porphyrin Containing COF (UCLA)

In the pursuit for the preparation of a material in which different metals can be inserted, we are exploring the synthesis of COFs containing porphyrin rings. Porphyrin is a well-defined molecule and much effort has been devoted to study nature of metal substituted porphyrins. Therefore, we implemented the imine condensation of tetra(4-aminophenyl)porphyrin with terephthaldehyde to obtain a new...
porphyrin COF (termed COF-366, Figure 2A) whose condensation manor is the same as COF-300 [1]. COF-366 was prepared by the following procedure: tetra(4-aminophenyl) porphyrin and terephthalaldehyde in a solvent mixture of ethanol/mesitylene/acetic acid were placed in a pyrex tube. The tube was sealed at 77 K and under vacuum, and heated at 120°C for three days. The obtained purple powder was washed with absolute ethanol and immersed in anhydrous tetrahydrofuran for 24 h. The solvent was removed under vacuum at room temperature, yielding a porous material (yield: 79% based on the porphyrin).

A PXRD pattern of COF-366 showed an intense peak at 3.5° matching the unit cell of the simulated crystal, indicating that the distance between neighboring porphyrin rings is roughly 25.6 Å. It is likely that the connectivity of obtained COF has a sql topology (i.e. 4,4-grid type layered material). However, it is not clear if the layers are piled by an eclipsed fashion based on the PXRD data. We will discuss this point later in conjunction with gas adsorption measurements.

This solvent exchanged sample was activated on a supercritical CO2 dryer to obtain porous crystalline solids. The Langmuir and BET surface areas of COF-366 were estimated based on the N2 isotherm measured at 77 K (1,270 and 990 m2 g⁻¹, respectively). It should be noted that the profile of the isotherm is classified into Type I. If the sample has a one-dimensional channel, the isotherm should show a significant step around \( P/P_0 = 0.1 \) to 0.2, because the distance between neighboring porphyrins (\( >20 \) Å) will be large enough to cause micropore filling of \( \text{N}_2 \). The lack of step in isotherms implies that the porphyrin layers are staggered, leading to the micropore. We also tested low-pressure \( \text{H}_2 \) uptake capacity for COF-366 (Figure 2B). The \( \text{H}_2 \) uptake at 1 bar and 77 K is 1.0 wt%. Based on the 77 and 87 K isotherms, the \( Q_{st} \) was estimated. Calculated \( Q_{st} \) at the zero coverage (6.6 kJ mol⁻¹) is better than other COFs (COF-1, 5, 10, 102, 103) except COF-6 (7.0 kJ mol⁻¹). To improve the number, we plan to perform a metalation reaction.

3. Pore Structure from Low-Resolution PXRD Data (UCLA)

One of the difficulties in the COF projects is precise structure determination. Since COFs are synthesized by a condensation reaction of organic materials, it is possible to predict the connectivity of these building units. However unlike MOFs, COFs are comprised of light elements; therefore, obtained PXRD patterns may not provide enough diffraction lines and resolutions to resolve the structure. Indeed, we have encountered the problem when we prepared COF-300 [1]. Recently, ab initio charge-flipping method was developed [2,3]. In this method, unit cell parameters are required (i.e. hkl indices with intensity); while no information related to the connectivity and space group is necessary. Since it can be possible to determine the atomistic connectivity based on the PXRD data, we applied this technique to solve the COF structure.

Originally, we tried to solve the structure of as-synthesized COF-300, because the degree of interpenetration is not clear. However, due to the disordered solvent molecules, we could not obtain meaningful result. Therefore, we used activated COF-300. Figure 3 demonstrates the PXRD pattern of COF-300. We refined the pattern with 2-Å resolution. Using obtained hkl information (including intensity of each diffraction), electron density map was generated on Superflip [3]. Figure 3 (left) demonstrates the electron density map for COF-300 along the c-axis. As we expected, square channel was observed, and the dimension of the pore is almost identical to the space filling model of COF-300.

For the structure determination, reasonable resolution (preferably shorter than bond distance) and intense diffraction lines (at least 10 lines, although it depends the space group) are required. So far, we could not solve COF-366 structure due to the insufficient X-ray diffraction pattern. However, we believe that
pore structure should be revealed when a better PXRD pattern is obtained.

4. Interaction Energies for Imine COFs (Caltech)

We performed ab initio quantum mechanics to investigate the interaction of the H₂ molecules with different building blocks for potential COFs. We decided to use density functional theory (DFT) at M06 level which has been shown to predict accurately interaction energies for non-covalent interactions [4,5] including that of H₂. We used the algorithm as implemented in Jaguar 7.0 [6] using the LACVP basis set.

We chose the structures shown in Figure 4, because we found similar building blocks in the literature that have been synthesized and are reported in the Cambridge structural database [7]. We chose the metals in the light on the easiness of synthesis and handling; such as, Cu, Pt, Cu, and Zn. We also propose to use some other lighter early transition metals like Cr, Mn, Fe, Co, and Ni that given the lighter mass character can help us in gravimetric units. The reasoning behind selection of such targets is that we want the metal site to interact as direct as possible with H₂ molecules, so we chose metal that can form square planar or tetrahedral geometries.

Using our DFT-MO6 method we calculated the adsorption enthalpy ($H_{ads}$) at 298 K and 1 atm (Figure 4, right). From these calculations, the best performers are Cu, Pt, Co, and Zn (i.e., Models P, N, G, A, and J, respectively). The $H_{ads}$ of these complexes are greater than 15 kJ/mol, but these values are still below threshold interaction energy for an optimal H₂ adsorption.

It is worth noting that the degree of metalation is directly related to the value of $H_{ads}$. This can be seen when we compare similar models such as: B vs. F, C vs. G. This is more obvious when comparing D vs. E and L vs. P, where the $H_{ads}$ increased by roughly 5 and 10 kJ/mol, respectively. Considering that the similar trend (addition of more metals to the complex improves the $H_{ads}$) is presented in other systems, it can be said that the H₂ near the metal complexes is stabilized by metals. This behavior can be potentially used to tune the $H_{ads}$ and obtain a desirable system with the adequate degree of soft chemisorption. We can keep increasing our $H_{ads}$ in systems such as models I to P.

Conclusions and Future Directions

This year we experimentally demonstrated how to connect di-, tri-, and tetra-topic building units through condensation reactions (i.e. hydrazone, imine, and boronate COFs). Since the atomistic connectivity and pore structure can be predicted based on the reticular concept, we plan to find candidates for metalation reactions of COFs through modeling studies. In addition, we will predict the binding energy between H₂ and metal unit.

- Material design assisted by the reticular synthesis.
- Theoretical prediction of the binding energy between H₂ and metalated COFs.
- Employ metals to create strong binding sites.
- Supercritical CO₂ drying to optimize the porosity.

Special Recognitions & Awards/Patents Issued

IV.F.2 New Carbon-Based Porous Materials with Increased Heats of Adsorption for Hydrogen Storage

Technical Targets
- This project is developing and testing new materials for hydrogen storage. These new materials can be applied in the future in the design of hydrogen storage systems that meet the following DOE 2010 hydrogen storage targets:
  - System Gravimetric Capacity: 1.5 kWh/kg = 0.045 kg H\(_2\)/kg system
  - System Volumetric Capacity: 0.9 kWh/L = 0.028 kg H\(_2\)/L system

Accomplishments
- Synthesized a new MOF that exhibits an 11 kJ/mol heat of adsorption for hydrogen. As a comparison, note that unfunctionalized MOFs and carbon-based sorbents typically have hydrogen heats of adsorption around 4-5 kJ/mol. Modeling from several groups indicates that heats of 15-20 kJ/mol will be required to meet DOE hydrogen storage targets.
- Synthesized a variety of new POFs, some with surface areas over 1,500 m\(^2\)/g. These materials have functional groups that can be tailored to increase the hydrogen heat of adsorption. One material synthesized has a hydrogen heat of adsorption of 8 kJ/mol before functionalization.
- Used molecular modeling to rule out catenation as a viable strategy for achieving room temperature hydrogen storage targets in unfunctionalized MOFs.
- Developed a model for MOFs containing alkoxide groups. Identified alkaline earth alkoxides as promising synthetic targets.
- Computationally constructed and subsequently experimentally synthesized a MOF material showing: a) record-high gravimetric uptake of H\(_2\) under cryogenic (77 K) conditions (99.5 mg excess H\(_2\) per g of MOF; 164 mg total H\(_2\) per g of MOF at 70 bar) and b) record-high Brunauer-Emmett-Teller surface area (6,500 m\(^2\)/g [modeled]; 6,200 m\(^2\)/g [measured]).
- Showed that a recently published claim of 6 wt% uptake of H\(_2\) by a comparatively low-area POF material is in error.

Introduction

One option for storing hydrogen on vehicles is to use tanks filled with porous materials that act as
“sponges” to take up large quantities of hydrogen without the need for extremely high pressures. The materials must meet many requirements to make this possible. This project is developing two related classes of porous materials to meet these requirements. All materials are synthesized from molecular constituents in a building-block approach. This allows us to create a wide variety of materials in a tailorabilf fashion. The materials have extremely high surface areas, to provide many locations for hydrogen to adsorb. In addition, they are designed to contain cations that create large electric fields to bind hydrogen strongly but not too strongly.

Approach

The approach in this project is to introduce cations into MOFs and POFs to increase the hydrogen heats of adsorption, which will, in turn, increase the amount of hydrogen that can be stored near room temperature. Many MOFs have enough surface area to meet the DOE hydrogen storage targets if the entire surface were covered with a monolayer of hydrogen. However, at room temperature, the energetic interactions between hydrogen and the surfaces are too weak to bind hydrogen. Thus, we are focused on increasing these energetic interactions. A variety of synthetic chemistries are being explored to increase the chances of success. In addition, molecular modeling is used to help explain experimental observations and provide guidance to the synthetic efforts.

Results

We designed and synthesized the first two examples of unique zwitterionic MOF materials (2H-BTBA and 2Br-BTBA). These materials are permanently microporous and feature fixed cationic sites on vertical struts and fixed anionic sites on horizontal struts. Together the struts (and associated metal nodes) define cavities having sizable electric fields. We reasoned that these cavities might stabilize polarizable molecules (dihydrogen has a small, but finite, polarizability), resulting in enhanced heats of adsorption. As shown in Figure 1, the limiting (low pressure) isosteric heat of adsorption is 11 kJ/mol for H₂ uptake by 2H-BTBA. To our knowledge, this is the first time the zwitterionic concept has been proposed or explored for enhancing framework/gas interactions.

Figure 2 shows the behavior of a new ultra-higharea MOF that was computationally characterized prior to experimental synthesis. Importantly, the computational studies promised record-high uptake of hydrogen by the new material (at 77 K). Using a supercritical activation methodology pioneered at Northwestern we were able to access essentially all of the MOF interior, i.e. little, if any, framework collapse or blockage occurred. The activated MOF exhibited, as predicted, exceptionally high hydrogen uptake. Ultimately, to reach desired ambient-temperature hydrogen storage goals, it will be important to combine the findings here with the advances we are making in the area of improvement of heats of adsorption.

We have synthesized an important new variant of a well-known single-channel MOF. The variant features substituent alcohols that are amenable to conversion to metal alkoxides. We anticipate that this new MOF will enable us to test our computational predictions regarding enhanced interactions between H₂ and MOF components.
We have developed two new families of microporous POFs. The first family of POFs (imine-linked) were synthesized via Schiff base condensation between 1,3,5-triformylbenzene and several readily available diamine monomers. Our facile, one-pot approach results in quantitative yields (~90%) of POFs with the flexibility to incorporate several functional groups in their pores for tuning the interaction of their surface with different guest molecules.

We initially prepared POFs using *para* diaminobenzene and *meta* diaminobenzene. Because the specific surface area of the POF prepared using *meta* diaminobenzene (POF-2) was higher than the POF prepared using *para* diaminobenzene (POF-1), we focused on *meta* diamines as the amine building blocks most likely to give rise to materials with high surface areas. We also optimized the reaction conditions to maximize surface area and micropore volume. A surface area of 1,063 m² g⁻¹ (POF-2) was initially obtained by combining monomers at the beginning of the reaction. Notably, slowly adding amine monomer to a solution of aldehyde monomer significantly increased this surface area by ~50%, to 1,521 m² g⁻¹ (POF-3), which is the highest specific surface area obtained among our synthesized POFs. POF-3 was found to possess H₂ adsorption capacity of 1.5 wt%, at 1 bar and 77 K and a good isosteric heat of H₂ adsorption of 8.2 kJ mol⁻¹ at low coverage (Figure 3a). In addition, the H₂ adsorption measurement performed for this POF, at high pressures and 77 K, shows an increase in H₂ uptake with the increase in pressure giving maximum H₂ uptake of 4.3 wt% at 70 bar (Figure 3b). Pore size distribution analysis for POF-3, performed using non-local density functional theory, confirms a primary pore width of 6 Å. Interestingly, even though the synthesized POFs are amorphous, their pore size distributions are not wide.

The second POF family is based on reaction between phloroglucinol and aldehydes. This is a straightforward reaction that produces highly cross-linked polymers. The polymerization took place under solvothermal conditions using dioxane as solvent at 220°C producing solid materials in high yield (~90%). These synthesized POFs contain large numbers of hydroxyl groups which are available for functionalization. All these POFs are microporous materials, and they exhibit specific surface areas from 600 to 900 m² g⁻¹ and a main pore width of 6 Å. Scanning electron microscope images of POF-4 show spherical particles with smooth surfaces in the range of 1–3 μm. Phloroglucinol POF samples were tested for H₂ adsorption at 77 and 87 K up to atmospheric pressure (Figure 4a). POF-4 shows H₂ uptake of 1.25 wt%; POF-5 and POF-6 show uptake of 1 wt%. Heat of H₂ adsorption is estimated to ~8.3 kJmol⁻¹ at low coverage for all samples (Figure 4b).

A rather astonishing experimental and computational report of very substantially enhanced uptake of H₂ by a permanently microporous, organic framework material appeared earlier this year in the literature (*Angew. Chem., Int. Ed.* 2010, 49, 3330-3333). The report was remarkable on three counts. First, doping with a very small amount of lithium led to a quadrupling of hydrogen uptake. Secondly, the material features only a modest internal surface area – raising the question of how the material could imbibe such large amounts of H₂. Thirdly, we had previously examined a related material (unpublished) but not encountered the spectacular enhancements reported in the new article. While we have previously described large lithium-based enhancement effects upon sorption of hydrogen by three MOF materials, the mechanism invoked to account for the MOF results is inapplicable to the new POF material. Follow-up work in our labs has now clearly established that the stunning new results described in
Using classical grand canonical Monte Carlo (GCMC) simulations, hydrogen storage and delivery in eight representative MOFs was investigated. The simulations demonstrate that the optimal isosteric heat of adsorption (Qst) for maximum hydrogen delivery using MOFs is approximately 20 kJ/mol. We considered the delivered hydrogen as the amount adsorbed at 120 bar minus the amount adsorbed at 1.5 bar. The results also suggest that increasing Qst for MOFs with large surface areas is required to attain current hydrogen storage targets in terms of deliverable capacity. Using the same model, hydrogen adsorption isotherms in 20 MOFs were obtained from GCMC simulations and used to develop quantitative correlations to quickly estimate the H₂ uptake of MOFs at 120 bar from the free volume of the adsorbent. These correlations were subsequently validated with a diverse set of 22 MOFs that were not used in developing the correlations.

We also used classical GCMC simulations to assess whether catenation is a viable strategy for meeting DOE hydrogen storage targets. We simulated hydrogen uptake in a series of catenated MOFs along with their non-catenated counterparts. The MOFs were chosen to cover a wide range of pore sizes and free volumes. The results indicate that catenation does increase the heats of adsorption, as expected. However, the effect is not enough, at room temperature, to compensate the loss of free volume that also arises from catenation. These results indicate that catenation is not a viable strategy for meeting room temperature hydrogen storage targets in unfunctionalized MOFs. Strong binding sites that increase the heats of adsorption will be required. These calculations support the main premise of this project.

Finally, we have developed a model for simulating hydrogen uptake in MOFs containing alkoxide groups. MP2 calculations with a large basis set (6-311+G**) were performed for a hydrogen molecule in 200 different geometries near the alkoxide group, and these energies were fit with a combined Morse + Coulomb + Lennard-Jones potential. Models were developed for a range of metal alkoxides, including Na, Li, Mg, and some transition metals. GCMC simulations have been performed using these models to predict the hydrogen adsorption isotherms. In addition, the Second-order Møller-Plesset perturbation theory calculations provide useful details of the orbitals involved in the hydrogen-metal interactions. There has been much attention in the literature on Li-functionalized MOFs, but our calculations indicate that Mg provides a larger enhancement in hydrogen uptake. Based on these calculations, synthetic efforts in the group are now focused on Mg alkoxides in addition to Li.

**Conclusions and Future Directions**

**Conclusions**

- Multiple strategies have now been demonstrated in our labs for introducing sites into MOFs that increase hydrogen heats of adsorption, including framework reduction, alkoxide formation, and zwitterionic cavities. These provide a powerful platform for tailoring MOFs to increase the heats of adsorption toward meeting DOE hydrogen storage targets.
- One MOF synthesized in our labs exhibits an 11 kJ/mol heat of adsorption for hydrogen.
- A variety of new POFs, some with surface areas over 1,500 m²/g, have been synthesized in this project. These materials have functional groups that can be tailored to increase the hydrogen heat of adsorption. One material synthesized has a hydrogen heat of...
adsorption of 8.3 kJ/mol at low coverage before functionalization.
- We showed that a remarkable new claim in the literature of 6 wt% uptake of hydrogen by a comparatively low-area POF material is, in fact, in error.
- Catenation is not a viable strategy for achieving room temperature hydrogen storage targets in unfunctionalized MOFs.
- A new MOF displaying record-high internal surface area and record-high (cryogenic) uptake of H₂ (total H₂ of 14.4 wt%) has been synthesized.
- Modeling indicates that alkaline earth cations may be more promising than alkalis for increasing hydrogen heats of adsorption in alkoxide-containing MOFs.

Future Directions
- Synthesis of Mg and other alkaline earth alkoxide MOFs.
- Characterization of a new “framework reducible” MOF designed to localize added dications (i.e. alkaline earth and transition-metal species) on the reduced strut, rather than at comparatively inaccessible metal-carboxylate node sites.
- Functionalization of POFs, especially with alkaline and alkaline earth alkoxides.
- Initiation of POF synthesis using “click” chemistry.
- Combination of strategies for introducing cations into MOFs and POFs and strategies for producing MOFs and POFs with very large surface areas.
- Modeling of additional metal-substituted MOFs.
- Modeling of POFs.

IV.F.3 Hydrogen Trapping through Designer Hydrogen Spillover Molecules with Reversible Temperature and Pressure-Induced Switching

Objectives

- Synthesize designer microporous metal-organic frameworks (MMOFs) mixed with catalysts to enable H-spillover for H₂ storage at 300 K to 400 K and moderate pressures.
- Adapted volumetric measurements to enable rapid screening tests (RSTs) at high-pressure, towards Go/No-Go decision point. Validate RSTs against published activated carbon and spillover materials at P<80 bar and 298 K.
- Use RST to down-select MMOFs and determine effect of structure and surface chemistry.
- Explore methods for pressure-induced hydrogen/gas trapping.

*Meets or Exceeds Benchmark for PtC/IRMOF8 in Ref. 1.
†Reproducibility Measurements, four measurements
‡Increased mixing intensity relative to b

Accomplishments

- A total number of eight MMOFs synthesized, with variations in surface chemistry and porosity.
- RST was developed and validated against published data for GX-21 activated carbon. Propagation of error and reproducibility measurements insured precision of method and demonstrated effect of preparation conditions when mixing with standard catalyst.
- IRMOF-8 with Pt/C confirms literature data; multiple tests indicate reproducibility of volumetric RST method and track how subtle variations in synthesis leading to increased/decreased uptake.
- PtC/CuBTC and PtC/IRMOF8 showed importance of preparation conditions: pretreatment, handling, mixing, and gas exposure are key parameters to ensure reproducibility.
- Oxygenated ligand exceeds uptake of IRMOF-8 benchmark with rapid initial uptake.
- On-going development of models to understand P-switching behavior and validate experiment with theory.
Introduction

The term hydrogen spillover has been used to describe a synergistic effect between high-surface area adsorbents and associated catalysts. The associated catalyst may act to dissociate molecular H\textsubscript{2} into atomic H species. The atomic H is then free to migrate to surface sites on the high-surface area support; the net surface H concentration is a function of the relative rates of surface migration versus desorption from the surface. This process increases the active adsorption temperature of the high-surface area adsorbent and generally leads to a much higher uptake than expected for the metal catalyst alone. To date, hydrogen storage reports for spillover systems suggest moderate temperature adsorption (i.e. 300 K) can be achieved, with uptake approaching DOE goals at 298 K and 100 bar. The highest uptake reported for spillover materials has utilized MMOFs as the receptor for spilled over hydrogen: bridged (‘br’) PtC/IRMOF8 achieved 4 wt% excess adsorption at 100 bar and 298 K [1]. Independent groups have demonstrated up to 4.2 wt% at 6.9 MPa after extended equilibration for brPtC/IRMOF8 [2]. As the process is highly dependent upon synthesis, measurement, and catalytic particle size, [3,4] the process remains poorly understood. It is anticipated that optimization of the MMOF structure, surface chemistry, and porosity will further increase uptake via spillover. Meeting DOE hydrogen storage targets at moderate temperature will have significant engineering advantages for mobile applications, as temperature of operation has implications for system weight.

Approach

The project relates to materials development and optimization of surface chemistry, crystal and pore structure, catalyst, and system parameters for the hydrogen spillover phenomenon. In this stage of the project, we are screening materials against benchmark spillover data for brPtC/IRMOF8 mentioned above. Our current gravimetric goals are relative to this benchmark in the literature, with the assumption that bridging will further improve excess adsorption to bring total uptake to DOE goals. Prior to bridging, the PtC/IRMOF8 material had 1.4 wt% and 1.8 wt% of hydrogen uptake at 298 K and 80 and 100 bar, respectively [1]. Other relevant literature data listed in Table 1 include variation of MMOF structures in Ref 5. The project is currently exploring materials without bridging, as bridging has unknown effects on the surface chemistry and structural parameters we hope to optimize. The project is currently using secondary spillover studies such that the catalyst, or H species ‘supply’, remains constant in order to independently determine the effect of MMOF structure. A later phase will explore direct incorporation of catalytic sites into the MMOF structure for further optimization of the hydrogen spillover process. As spillover equilibration times may be significant, a RST (i.e., one-point isotherm at 80 bar) has been developed and validated against published data [6] for GX-31 superactivated carbon. Materials that exceed benchmark uptake, or are deemed interesting from a mechanistic standpoint, are moved from the volumetric RST to a gravimetric unit equipped with mass spectrometry for more detailed mechanistic and temperature studies. The latter, along with rate determinations, are relevant to the temperature-switching for decoupled adsorption-desorption optimization, outlined above.

Our approach for optimization of system parameters for spillover considers decoupling of adsorption and desorption, such that optimization of temperature and pressure for each may be considered separately. Towards this end, we are exploring MMOF structural changes that are pressure-induced in order to incorporate this phenomenon into hydrogen trapping, via both physisorption and hydrogen spillover. We are validating theoretical models with extensive adsorption isotherms for a MMOF with demonstrated pressure-induced structural changes (Zn\textsubscript{2}(bpdc)\textsubscript{2}(bpee)), and exploring the effect of adsorption time, adsorbate, pressure, and temperature. Once validated, it is anticipated the theoretical model will be able to predict the feasibility of using various MMOFs for hydrogen trapping at pressures and temperatures of interest.

Results

A total of eight MMOFs were synthesized in 2009-10 (Figure 1), with variations in ligands and secondary building units (i.e. corners) leading to expected differences in structure, surface area, pore dimension, and surface chemistry. RST adsorption results (Figure 2) show no real trend with surface area or pore dimension, contradicting previous claims, [5] and suggesting coverage from spillover is not related to surface area in a simple fashion. Two PtC/MMOFs had uptake exceeding that of literature benchmarks (IRMOF8 and MMOF=O, Figures 1-2 a-b). The latter significantly exceeded benchmark data, with 2.4% at 80 bar and 298 K, suggesting that surface chemistry will play a predominant role in surface coverage via spillover. These findings (correlation with surface chemistry not area) are consistent with a chemical kinetic consideration of spillover, in which the relative rates of adsorption, desorption, and surface diffusion must be considered [7].

Previous published spillover data has suffered from reproducibility issues. Recent data for brPtC/IRMOF8 varies from 1.5-4.0 wt% at 298 K and 100 bar; [4] with little concrete explanation provided to explain the discrepancy. Therefore, PtC/IRMOF8 was chosen to
study the effect of various synthesis and measurement parameters on instrument precision and material reproducibility. The accuracy of the RST measurement is calculated at ±0.026 mmol (±0.05 wt% for 100 mg sample) via propagation of error when a He blank measurement is done to determine the differential pressure due to volume differences. Validation of the equipment with GX31 shows agreement within 20% relative to published data [6] at 80 bar, a difference which can be attributed (in part) to slight variations in pretreatment and sample. When equipment, sample, and pretreatment are the same, the RST reproduces a multiple point isotherm within 8% at 80 bar. For PtC/IRMOF8, multiple experimental RST replicates with identical procedural and temporal conditions show a standard deviation of less than 10% (i.e. 0.31 ± 0.03 wt%, Table 1), even with a 10 bar variation in the equilibrium adsorption pressure (i.e. 75-85 bar). With this level of precision in uptake, we were able to confirm that increased mixing intensity leads to increased uptake via spillover for PtC/IRMOF8: from 0.31 wt% to 0.78 wt%. The increase cannot be directly attributed to differences in catalyst size, as the catalyst source is identical in the secondary spillover studies, unlike previous reports [4,8]. Despite the increased uptake, no significant changes in MMOF structure were detected by power X-ray diffraction, suggesting

FIGURE 2. Rate data for one-step adsorption isotherm, i.e. 'rapid-screening test'. Data is labeled as in Figure 1.
mixing intensity may affect particle size and/or interface. Currently, additional mixing parameters are being tested with alternate characterization of the physical properties after mixing. Sample handling for PtC/CuBTC is also shown to drastically affect overall uptake and material integrity. When mixed in an inert environment, PtC/CuBTC has 0.61 wt% at 20 bar, exceeding published reports by a factor of three. The uptake due to spillover at low-pressure is found to be pronounced using gravimetric methods (Figure 3).

In an attempt to develop a means for hydrogen trapping and to facilitate decoupled optimization of adsorption vs. desorption, work to validate and understand pressure-induced MMOF structural changes is ongoing. Although adsorption-induced gate opening (GO) in MMOFs is well documented, it is poorly understood. Experimental data collected for Zn₄(bpdc)₂(bppe) suggest the process is highly sensitive to adsorbate, time, temperature, and pressure. The process behaves consistently, but in a unique and often unpredictable way. Parallel theoretical studies are seeking to understand experimental data and validate models, and further, to use the concepts towards predictive understanding of the phenomenon. Current studies have used well-defined and analogous systems to demonstrate that GO is favored when the relative gas-solid interaction energy exceeds the energetic cost of structural rearrangement. Parametric studies with mean-field theory are also on-going. We anticipate the modeling will provide a means to expedite experimental studies such that the behavior of a MMOF can be correlated to its adsorption potential. Such modeling is intended to provide a road map to utilize this process for hydrogen trapping.

Conclusions

Hydrogen spillover continues to show promise for considerable excess adsorption at moderate temperatures and pressures (i.e. 300 K, 100 bar). On-going studies aim to provide a mechanistic understanding of the spillover process. Current data suggest that surface chemistry, rather than surface area or structure, is the controlling factor in maximizing surface coverage via spillover. Further tests are on-going to validate this finding and increase mechanistic understanding. First, however, tests with PtC/IRMOF suggest laboratory environment and mixing conditions—rather than (or in addition to) catalyst particle size—may lead to significant differences in uptake via catalytic spillover and the effect is now being studied in a systematic way. Similarly, uptake for PtC/CuBTC is increased 3-fold (at 20 bar; 298 K) relative to published literature data when mixed in an inert environment. With the validated RST, introduction of a carbonyl group to the ligand led to 2.4 wt% (80 bar, 298 K), and significantly exceeded

![Figure 3](image-url)

**FIGURE 3.** (i) Hydrogen uptake for (a) Cu-BTC, and (b) Cu-BTC+PtAC, mixed 9:1 in an inert atmosphere, with adsorption temperature as noted. (ii) X-ray diffraction of (a) and (b) shows crystalline structure, whereas (c) mixing in atmosphere destroys crystallinity; (d) crystal structure in sample 'b' is retained after H₂ measurement shown in (i). Mixing in inert environment contributes to the three-fold increase in H₂ uptake for 'b' relative to published literature, shown as dotted lines in (i) at 20 bar and 298 K for (e) Cu-BTC, and (f) PtC+Cu-BTC. (iii) Adsorption isotherms for (a) at 77 K.
benchmark data (1.4 wt%, 80 bar, 298 K), prior to bridging. We anticipate uptake can be further increased with additional modifications of structure, bridging, and careful consideration of synthesis conditions. Methods to incorporate pressure-induced hydrogen trapping into the materials is on-going, and will provide a further means to increase pressure savings for the storage system relative to system targets.

**Future Directions**

- Finalize systematic studies of mixing environment on uptake.
- Detailed study of ligands with modified surface chemistry.
- Introduce pore modification in synthesis of like compounds.
- With validated measurements and optimized mixing conditions, develop correlations between porosity, surface area, and surface chemistry of PtC/MMOFs with overall H₂ uptake, kinetics, and hysteric adsorption-desorption.
- Write and submit papers on: (1) methods validation and reproducibility with a focus on PtC/IRMOF8 and brPtC/IRMOF8; (2) sample preparation on PtC/CuBTC; and (3) variation of MOF structure/chemistry with secondary spillover studies.
- Validate theoretical imbibition study with experiment; evaluate pressure-trapping of MOF structures at ambient conditions; assess opening via spilled over H.
- Evaluate potential for temperature trapping with PtC/MMOFs that exceed benchmarks using combined multiple temperature adsorption isotherms and temperature-programmed desorption studies.
- Develop MOF containing built-in catalytic functionality using metalloligands.
- Independent measurement of Tsao et al. sample.

Objectives

To develop storage materials that enable high H₂ loading under more economical temperature and pressure ranges; that have more controllable uptake/release dynamics; and that have moderate losses over a charge/discharge cycle. By using electric field enhanced adsorption, we expect to:

- Enhance adsorption binding energy (10-15 kJ/mole electric-field effect expected).
- Ultimately meet hydrogen loading goals at more practical combinations of temperature and pressure.
- Establish better control over hydrogen charge/discharge dynamics using field strength as a control variable in addition to thermal and/or pressure modulation.

Technical Barriers

Several technical barriers from the Storage section (part 3.3) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan are addressed by this project:

(C) Efficiency
(E) Charging/Discharging Rates
(J) Thermal Management
(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

The project centers on the fundamentals of hydrogen adsorption in porous adsorbents under the influence of externally applied electric fields. Electric-field enhancement of binding (capacitive storage) can integrate well with electric drive systems and the insights gained from these studies will be applied toward the design and synthesis of storage materials more likely meet DOE hydrogen storage targets. Outcomes of this work are expected to include:

- New insights into H₂ physisorption/chemisorption at sites of high local polarizability.
- Improvements in net efficiency of storage systems, i.e. acceptable hydrogen wt% at more accessible temperature and pressure.
- Better control over hydrogen charge/discharge dynamics using field strength as a control variable in addition to thermal and/or pressure modulation.

Accomplishments

- Continued of ab initio computations exploring effects of external field on electron density in organic constituents typical of metal organic frameworks. Modeling results are being used to guide chemical synthesis effort (e.g. organic linker selection).
- Refined capacitor test-cell design for use in measuring sorption under an applied electric field. Fabricated custom sorption rig – measurements underway.
- Substrate synthesis efforts now include more polarizable organic linkers. Focus remains on metal organic framework and related substrates.
- Modified dielectric properties of substrates and characterized using electrochemical impedance spectroscopy. Static dielectric constant, loss tangent, and leakage current are being measured and used to estimate time constants and losses over a charge-discharge cycle.
- Conducted experiments where dielectric breakdown was intentionally induced across the capacitor in the presence of hydrogen (addresses an important safety issue).
- Designed a neutron diffraction cell for use with static electric fields. Cell will ultimately provide insight into specific binding site locations.
Introduction

Capacitive storage involves establishing an electric field across a porous dielectric material designed to adsorb hydrogen. The field acts on localized regions of high polarizability to enhance binding within the cavities of the porous network through induction and dispersion forces (we hope by 10-15 kJ/mol). The enhanced binding energy, induced by the substrate’s response to the field, should allow storage goals to be met at more practical combinations of temperature and pressure. Upon discharge of the “capacitor” the electric field is removed, and in turn, the induced electrostatic moment stabilizing hydrogen dissipates. Thus a portion of the thermodynamic driving force for binding can in principle be switched on and off at will. Furthermore, some of the energy required to bind and release hydrogen is reversibly introduced into the system in the form of an electric field. Losses are expected to include dielectric losses and any leakage current through the capacitor during storage. As the field is removed, desorption will be promoted and cooling the substrate is expected. The decrease in temperature provides a larger driving force for heat diffusion into the substrate. Thus, improvements in the release dynamics and improved control over the release are anticipated. Two critical operational issues associated with hydrogen storage are potentially addressed with capacitive storage – hydrogen density and thermal management. Electric field-mediated storage has the ability to enhance the density of stored hydrogen at more practically accessible temperatures and pressures. For example, operating over the range –40 to 60°C should become less onerous. Charging and discharging, system cycling, and transient system response can now involve field modulation in addition to thermal and/or pressure swings and heat exchange within the adsorbent bed. The other outstanding challenges detailed in the On-Board Hydrogen Storage System Technical Targets, such as delivery pressure, charging/discharging kinetics, and system fill time may also benefit directly.

Approach

It is well-known that manipulation of temperature and pressure provides benefits in gas storage, however, it appears that combinations of these two intensive variables alone will not likely yield the desired end result, namely, high hydrogen loading under moderate (and economically attractive) conditions. As an alternative, we are examining the effects of also introducing an electric field to enhance hydrogen uptake in porous dielectric substrates. This materials discovery effort is based on the idea that local regions of high electron polarizability will respond strongly to an applied external field. In doing so, the expectation is that the resulting redistribution of electron density should enhance the hydrogen binding energy. This may involve a combination of enhanced binding energies, creation of new binding sites and/or formation of hydrogen clusters (as is reported in both clathrate-hydrate cages [1] and metal organic frameworks [2]). The key challenge is to determine how best to create localized polarizability within porous adsorbents. Electrostatic stabilizing forces can be locally enhanced by judiciously increasing the polarization of the host substrate at specific sites, or within sub-structures (cavities) favorable to molecular clustering. The metal organic frameworks (MOFs) are serving as the starting point for developing the new dielectric materials [3]. MOFs are composed of metal ions with coordinated organic ligands, where the nature of metal-to-organic ligand coordination provides versatility in the design and control of chemical and physical characteristics (of specific interest to us is the local polarizability). Thus in addition to being high surface area structures (>3,000 m²/g), MOFs can be chemically tailored by modifying the organic linkers between metal centers. This can potentially be done through introduction of more polarizable atoms and functional groups, tuning the band gap, and/or varying core metal electronic properties. Related materials such as the zeolitic imidazolate frameworks are also being examined. Other potential adsorbents include composites constructed by distributing small metal or semi-conducting clusters in porous structures (e.g. xero- or aero-gels) as another means of producing inorganic materials with extreme dielectric properties [4]. Our approach to developing these materials (structured dielectrics) combines both computational guidance and experimental probes/testing.

Results

Our recent computational modeling has focused on simple models for the structural motifs featured in the Cu-1,3,5-benzenetricarboxylate (BTC) MOFs and the effect on an applied electric on their interaction with hydrogen. For this purpose, we chose the copper acetate structure since it shares several structural similarities with Cu-BTC while consisting of discrete molecular units in the solid state. For example, the pinwheel coordination geometry is present about the copper center. Figure 1(a) shows a candidate binding geometry for the hydrogen molecule at the copper site. Quantum chemical calculations have been performed on this model in vacuum and with an applied electric field. In Figure 1(b), the calculated electrostatic potential has been projected onto the calculated total electron density for the molecule. It can be clearly seen that applied electric field induces a dipole in the molecule, and the calculated binding energy is enhanced by around 5 kJ/mol for an applied field of 20 MV/cm. The computations suggest that in order to effect the desired change at more modest field strengths, higher polarizability and/or low band gap ligands (linkers) are needed (Figure 2). Thus, new
ligands are being incorporated into MOFs with the aim of altering framework polarizability (e.g. replacing the 1,3,5-benzenetribenzoate [BTB] links in MOF-177 with more polarizable ring motifs or phosphazene derivatives). Known MOFs were also synthesized for baseline testing. A custom gas adsorption rig was also commissioned. Experiments are now underway using this rig and the matching capacitor assembly (Figure 3). We will also explore the role played by the electrostatic moment in the gas by comparing field-induced adsorption of hydrogen and carbon dioxide, which have very different electrostatic moments than hydrogen (e.g. relative quadrupole moments: CO$_2$ 4.3 esu; H$_2$ 0.662 esu [5]). We expect to have a robust quantitative assessment of the electric field enhancement on hydrogen adsorption in selected MOFs next year. Electrochemical impedance spectroscopy is being used to determine dielectric properties and estimate losses. Losses specific to electric field swing adsorption include the dielectric losses upon a charge-discharge cycle, which involves a time-varying (periodic) electric field. A simple (idealized) way to envision these is energy dissipation as a result of dipole rotation generating friction in the time-varying field. Dielectric losses over a charge-discharge cycle for a uniform dielectric in a periodic field can be estimated from classical
electrostatics \[6\] as: dielectric loss = \(\varepsilon'' E^2 \omega / 8\pi\)
where \(\varepsilon''\) is the imaginary part of the complex dielectric constant, \(E\) the electric field strength (e.g. MV/m), and \(\omega\) is the frequency of the periodic electric field. Calculations suggest that dielectric losses should be small (<1 watt/liter of dielectric) in the hydrogen storage systems, due primarily to the low frequency variation in the electric field over a charge-discharge cycle. Estimates of the leakage current have been made using electrochemical impedance spectroscopy and results fit to the Randles "equivalent circuit" model for a real capacitor. Initial estimates of leakage in MOFs placed in our current test rig were too high, but by increasing dielectric constants (via molecular design) and altering the electrode area to electrode gap ratio in the capacitor, it appears be possible to maintain charge for days. The ability to favorably modify the dielectric properties of MOFs were demonstrated (Figure 4). A capacitor cell for use in neutron diffraction experiment was also built. It will ultimately allow us to monitor hydrogen adsorption at specific sites. Hydrogen bonding sites will be refined from the neutron diffraction data and used to improve the next iteration in materials design/synthesis.

Conclusions and Future Directions

- Capacitive storage appears to offer a practical means of enhancing hydrogen storage. The approach is expected to result in more economical combinations of temperature and pressure in hydrogen storage systems. Higher efficiencies and better control over the charge/discharge dynamics are expected (via proper modulation of the field).
- The energy used to establish the field can largely be recovered upon discharge (the dielectric losses, and leakage currents are within acceptable limits).

Work in progress:
- Conducting quantitative demonstration of enhanced hydrogen loading.
Further assessments of H₂/substrate compatibility under dielectric breakdown.

Design/synthesis of high polarizability porous adsorbent frameworks.

Results will ultimately position us for design and testing of an integrated storage system.

Start Date:  October 1, 2004
Projected End Date:  September 30, 2013

Objectives

- Test thermal endurance and heat transfer rate.
- Test composite vessel outgassing and vacuum stability.
- Test para-ortho conversion at cryogenic temperatures and full scale (10 kg H₂).

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(D) Durability/Operability
(H) Balance of Plant (BOP) Components
(O) Hydrogen Boil-Off

Accomplishments

- Held 10.2 kg liquefied hydrogen (LH₂) in a 95% full vessel for eight days with no evaporative losses or hydrogen extraction.
- Demonstrated that para to ortho hydrogen conversion stabilized vessel temperature for about one week.
- Demonstrated capacity to maintain 75% of the liquid hydrogen stored in vessel after one-month parking.
- Directly measured para-ortho hydrogen conversion with rotational Raman spectroscopy.
- Developed and tested a kinetic model for para-ortho hydrogen conversion.
- Conducted vacuum stability tests and chemically analyzed composite outgassing.

Introduction

Cryogenic pressure vessels have potential for enabling practical vehicle range through a combination of dense hydrogen storage (LH₂) and efficient packaging density. Cryogenic pressure vessels can store LH₂ with dramatically improved thermal endurance – the main challenge facing conventional low pressure LH₂ tanks. Low sensitivity to heat transfer enables reduced insulation thickness (~1.5 cm vs. ~3 cm for low pressure LH₂ tanks), considerably improving packaging efficiency leading to vessels that meet DOE’s 2015 weight and volume targets and approach DOE’s ultimate weight target. Further increases in thermal endurance may result from endothermic para-ortho conversion during long parking periods.

§From Argonne and TIAX [1,2,3]
Approach

In previous years we dedicated our effort to demonstrating cryogenic pressure vessel weight and volume performance by building a prototype that met the DOE 2015 targets. This year we directed our attention to other critical issues: evaporative losses and long-term vacuum stability. The key experiment consisted on parking a vehicle with a nearly full (95%) cryogenic pressure vessel for a month to determine (1) heat transfer rate; (2) vacuum stability; and (3) para-ortho conversion. The results indicate that high performance thermal insulation, heat absorption due to para-ortho conversion, and favorable thermodynamics enabled completion of the 30-day experiment while retaining 75% of the initial hydrogen.

Results

Hydrogen has two phases of nuclear spin orientation: para-H₂ and ortho-H₂. Para-H₂ is the low energy form stable at liquid hydrogen temperature (20 K). As the hydrogen heats up from 20 K equilibrium shifts toward ortho-H₂, reaching normal composition (25% para and 75% ortho) at room temperature [4]. Liquid hydrogen (typically delivered as para-H₂ for stability) will therefore convert to ortho-H₂ as it warms up, absorbing considerable thermal energy (700 kJ/kg – comparable to vaporization) in the process. Para-ortho H₂ conversion has therefore much potential for augmenting thermal endurance.

While it may be possible to detect and quantify para-ortho H₂ conversion from calorimetry alone, LLNL has directly measured para-ortho population ratios using rotational Raman spectroscopy. In this approach, a hydrogen sample is collected inside a Raman cell (a small pressure vessel with windows at each end). A frequency-doubled Nd-YAG laser enters through a window in the Raman cell and the light is analyzed after interacting with the hydrogen (Figure 1). Most of the light leaving the Raman cell has the same frequency as the laser. This is filtered out leaving only light of different frequencies (inelastic scattering). A very small portion of the incident laser light scatters off the hydrogen molecules. An even smaller portion of the scattered photons give up some of their energy to the molecules. Thus they scatter with slightly less energy and are therefore shifted to slightly longer wavelengths. This is the Raman effect. The amount of this Raman scattered light is directly proportional to the number of molecules in each rotation energy state. Each energy state yields a slightly different Raman wavelength. Thus we are able to make a direct measurement of the relative populations of para (even quantum number rotational energy states) and the ortho (odd quantum number energy states) molecules.

The para-ortho conversion experiment was conducted onboard LLNL’s hydrogen-fueled Prius. The vessel was filled to 95% capacity (10.2 kg) with LH₂ and parked outside, exposed to the daily sun, to capture worst-case conditions. The vessel warmed due to ~4.5 Watts of environmental heat transfer, until reaching maximum working pressure of 5,000 psi after 8.25 days of parking (Figure 2). At this point, we released 1.2 kg H₂. This both reduced the pressure to 3,000 psi and cooled the remaining 9 kg of H₂ from ~70 K to ~60 K.

Para-ortho conversion occurred during the second pressurization cycle (days 12-24) as indicated from rotational Raman spectroscopy measurements (blue line in Figure 2). During this time, endothermic para-ortho conversion absorbs most of the environmental heat transfer, leading to a considerable reduction (from ~4.5 Watts to ~1 Watt) in apparent heat transfer into the vessel. Apparent heat transfer is calculated from the pressurization rate assuming no para-ortho conversion. Calculating the total internal energy absorbed (blue area in Figure 2) and dividing it by the baseline heat transfer rate (4.5 W), we were able to determine that para-ortho conversion increased vessel dormancy by ~1 week.

After day 24, para-ortho H₂ conversion was nearly complete as the composition approached equilibrium (Figure 3), and apparent heat transfer returned to the baseline level (4.5 W). After a few more H₂ extractions,
In addition to conducting the first (to the authors’ knowledge) full-scale para-ortho hydrogen conversion experiments, we also developed and tested a para-ortho conversion model. This model is derived from ortho-para conversion experiments in a small vessel (2 cm³) [4] and solves a set of differential equations that determine para-ortho composition as a function of density, temperature, and initial composition. After appropriate tuning, the model performed well for the full-scale vessel (Figure 3) accurately predicting para-ortho composition during the experiment. Further experiments are planned to validate the model under varying densities, with the final goal of determining how to best design cryogenic pressure vessels that take advantage of para-ortho conversion for considerable increases in thermal endurance.

In addition to the para-ortho experimental and modeling activities, we also completed outgassing experiments from fiber-wound pressure vessels. In these experiments, we tested the outgassing behavior of composite pressure vessels by storing them inside a steel vacuum chamber at specified temperatures (20, 60 and 80°C). We tested four small-scale (~1 liter) composite pressure vessels with aluminum lining and carbon fiber reinforcement. The vessels have four different surface and curing treatments: 1) regular pressure vessel with no special surface treatment; 2) vacuum cured pressure vessel; 3) ultraviolet (UV) protection coated pressure vessel; and 4) vacuum-cured and UV protection coated pressure vessel. The results can be summarized as follows:

1. Temperature is the most important factor in determining outgassing.
2. Vacuum quality remains high if the vessel remains cold (below 250 K).
3. Pressure cycling plays a relatively minor role in outgassing.
4. Vacuum curing did little to reduce outgassing and it is most likely not worth the effort. UV coating considerably increased outgassing and is therefore not recommended for cryogenic pressure vessels.
5. Chemical composition reveals a series of ~10 hydrocarbons that are produced in all experiments. The main species produced are n-heptanone, acetic acid butyl ester, and acetone – all oxygenated hydrocarbons most likely derived from the epoxy used in the tank.

Detailed composition and outgassing amounts are now being used for selecting appropriate getters that may preserve vacuum during long periods of operation.

**Conclusions and Future Directions**

- Demonstrated 1-month cryogenic vessel dormancy while extracting only 2.5 kg H₂.
Para-ortho conversion proved synergistic with cryogenic pressure vessel operation, extending vessel dormancy by approximately 1 week by absorbing heat during endothermic conversion. Developed and tested a kinetic conversion model of para-ortho conversion. Completed outgassing experiments that characterized the effect of temperature, surface treatment, and pressure cycles. Outgassing composition was also determined and is being used to find appropriate getters for long-term vacuum stability.

IV.G.2 Lifecycle Verification of Polymeric Storage Liners

Objectives

Perform durability qualification measurements on specimens of Type IV storage tank liners (polymers) at the nominal working pressure using thermal cycling commensurate with the design lifetime, followed by permeation measurements to determine if the steady-state leakage rate in the tank could potentially exceed the specification for hydrogen fuel cell passenger vehicles.

Technical Barriers

The project addresses the following technical barriers from the Hydrogen Storage section (3.2.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

(D) Durability/Operability

Technical Targets

This project addresses the following technical targets for on-board hydrogen storage systems research and development:

- Cycle life variation, expressed as % of mean (min) at % confidence:
  - Fiscal Year (FY) 2010: 90/90; FY 2015: 99/90
- Environmental Health and Safety:
  - Permeation and leakage: meet or exceeds applicable standards.
  - Loss of usable H₂ (g/h/kg H₂ stored): FY 2010: 0.1; FY 2015: 0.05.

Accomplishments

- Completed 3,000 temperature cycles on a specimen of Lincoln Composites Type IV tank liner (high-density polyethylene, HDPE) and performed periodic permeation measurements on liner specimen to assess temperature-cycling induced changes in permeation coefficients.
- Verified that permeability coefficients have changed only slightly through 3,000 temperature cycles.
- Observed small systematic changes in activation energy $E_a$ and constant $P_0$ in the liner during temperature cycling.
- Designed and assembled improved temperature-cycling apparatus. First temperature cycling results with new apparatus expected in 4th quarter of FY 2010.

Introduction

Modern high-pressure hydrogen storage tanks use a polymeric liner as a permeation barrier to hydrogen, typically HDPE. Storage tank liners can, however, be stressed by cyclical excursions between temperature extremes, and the cumulative effects of repeated stress could harm the tank's durability. Ultra-high environmental temperatures can promote large hydrogen permeation rates and hydrogen saturation in the liner material. Ultra-low environmental temperatures can severely stress liner materials and possibly induce microcracking. In addition, increasing the pressure of gas in such a tank during filling necessarily raises the temperature of the gas and therefore the enclosing tank. Over the course of many fill cycles during the lifetime of the tank this might affect the permeability characteristics of the liner. Failure modes for the liner's performance based on the interaction of high pressure and extreme temperature cycling—might be possible. Hydrogen leakage through a liner microcracked by extreme temperature cycling could accelerate under sustained high temperature and pressure, or hydrogen saturation of the reinforcement layers external to the liner could put backpressure on the liner as the tank pressure decreases during vehicle operation, thereby causing the liner to separate from the reinforcement layers. Minimum temperatures during winter months in northern states may reach -40°C, and maximum temperatures after filling during summer months may reach 125°C. Thus, the purpose of this project is to cycle typical tank liner materials between these temperature extremes to determine whether such a degradation in properties occurs, and, if so, its extent.
Approach

Hydrogen permeation verification measurements for storage tank liner materials are being carried out using ORNL’s internally heated high-pressure permeation test vessel (IHPV). The IHPV was previously used in the Hydrogen Delivery sub-program to measure real-time hydrogen permeation in low-carbon steels and polymer materials at constant temperatures. Materials properties such as the temperature- and pressure-dependent hydrogen solubilities, diffusion coefficients and permeation coefficients are extracted from measurements of real-time hydrogen flux through steels and polymers. In the previous project year we modified the IHPV to enable rapid temperature cycling in polymer specimens.

We are using the relevant portion of the test protocol specified in SAE J2579 to guide our performance of durability test cycling measurements of high-pressure polymeric tank liners [2]. The J2579 test protocol for compressed hydrogen storage systems prescribes long-term thermal cycling at high pressures of hydrogen. The requirement is to subject tank liner specimens to 5,500 thermal cycles over the temperature range -30 to 85°C at hydrogen pressurizations of 43 MPa (6,250 psia) and then 86 MPa (12,500 psia). Testing at 43 and 86 MPa, with cycling between -30 and 85°C, requires an automated temperature control strategy. To replicate the rapid temperature rise in the tank liner during fill cycles (approximately 100°C rise in 3 minutes) we decoupled the cooling and heating control systems in the IHPV. A low-temperature chiller with low-temperature refrigerant circulating to and from a sealed reservoir cools the IHPV’s exterior containment vessel to approximately -40°C. A resistive heater situated in the permeation cell is used to ramp the specimen temperature from -30°C to 85°C. A heater controller controls the thermal cycling of the polymer specimen in the cell by applying and removing power to the heater. Process control software that was developed for the temperature controlled permeation measurements in steels and polymers was modified to provide automated, unattended operation and internet access so the tests can be remotely monitored and controlled. A complete heating and cooling cycle requires 33.3 minutes (see temperature cycle profile in Figure 1), and approximately 127 days are required to perform 5,500 temperature cycles.

The verification measurements occur at regular intervals during the 5,500 temperature cycles. The hydrogen flux is to be measured at three temperatures (-30, 25 and 85°C) at each interval, if practicable. The first measurements occur after the completion of 250, 500, 750, 1,000, 1,250 and 1500 cycles. The remaining measurements occur at 500 cycle intervals until 5,500 temperature cycles have been reached. A second verification test on a fresh tank liner specimen will be carried out at 86 kPa following the same protocol.

Results

Permeation measurements on the specimen of Lincoln Composites Type IV tank liner (HDPE) indicate that permeability coefficients $P$ are relatively unchanged through 3,000 temperature cycles (see Figure 2). Small systematic changes in activation energy $E_A$ and constant $P_0$ in Arrhenius relationship $P = P_0 \exp(-E_A/kT)$ as a function of the number of temperature cycles were observed, which could indicate microstructural changes are occurring in the polymer during temperature cycling (see Figures 3 and 4). Assembled and tested an improved temperature-cycling apparatus that will enable us to complete cycling measurements faster. First results temperature cycling results using new apparatus expected in 4th quarter of FY 2010.

Conclusions and Future Directions

Through 3,000 temperature cycles we have observed no statistically significant departures from the Arrhenius relationship between permeation coefficient and temperature that would indicate the occurrence of microcracking or changes in glass transition temperature in the Lincoln Composites HDPE liner specimen.

FY 2010

- Complete initial lifecycle verification measurements and report durability assessments of Lincoln Composites specimen through 5,500 cycles.
Begin temperature cycling of Lincoln Composites specimen at 860 bar (12,500 psia).

Begin temperature cycling of Quantum Technologies specimen at 430 bar (6,250 psia).

Complete all lifecycle verification measurements and report assessments for Lincoln Composites and Quantum Technologies.

Complete temperature cycle testing of an alternative liner material (PA-6, PA-11, PPS) and compare to HDPE liner materials.

Measure hydrogen solubility in tank liner materials.

Project Start Date: November 2006
Project End Date: Project continuation and direction determined annually by DOE

**Objectives**

- Reduce the manufacturing cost of high-strength carbon fibers by using melt-spun polycrylonitrile (PAN) precursor technology which has the potential to reduce the production cost by >30%.
- Develop advanced conversion techniques that will significantly reduce the production cost of high-strength carbon fibers suitable for use in compressed hydrogen storage vessels by an additional 20%.

**Technical Barriers**

High-strength carbon fibers account for approximately 65% of the cost of the high-pressure storage tanks. This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- **System Weight and Volume**
- **System Cost**
- **Durability/Operatability**
- **Materials of Construction**

**Introduction**

The exceptional strength-to-weight ratio of carbon fiber composite tanks makes them prime candidates for use with materials-based, cryogenic, or high-pressure gas for both vehicular and stationary storage applications. Cost is the primary issue with composite tank technology. A critical challenge lies in the cost of the fiber and the manufacture of composite tanks. Current projections of the manufactured cost per unit for high production volumes are about a factor of nine above storage system targets, and it is estimated that about 40-70% of the unit cost is due to the base cost of the carbon fiber (approximately 40% of the fiber cost is
due to the precursor and the remainder due to thermal processing). Costs for compressed gas storage systems stored at 350 and 700 bar (5,000 and 10,000 psi) can be reduced by lowering the cost of carbon fiber through materials and process improvements and moving to higher volume manufacturing processes through advanced manufacturing research and development (R&D). R&D is needed as composite storage technology is most likely to be employed in the near term for transportation applications and will be needed for most materials-based approaches for hydrogen storage.

Currently, composite tanks require high-strength fiber made from carbon-fiber grade polyacrylonitrile precursor. Manufacturing R&D is needed to develop lower cost, high quality polyacrylonitrile or alternate precursors and reduced energy or faster carbonization process for carbon fiber, such as microwave or plasma processing. In addition to improved carbonization processes, other steps in the process, such as oxidation and graphitization need to be improved. Developing and implementing advanced fiber processing methods has the potential to reduce cost by 50% as well as provide the technology basis to expand U. S. competitiveness in high-strength fiber manufacturing [1].

Most carbon fiber in use today is based on the technology developed over many years for production of aerospace grade materials where performance requirements clearly justifies higher costs than for other structural materials. The major contributors to the cost of high strength fiber are: 1) presently, all high-strength carbon fibers are manufactured from relatively costly PAN precursor which is wet spun into fiber in an expensive process; 2) precursor fiber is converted into carbon fiber in bundles, or “tows”, which are optimized for performance versus cost; 3) carbon fiber is typically processed at line speeds optimized for “conservative” production of aerospace properties; 4) conventional fiber production utilizes large, massive furnaces in which most energy is lost to the environment; and 5) rigorous qualification, certification, inspection, and documentation requirements can contribute very significantly to the cost of aerospace grade fibers. This project addresses all of these factors, the most critical of which is the raw material and processing costs involved with precursor production.

This project will leverage previous and ongoing work of the FreedomCAR’s program to develop a low-cost, high-strength carbon fiber. At this time, the cost and property targets needed for compressed hydrogen storage are not well understood. Analysis is underway at DOE to determine appropriate targets. Until targets are definitively established, this project will seek to develop carbon fibers with properties equivalent to Toray’s T700/24k fiber (24k tow, 700 ksi ultimate tensile strength, 33 Msi tensile modulus), and reduce production costs by at least 25%.

Approach

This project is structured into tasks focused on precursor development, conversion process improvements, process integration, and business analysis. Development and demonstration of melt-spinnable PAN is the project’s primary precursor option. This requires concurrent activities in both development of melt-stable PAN copolymer and blends as well as the processes necessary to successfully spin the formulations into filamentary tows. Backup options include textile PAN, polyolefins, and incorporation of nanomaterials. Demonstrating and down-selecting a precursor capable of meeting performance targets utilizing conventional conversion processing defines the pathway for the balance of project activities. In conversion, critical processability parameters include: (i) highly controlled stretching, especially during pre-treatment and stabilization; (ii) residence time in various conversion modules; (iii) optimal graphitization for maximum strength; (iv) uniform treatment of fibers throughout the tow; and (v) characterization of filaments at various stages of conversion operation. Related ORNL work in advanced processing technologies address these issues, with a focus on increasing line speed in a reduced footprint, with reduced energy consumption. Means to adapt these emerging processes will be developed and evaluated for applicability to meeting requirements of this program area. As these technological advances are demonstrated independently, work will also be initiated to make all the modules work together as a robust system focusing on the implementation of an optimized system design and operating procedures to satisfy technical targets at minimum cost. As the system integration is completed, the energy efficiency and overall economics of the complete system will be evaluated and forecast for production scale up.

Results

As described in the approach, our initial focus is on developing and demonstrating melt-spinnable PAN, the necessary processes to spin these material into fibers, and projecting converted carbon fiber properties adequate for down-selecting this or other candidate precursor materials for system integration and technology demonstration. Accordingly, ORNL and its project partners at Virginia Tech have devoted most project resources to this effort as described below.

Alternative Precursor Synthesis

Earlier research has shown that partially sulfonated PAN copolymers (PAN-AMPS) affords highly miscible blends with poly(ethylene glycol) (PEG) due to an apparent intermolecular interaction between the sulfonated groups and PEG. This enables effective depression of the Tg of the blends. In addition to this
The characterization results of the grafted copolymers are summarized in Table 1. From the gel permeation chromatography (GPC) and 1H-nuclear magnetic resonance (NMR) results, it has been confirmed that copolymers with sufficiently high molecular weight and target compositions were synthesized. Our differential scanning calorimetry (DSC) results also indicates that copolymerization of the macromonomers with AN can lead to effective Tg depression. Molecular weight characterization of the graft copolymer is in progress.

The next step is to control the molecular weight which is critical for melt processing. Both initiator concentration and the use of chain transfer agents such as dodecyl mercaptan will be employed.

**Fiber Spinning**

A key accomplishment was successful generation of a four-filament mini-tow with AN/VA copolymer. The scanning electron microscope (SEM) micrographs from this work showed that the fibers have void size similar to that of as-spun fibers produced by BASF as reported in their patent. At the conclusion of this period we are working to generate a 10-filament mini-tow using a new 10-hole spinneret to meet the new milestone. The new spinneret works but more work needs to be done to get filaments with the desired size. We also tried using PAN/methyl acrylate (MA) copolymers in fiber spinning and succeeded in generating some fibers from polymers containing 95% AN. To investigate the stability of hydrated PAN/VA melt, the time dependence of melt pressure was measured during the fiber spinning. The result showed that, under the spinning condition (195°C), the hydrated P(AN/VA) melt was stable as long as the residence time was less than 30 minutes (a time that is long enough for melt spinning). In addition, the DSC thermogram of PAN/VA fibers was measured and compared with that of pristine copolymer. The two thermograms observed are quite similar, indicating that no serious degradation took place during the fiber spinning process.

TBD – to be determined
SEM Micrograph of As-Spun PAN/VA Fibers

SEM analysis was carried out to study the morphology of melt-spun PAN/VA fibers, including single filament and four-filament fibers produced in the last quarter. The as-spun fibers are substantially void free when examined in cross section at 2,000X or lower magnification (see Figures 1a and 2a). Any voids which are observed in the as-spun fibers when a cross section is examined are generally \( \leq 0.2 \) micron (see Figures 1b and 2b). Note that this size of voids is at the same level as that observed in the as-spun acrylic fibers produced by BASF (see U.S. Patent 5,168,004). That is, we were able to use just water to produce precursor fibers with the same void size as that generated by using water and acetonitrile.

Spinning of PAN/VA 10-Filament Mini Tow

In order to meet the milestone on spinning of the 10-filament mini-tow, we designed and fabricated a new spinneret with 10 holes (0.01” in diameter). We have made trial spinning runs with the new spinneret several times. Some 10-filament mini-tows were generated successfully with PAN/VA mixed with 17 wt% water. However, we still could not produce a 10-filament tow with fibers of diameter \( \leq 50 \) microns continuously. Some filaments broke easily as we tried to increase the take-up speed and the draw ratios. We are working to find the solution and generate a 10-filament tow with filaments of desired size and properties. The appropriate conditions seem to be a function of the melt temperature and the subsequent drawing and cooling conditions.

Spinning of PAN/MA Copolymer Fibers

We also tried to spin PAN/MA fibers with three copolymer samples (see Table 2) made available to us. Fiber spinning was carried out by using the same conditions as were used for generating PAN/VA copolymer fibers. It turned out that neither sample #1 nor #2 worked. The molecular weight (and viscosity)
of sample #2 is so high that we could not even extrude the melt out of the capillary. In contrast, the spinning of sample #3 went quite well. Some fibers were generated successfully. Because the PAN/MA sample has higher AN content and is more stable in comparison with the PAN/VA samples, using new PAN/MA samples could improve the properties of PAN fibers as carbon fiber precursors.

Stability of Hydrated P(AN/VA) Melt

The viscosity of the polymer melt is sensitive to the polymer structure. Under constant extrusion temperature and speed, the shear viscosity of the polymer is proportional to the pressure drop over the die hole (capillary) and approximately proportional to the melt pressure in the barrel. For this reason, if molten polymer undergoes structural change or becomes unstable, the viscosity of the melt may change and so would the melt pressure. So time dependence of melt pressure could provide information about melt stability or degradation of polymer melt.

Figure 3 presents the time dependence of the hydrated AN/VA copolymer melt pressure during the fiber spinning at an extrusion temperature of 195°C. The extrusion (plunger) speed is 0.06 cm/min. Note that t=0 was set as 6 minutes after the sample was inserted into heated barrel of an Instron Rheometer. It shows that, when t is less than 30 minutes, the melt pressure was approximately constant, suggesting that the melt was stable during this period of time. In contrast, when t is greater than 30 minutes, the melt pressure went up quickly, indicating that the polymer might undergo structural change and become unstable. As 30 minutes should be long enough for melt spinning, it can be concluded that the P(AN/VA) – water system is suitable for application in the melt-spinning process.

DSC Analysis of Melt-Spun AN/VA Copolymer Fibers

The DSC analysis was carried out for both AN/VA copolymer (pristine powder) and melt-spun AN/VA fibers (as-spun fibers with t < 30 min). Both samples were dried in a vacuum oven at 80°C for 20 hours before testing to remove any residual water/moisture in the polymer or fibers. A heating rate of 20°C/min was used in the analysis. The result is shown in Figure 4. It is apparent that the thermograms for the two samples are quite similar, especially in the temperature range less than 280°C. At temperatures higher than 280°C there is a large exotherm produced by the cyclization reaction of adjacent nitrile groups. Both samples exhibited the same glass transition temperature (102–103°C) and the exothermic reaction (cyclization reaction) which starts at

about 280°C. However, the positions (temperatures) of the exothermic peaks are different. For the fiber sample, the peak temperature is 324°C, which is some 14°C lower than that of the pristine polymer sample. It suggests that the cyclization reaction of fiber is faster than that of pristine polymer. From this result and the fact that the fiber sample has much higher molecular orientation than the pristine sample, it is possible that the orientation of polyacrylonitrile molecules may accelerate the cyclization reaction of adjacent nitrile groups.

Based on the above thermal analysis and melt pressure data, we believe that the melt-spun fiber generated with the continuous technology (t <30 minutes) would have a chemical structure similar to or very close to that of the pristine polymer samples.

Conclusions and Future Directions

Significant accomplishments were achieved in precursor development during the past year in successfully synthesizing copolymers with sufficiently high molecular weight and target compositions and demonstrating that copolymerization of macromonomers with AN can lead to effective Tg depression. We were also able to successfully melt-spin a four-filament mini-tow with AN/VA copolymer. Plans are to build on this work in progressing towards a melt-spinnable 95/5 AN/MA system. The development of a melt processing scheme for the AN/MA copolymer system will require an intensive effort involving synthesis and rheology along with refinements of the processing scheme. The first phase of the project is to develop a correlation between the copolymer ratio and molecular weight. The molecular weight distribution and intrinsic viscosity of various copolymer systems will be determined using GPC and solution viscosity techniques, respectively. Although some of these resins will be provided by ORNL, others will be synthesized by the Virginia Tech group in order to find an acceptable AN/MA copolymer suitable for melt processing. In addition to molecular weight, the melting, and Tg temperatures will be determined via DSC.

The new resins after plasticization with water will then be evaluated rheologically using a specially designed rheometer capable of measuring viscosity of materials containing plasticizers such as water which require pressurization of the extruded material. These measurements will allow us to determine conditions (processing temperature, thermal stability, viscosity, spinning pressure) suitable for melt spinning a given composition (i.e. AN/MA ratio and molecular weight). Once these conditions are established, then suitable amounts of the composition will be synthesized and then spun into fibers.

In addition to the synthesis of AN/MA, copolymers will be synthesized for evaluation as well. Macromonomers containing methacrylate functionality and a side chain of poly(caprolactone) with molecular weights of 1,000 to 5,000 will be prepared and core-polymerized with AN and MA to assess whether they can improve melt processibility.

Once the desired composition (i.e. AN/MA ratio and molecular weight) is identified, the processing conditions are established, and sufficient quantities of polymer are synthesized, the resins will be spun using a specially designed spinning system being developed. The spinning system allows the extruded filaments to be spun into a pressurized environmental chamber which cools the filaments and suppresses foaming. The filaments leaving the chamber will then be drawn on heated draw rolls to remove water and impart orientation and increased tensile strength. The mechanical properties of the filaments will be measured to obtain the modulus and tensile strength.

ORNRL will characterize the fiber and conduct conversion trials on precursor filaments generated using its precursor evaluation system. The filaments at various steps of the conversion process will be fully characterized and the data used to commence optimization of precursor chemistry and the filament generation process. We expect to achieve carbon fiber tensile properties of 15 Msi elastic modulus and 150 ksi tensile strength with first generation filaments. We are targeting 18 Msi modulus and 200 ksi strength in second generation filaments.

FY 2010 Publications/Presentations

References

### Objectives

- Develop and demonstrate a controllable hydrogen generation system based on sodium silicide powder for portable fuel cell applications.
- Develop specific reaction control mechanisms which encompass water feeding, thermal management, and reaction site maximization.
- Verify operation of all core balance of plant and reaction control components in a laboratory setup.
- Design, fabricate, and assemble a prototype system packaged in a professional manner which generates hydrogen in a controlled manner with minimal user intervention.
- Demonstrate operation with a fuel cell system capable of 250 W.
- Conduct core research to evaluate the potential for ultra-high performance sodium silicide materials.
- Develop the appropriate manufacturing methods to readily scale production of sodium silicide in follow-on activities.

### Technical Barriers

This project addresses the following Storage technical barriers of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (J) Thermal Management

### Technical Targets

The developed sodium silicide technology is specifically focused on portable power applications such as back-up power, mobile workstations, and emergency responders. The specific target range includes applications from 50 to 500 W. The developed technology is expected to be scalable to at least 1 kW for applications such as lawn mowers (known to be highly polluting) and electric bicycles.

The developed technology will likely not meet all DOE technical targets, but there has been a significant focus on customer attributes such as safe operation, fast starting, rapid restarting, low-pressure operation, and ease of use. While this work addresses many of the technical barrier topic areas as outlined in the Fuel Cell Technologies Program Plan, this work is focused on portable power applications that do not have defined DOE targets.

The current effort seeks to establish system technology using sodium silicide. Not only does sodium silicide enable systems that are low cost and reliable, sodium silicide has a high energy density of 3,267 Wh/kg (lower heating value, LHV). SiGNa anticipates the development of advanced silicides with comparable system control architectures which will further increase performance metrics and are capable of over 4,200 Wh/kg (LHV).

The cost of energy storage for portable power applications is expected to approach DOE targets compared to those for vehicle technologies as it is expected to reach $4.47/kWh. Further cost reductions may be realized through manufacturing scale up and other industrial usage demands of sodium silicide and the waste product, sodium silicate.

### Accomplishments

Significant progress has been made in the development hydrogen generation system technology for fuel cell applications. The work in this program includes the following accomplishments:

---
Fabricated and tested a laboratory system which demonstrated key performance attributes: 9.8 wt% hydrogen yield on a powder basis, multiple re-starts with up to one week of off time, and controlled generation (~3 slpm) at low pressures (~30 psi).

Successfully completed bench top testing and sustained operation of a 300 W fuel cell-powered electric bicycle.

Developed a hydrogen filtration system and verified results with gas chromatography verifying 99.99% hydrogen purity.

Completed construction of standalone hydrogen generation development unit capable of 4 slpm and a capacity of 1,000 liters of hydrogen.

Produced (via toll manufacturer) over 25 kg of sodium silicide.

Demonstrated combined water/powder energy density of 1,600 Wh/kg LHV (1,854 Wh/kg if 50% water recirculation is assumed).

SiGNa Chemistry, Inc. is developing a unique hydrogen storage mechanism utilizing SiGNa's air-stable sodium silicide powder derivatives (e.g., Na₄Si₄). SiGNa's stabilized powders have been shown to produce 9.8 wt% H₂. The primary goal of this work is to develop a prototype system including all balance-of-plant components which controllably generates hydrogen based on usage requirements. SiGNa Chemistry will initially target a 3 slpm (~250 W net output) hydrogen generation system. This flow rate generation can support a wide range of applications such as:

- supplemental hydrogen for diesel trucks for improved fuel efficiency and reduced emissions
- primary power for small vehicles (i.e., scooters, mini-bikes)
- emergency responder stations
- backup power
- surveillance
- other off-grid applications

While numerous hydrogen production chemistries have been explored for portable systems such as sodium borohydride or methanol reforming, commercialization has been limited to high-pressure tanks and metal hydrides - both of which have significant usability issues. SiGNa's newly developed class of sodium silicides such as, Na₄Si₄, rapidly react with water to form hydrogen and a benign, industrially useful, by-product, sodium silicate.

2 NaSi(s) + 5 H₂O(ℓ) → 5 H₂(g) + Na₂Si₂O₅(aq)

SiGNa has developed system implementation technology to facilitate this reaction in a manner that is highly controllable with high flow capability at low pressures with excellent re-start characteristics.

### Approach

The overall approach is summarized in Figure 1. The basic architecture is straightforward; simply add water to powder. Water solutions, such as salt water and water/alcohol mixtures, were also tested and verified to yield a controllable hydrogen flow rate with no impurities (as tested on an Agilent 6850 gas chromatograph). A micro-spray water distribution system has been developed to increase the active reaction area. For a “single-start” reaction, this distribution system is not necessary as the bed will self-mix and fully react large quantities of powder. To rapidly start a cold, partially reacted solution, the micro-spray system sprays water streams on un-reacted powder regions throughout the chamber.

SiGNa first developed a series of clear reaction vessels to visualize the reaction and optimize the parameters. This series of breadboard test vehicles was used to test the various control components and demonstrate core reaction characteristics. The results of these experiments have been incorporated to develop a standalone hydrogen generation system. Basic operation of the hydrogen generation system (Figure 2) has been verified with a Trulite 300 W fuel cell system (Figure 3) and then modified to fuel a hydrogen-fueled electric bicycle (Figure 4). During this project, material production has jumped from a 100 gram laboratory process to a >4 kg batch reactor. SiGNa is currently working with an established toll manufacturer with expertise in alkali metals to continue the scale-up of a next-generation manufacturing process.

### Results

#### Cartridge

A number of reaction vessels have been tested ranging from 30 to 1,200 ml. This work led to the development of a 1.2 liter cartridge fabricated using an impact extrusion process - similar to a paint can - for low-cost production. The cartridges have a quick-connect interface and are used in conjunction with both the Trulite 300 W fuel cell and a 300 W electric bicycle.

#### Reaction

The water feed and distribution system primarily consists of the pump and a micro-nozzle network. In practice, there are significant challenges in getting a far reaching spray at very low water flow rates (<1 ml/min).
The water distribution network is almost exclusively required for re-start conditions. Systems using this micro-nozzle manifold were shown to rapidly restart after storage at room temperature for seven days after first reacting 80% of powder.

**Control**

A predictive proportional-integral-derivative control system was developed to generate hydrogen at a near constant pressure even when using two canisters in parallel controlled via a single water...
pump. By using calibrated pump data in conjunction with a measurement of the change in pressure over time (dp/dt), the microcontroller estimates the actual hydrogen flow. The hydrogen generation system also indirectly measures hydrogen flow rate by monitoring the fuel cell electrical current. However, pump data and pressure measurements have proven sufficient to control the pressure to within approximately +/- 5 psi at a nominal pressure of 30 psi.

**Water Pump System**

In addition to active pump control, SiGNa has developed a passive, disposable, orientation-independent water pumping system and water reservoir within the hydrogen cartridge. This system has demonstrated a near constant hydrogen pressure of 3 psi for regulator-free, low-cost fuel cell operation. This has only been tested on a smaller cartridge with a capacity of 50 liters - although it is anticipated to be scalable to the 1.2 liter vessel, this will not be demonstrated in the project.

**Testing**

Hundreds of tests and thousands of hours of hydrogen generation have been performed over the course of the project. Hydrogen yield is reliably at or near the theoretical maximum of 9.8 wt%. A combined water/powder energy density of over 1,300 Wh/kg LHV was achieved. In addition, an advanced sodium silicide mixture was shown to yield over 1,600 Wh/kg LHV and over 1,854 Wh/kg when recirculating 50% of the fuel cell waste water.

**Conclusions and Future Directions**

Sodium silicide is capable of controlled hydrogen flow for a range of portable applications. A number of implementation issues that have plagued other hydrolysis systems – particularly impacting restart capability – have been resolved. All results continue to indicate that sodium silicide is capable of near-term commercialization while providing a hydrogen source that is safe and easy to use. The balance of work in this project will be focused in the following areas:

- Final testing and verification of the hydrogen generation system.
- Continued testing on larger powder quantity runs to optimize control characteristics and minimize water usage.
- Continued testing and improvements on the hydrogen generation control system.
- Operation of the hydrogen generation system by a fuel cell system developer for independent performance verification.

**FY 2010 Publications/Presentations**

IV.H.2 Purdue Hydrogen Systems Laboratory: Hydrogen Storage*

Objectives

- Develop an energy efficient recycling protocol for ammonia borane (AB) from spent borate.
- Develop AB slurry-based subscale onboard hydrogen storage systems.
- Develop a new noncatalytic method for hydrogen generation from AB and water.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (Revision 2007):

(A) System Weight and Volume
(B) System Cost
(J) Thermal Management
(R) Regeneration Process
(S) By-Product/Spent Material Removal

Accomplishments

- AB was prepared in kilogram-scale from sodium borohydride and ammonium sulfate in the presence of ammoniated tetrahydrofuran (THF) at room temperature in 92% yield and ≥98% purity.
- Trimethylborate was reduced using diethylsilane in the presence of N₁,N₁,N₂,N₂-tetramethylethane-1,2-diamine (TMEDA) to TMEDA-Bisborane complex.
- TMEDA-Bisborane complex was converted to AB via transamination in 80% yield.
- For the first time, characterized rheological properties of AB spent fuels.
- For the first time, captured the details of fast hydrogen evolution at the initial stage of the AB thermolysis process.
- Designed, constructed and tested a 10 g capacity batch reactor for neat AB thermolysis. Reactor capable of operating at up to 200°C and 8 bar.
- Investigated noncatalytic AB hydrothermolysis at near proton exchange membrane fuel cell (PEMFC) operating temperatures over a wide range of AB concentrations and pressure. The maximum hydrogen yield, obtained at 77 wt% AB and T<sub>reactor</sub> ~85°C along with rapid kinetics, was 11.6 and 14.3 wt% at pressure 14.7 and 200 psia, respectively.
- Using the neat AB thermolysis process, ~15 wt% H<sub>2</sub> yield was obtained at 14.7 psia and T<sub>reactor</sub> ~90°C with rapid kinetics also near the PEM fuel cell operating conditions.

Introduction

This project allows the creation of a Hydrogen Research Laboratory in a unique partnership between Purdue University’s main campus in West Lafayette and the Calumet campus. This laboratory is engaged in basic research in hydrogen production and storage and has initiated engineering systems research with goals established as per the U.S. DOE Fuel Cell Technologies Program. Hydrogen production research of this project...
is reported in Purdue Hydrogen Systems Laboratory: Hydrogen Production.

The hydrogen storage research has been focused on improving the engineering performance of AB-based onboard hydrogen storage and finding energy efficient ways to recycle the byproducts. To that end, a task is focused on finding energy efficient ways to recycle the ammonium borate to AB. The AB slurry dehydrogenation work was dedicated to measuring engineering properties of onboard hydrogen discharge and fresh/spent fuel transfer and developing a subscale reactor module to provide a platform for the studies of AB and other potential off-board recyclable hydrogen storage materials. With the advantage of transportability of byproduct obtained from neat thermolysis of AB, a scaled AB dehydrogenation batch reactor capable of handling at least one gram AB per batch was designed. The lessons learned in designing, testing, and analyzing the data obtained with the neat AB reactor system are guiding the modeling and future design of a slurry-based reactor. A third task was devoted to developing a new approach to release hydrogen by noncatalytic hydrothermolysis of AB in aqueous solutions and slurries. It is known that the release of hydrogen from AB via both thermolysis and hydrolysis is exothermic. In AB hydrothermolysis process, it was found that the heat generated by hydrolysis initiates thermolysis near PEMFC operating temperature (85°C) along with rapid heat evolution. On the other hand, for neat AB thermolysis, the sharp evolution was not observed at 85°C, indicating that water (hydrolysis) drives the sharp heat evolution resulting in high H₂ yield. Nevertheless, since the release of hydrogen from AB via thermolysis (release of first and second H₂ moles) is exothermic, it was expected that with effective heat management, the sharp heat evolution could be observed near PEMFC operating temperatures during neat AB thermolysis as well.

**Approach**

The spent fuel, ammonium borate will be converted to triacyl- or trialkyl borates, which will provide molecules with the weaker B-O bond. The reduction of triacyl- or trialkyl borates in the presence of TMEDA, followed by the displacement of TMEDA using ammonia will lead to efficient ammonia borane regeneration.

To facilitate the design of thermal management and spent fuel removal, we investigated neat and ionic-liquid aided AB dehydrogenation kinetics, especially at the initial fast hydrogen evolution stage. A neat AB batch reactor module was designed and assembled at the Hydrogen Systems Laboratory. Made of stainless steel, the cylindrical reactor is designed to handle reactions with starting temperatures of about 155±5°C and a nominal batch reaction time of 10 minutes. On-going tests with batches of up to two grams AB are providing data and design guidance for the development of an AB-based reactor. We also developed a computational fluid dynamics (CFD) model to simulate the thermo-chemical process in an AB slurry reactor. In addition, we measured elastic stiffness and viscous damping of AB spent fuels from various reactions including hydrolysis, thermolysis and hydrothermolysis.

The AB hydrothermolysis method for H₂ generation was investigated over a wide range of AB concentration in water, pressure, and heating rate. The neat AB thermolysis was also studied near PEMFC operation temperatures. To better understand the reaction exothermicity (heat evolution), we developed a smaller size reactor (70 ml). Apart from the reactor temperature, the sample temperature (Tsample) was also measured by inserting a thermocouple inside the sample. In addition to mass spectrometry, ammonia was also measured by titration technique.

**Results**

AB was prepared in kilogram-scale from sodium borohydride and ammonium sulfate in the presence of ammoniated THF at room temperature in 92% yield and ≥98% purity. We have recycled ammonia borate to AB via conversion to trimethyl borate followed by the reduction using diethylsilane (Figure 1). We developed novel protocol for the reduction of trimethylborate in the presence of TMEDA using diethylsilane resulted in the formation of the diamine bisborane complex in very high yield (90%). The solid bisborane complex could be readily separated by filtration. The preparation of AB from this diamine bisborane complex was achieved in 80% yield by exchange with ammonia. We have initiated energy efficient schemes to convert NH₄B(OH)₄ to AB via triacylborates. The advantage of conversion to such acylborate esters over simple alkylborate esters is that the B-O bond will be weakened enough to be reduced with mild hydride sources.

We measured the reaction kinetics of neat and 1-butyl-3-methylimidazolium chloride (bmimCl)-aided AB thermolysis under quasi-isothermal conditions in the

![FIGURE 1. AB recycling.](image-url)
The measured hydrogen storage capacity of the 80/20 AB/bmimCl mixture was 11.2 wt% at 120°C and foaming during AB thermolysis was partially suppressed by the ionic liquid. Hydrogen yield reduction caused by impurity and aging of bmimCl should be further addressed. bmimCl aided thermolysis should be implemented at sufficiently high temperature (>107°C) to achieve a noticeable gain in the hydrogen storage capacity when comparing to the neat AB thermolysis.

We also quantitatively revealed the visco-elastic differences between the spent fuels obtained from the various AB dehydrogenation methods. It was demonstrated that spent fuels obtained from AB neat thermolysis and hydrothermolysis are the most transportable, followed by its hydrolysis and ionic liquid-aided thermolysis, respectively. The spent fuels obtained at higher temperatures exhibit improved transportability.

A reactor system for neat AB thermolysis of up to two gram batches of AB was designed. The system is characterized by modularity and highly repeatable batch operation. It consists of an AB feeder, a reactor and a gas processing unit (Figure 2). Safety features such as remote operation and cooled AB reservoir make the operation very safe and reliable. Operation of the system was tested with AB batches weighing up to two grams. The average temperature for batch reactions was 160°C. Results of the batch tests are compared in Table 1 with those obtained with a bench top unit. In addition, we developed a CFD code to simulate an AB slurry reactor for on-board hydrogen storage. For 80/20 ammonia borane/ionic liquid slurry, a reactor was simulated at a H₂ release rate of 1.6 g/s with a reactor total weight of ~2.4 kg.

AB hydrothermolysis was investigated in a 70 ml stainless steel Parr reactor over a wide range of AB concentration, pressure, and heating rate. The maximum observed hydrogen storage capacity, obtained at 77 wt% AB concentration and T<sub>reactor</sub> ~ 85°C, was 11.6 and 14.3 wt% at pressure 14.7 and 200 psia, respectively (Figure 3). For 200 psia and heating rate 1°C/min, AB converted to NH₃ (NH₃/AB) in the gaseous product decreased with increasing AB concentration. It is worth noting that even for neat AB thermolysis (in absence of water), 2-4% of AB was converted to NH₃, which must be removed for use in PEMFC. With increasing

Conclusions and Future Directions

We investigated the fundamental chemistry of AB recycling and achieved conversion of trimethyl borate to AB. The reduction of trimethyl borate using diethylsilane will be optimized with respect to temperature and pressure, silane and amines. The displacement of TMEDA from the corresponding bisborane adduct using ammonia will be further optimized for the quantitative isolation of ammonia borane. Computations of the recycling of energy efficiency will be done.

We achieved 11.2 wt% (material) hydrogen storage capacity from the 80/20 AB/bmimCl mixture thermolysis, which is within the uncertainty limits of the highest ever reported in the literature. We measured the hydrogen yield and characterized the operation of a neat AB batch reactor. We obtained similar yield rates and chemical kinetics results for bench tests and batch reactions. However, the challenges associated with AB byproduct removal and transient mass flow rate measurement of gas yield need to be further addressed. We will apply the lessons learned with the neat AB batch reactor, the results of CFD simulations and overall engineering performance analyses to the design of the AB slurry reactor.

It was demonstrated that noncatalytic AB hydrothermolysis is a promising method for hydrogen storage. This process was studied over a wide range of AB concentrations, pressure, and heating rate. It was found that hydrogen yield, ammonia generation and thermal characteristics were influenced by these operating conditions. The maximum hydrogen storage capacity, obtained at 77 wt% AB and T\textsubscript{reactor} ~ 85°C along with rapid kinetics, was 11.6 and 14.5 wt% at pressure 14.7 and 200 psia, respectively. The kinetics of neat AB thermolysis under various operating conditions were also investigated. For neat AB thermolysis, ~15 wt% H\textsubscript{2} yield (2.3 H\textsubscript{2} molar equivalent) was obtained at 14.7 psia and T\textsubscript{reactor} 90°C with rapid kinetics under effective heat management. To our knowledge, this value is higher than by any other method using AB at near PEMFC operating temperatures.

**Archival Papers**

**Conference Papers and Presentations**

Objectives

The ultimate vision of this project is to develop glass-based materials with structural properties that would make them promising candidates for use in H-storage: either as material for glass microspheres or for sponge-type storage.

- This is an extensive research project in physics and chemistry of glasses and of glass-based nano-crystalline materials.
- It will fill gaps in the current understanding of these very complex materials.
- It will shed more light on nucleation and crystallization phenomena in glass matrices, which could extend their technological applications.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume
(B) System Cost
(D) Durability/Operability

Technical Targets

This project is conducting studies of glasses and of glass-based nano-crystalline materials. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2010 hydrogen storage targets:

- Weight and Volume: 0.045 kg H₂/kg system; 0.028 kg H₂/L system
- Cost: $4/kWh net

Approach

The most desirable candidates for hydrogen storage are systems which do not interact chemically with hydrogen and possess high surface area to host substantial amounts of hydrogen. From this point of view, glasses built of a disordered network with ample void spaces, which are permeable to hydrogen and glass-derived nanocomposites, hybrids of glass and nanocrystals, appear to be promising candidates. Other essential advantages of glasses include simplicity of preparation, flexibility of composition, chemical durability, non-toxicity and mechanical strength, as well as low production costs and environmental friendliness.

This project will challenge to extend the concept of using glass-based materials as hydrogen storage media. The focus will be on research of specific glass compositions with emphasis on their fabrication process and characterization using multi-technique experimental approach. The endeavor is to show ways how to tailor the structure of disordered amorphous networks in selected glasses by taking advantage of controlled nucleation and crystallization phenomena and by transforming them into glass-crystal hybrid complex nanocomposites. The ultimate goal of this project is the successful development of glass-derived composite materials with structural properties that would make them promising candidates for potential use as hydrogen storage media: either as material for glass microspheres or for sponge-type storage. Moreover, this research will fill gaps in the current understanding of a very complex group of materials – glasses – and will shed more light on nucleation phenomena in glasses which will extend the existing variety of their technological applications.

Accomplishments

- Project begun in January 2010.
- This is a brand new project and requires the establishment of two new laboratories. The
execution of the project is conditioned by laboratory reconstruction/adaptation and by purchase of state-of-the-art experimental instrumentation.

- The project is composed of several experimental tasks which are sequential and depend on the completion of the new laboratories that is currently in its final phase.

**Future Directions**

Experimental work is scheduled to commence in September/October 2010.

**FY 2010 Publications/Presentations**

Objectives

- Investigation of maximum hydrogen storage capacity, adsorption/desorption kinetics, and catalyst effects in thin films and nanostructures of magnesium borohydride for hydrogen storage.
- Experimental investigation of methods to destabilize borohydrides in order to lower the temperature, and increase the rate of dehydrogenation/rehydrogenation.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Engineered Nanostructures

Successfully fabricated magnesium boride nanostructures at room temperature using GLAD.

System upgrades on our homemade quartz crystal microbalance (QCM) hydrogen storage measurement unit has been done and new measurement procedures has been introduced for accurate hydrogenation/dehydrogenation tests.

Performed material characterization and preliminary hydrogen storage experiments on GLAD magnesium boride nanostructures.

Introduction

After our previous studies on the model system nanostructured magnesium, we focused our studies on the fabrication and hydrogenation properties of nanostructured magnesium boride during past year. Magnesium borohydride Mg(BH₄)ₓ, which is the fully hydrogenated form of magnesium diboride (MgB₂), was the choice of material due to its promising properties for hydrogen storage applications with a high gravimetric (14.9 wt%) and volumetric density of hydrogen. Many theoretical and empirical studies state the reversibility of Mg(BH₄)ₓ is possible [1]. The chance of hydrogenating MgB₂ at reasonable pressure and temperatures has been shown in the LiH-MgB₂ systems [2]. The general
approach in the literature has been first starting with the synthesis of magnesium borohydride, dehydrogenate it, and trying to re-hydrogenate it back to magnesium borohydride. However, complete dehydration of \( \text{Mg(BH}_4\text{)}_2 \) was not possible at reasonable temperatures, making the following hydrogenation step even more difficult. It has been recently suggested that it may be easier to start hydrogenation process from the fully decomposed magnesium boride (\( \text{MgB}_2 \)) [3]. In addition, due to the reduced size and high surface/volume ratio of nanostructures, it is expected that kinetics of hydrogen adsorption/desorption can be further enhanced for nanostructured magnesium boride.

**Approach**

The GLAD [4] technique has been utilized for the growth of nanostructured magnesium boride coatings. For GLAD, a sputter/evaporation deposition system with a sample rotation and tilt control capability has been utilized. We used a new QCM gas chamber system that we developed for the hydrogen storage measurements on nanostructured magnesium boride.

**Results and Discussion**

After various experiments on optimizing the deposition parameters such as sputter power, deposition angle, deposition rate, and initial substrate patterning, the successful method for room temperature fabrication of nanostructured GLAD magnesium was determined to be placing the sample at 90° deposition angle from both sources of magnesium and boron. The sources were located across each other at 180° during the deposition where the sample was rotated around its surface normal axis. At the initial stages of growth, we introduced a formation of a few tens of nanometer long Mg nanoblades by a short Mg-only GLAD thermal deposition. This short pre-deposition was used as a template for the further enhancement of shadowing effect [4] during the following GLAD magnesium boride deposition. Figure 1(a) and (b) shows the top view scanning electron microscope (SEM) images of 270 nm (60 min deposition time) and 540 nm (120 min) thick columnar Mg+B nanostructures obtained from our GLAD experiments. Cross-sectional SEM images (not shown here) also confirm the isolated nanostructure formation. The columnar feature sizes are around 100 nm in diameter for 270 nm long magnesium boride nanostructures and it is about 200 nm for the 540 nm long nanostructures. In addition, Figure 2 shows the X-ray diffraction (XRD) profiles of these Mg+B samples as well as that of uncoated silicon substrate, XRD results indicates that we were able to form a nanostructured MgB\(_2\) coating. However, Figure 2 also shows relatively weak peaks of magnesium, which indicates that the some magnesium atoms couldn’t form a boride structure, possibly due to the lack of B or due to the low substrate temperature.
In addition, we deposited nanostructured magnesium boride onto QCM crystals in order to analyze its hydrogen absorption properties using our custom designed QCM chamber. Preliminary QCM results shown in Figure 3 indicate a ~2.9 wt% hydrogen absorption in nanostructured magnesium boride at 300°C under 30 bar hydrogen pressure. The SEM image in Figure 4(a) shows that morphology of the hydrogenated sample is significantly different than the initial product (Figure 3). Columnar features before the hydrogenation process disappeared and a cracked film with finer nano-scale features has formed, possibly due to the coalescence of the magnesium boride nanostructures and crack formation as a result of the volume expansion of the hydrogenated coating. The hydrogenated film did not delaminate from the substrate and was stable after the QCM experiment. XRD analysis on the hydrogenated magnesium boride sample (Figure 4(b)) shows the partial formation of Mg(BH₄)₂.

**Conclusions and Future Directions**

Our results show that we successfully fabricated magnesium diboride (MgB₂) nanostructures at room temperatures using the GLAD method. Preliminary QCM test indicate that we were able to partially hydrogenate MgB₂ at 300°C to form Mg(BH₄)₂ with about 2.9 wt% hydrogen storage. However, this storage value is still far below the theoretical maximum value of 14.9 wt%. Therefore we plan to investigate the fabrication of nanostructured magnesium boride with improved crystal and morphological properties and also study the effect of catalyst additives.

**Plan for Future Studies**

Fabrication of nanostructured GLAD MgB₂ at elevated substrate temperatures for enhanced crystallization, with catalyst additives for enhanced hydrogenation/dehydrogenation kinetics, and investigating their hydrogen storage properties.

**Borohydrides**

**Accomplishments**

- Examined the catalytic benefits on encapsulation of organic borohydrides in mesoporous silica. Surface chemistry was probed with neutron scattering showing involvement of the surface in decomposition.
- Tested the predicted thermal destabilization effects of the coupled decomposition of LiBH₄ and Ca(BH₄)₂.
- Performed a thorough investigation of a novel preparations for Ca(BH₄)₂ by solid state synthesis.

**Introduction**

**Borohydrides in Mesoporous Silicate**

The thermodynamic parameters obtained via ab initio studies predict that many borohydrides are theoretically capable of thermolysis at reasonably low temperatures [5,6]. In practice, much higher temperatures are required, and the rate of reaction is often sluggish except in the presence of a catalyst [7-9]. This implies that the limiting factors are associated with kinetics and the activation energy barrier. Fang et al. have shown that that dispersing LiBH₄ with a carbonaceous mesoporous network encourages thermal decomposition [10]. The nature of the interaction between the borohydride and its host network has not been thoroughly investigated as of yet. As a model system, we load organic borohydrides (R₄NBH₄) inside a mesoporous silicate MCM-48. MCM-48 was chosen because it has a regular structure that can easily be probed with XRD, whereas mesoporous carbons derived by templating have irregular pore ordering. Borohydrides with an organic cation provide high visibility of both the cation and anion to neutron scattering and better solvent options for loading the porous networks.

We conducted an additional study on mesoporous silicate loaded with inorganic molecular borohydride Zr(BH₄)₄. In addition to thermodynamic benefits, it was anticipated that the silicate will mitigate some of...
Calcium Borohydride Destabilization

Ca(BH₄)₂ is a promising candidate for a hydrogen storage material due to its rich hydrogen composition, and lower decomposition ΔH of ~41 kJ mol⁻¹ [1]. However, the decomposition of the neat material is sluggish. In practice, the temperatures required to decompose Ca(BH₄)₂ are also much higher than the thermodynamics imply [11]. This discrepancy may be due to kinetics. Both of these difficulties may be aided in part by destabilization by coupled decomposition. The following reaction was predicted by Ozolins et al. to have a slightly more attractive enthalpy of ~57 kJ mol⁻¹ and comparable hydrogen emission of bulk Ca(BH₄)₂ [12].

\[
5\text{Ca(BH}_4\text{)}_2 + 2\text{LiBH}_4 \rightarrow \text{Li}_2\text{B}_{12}\text{H}_{12} + 5\text{CaH}_2 + 13\text{H}_2
\]

Additional decomposition with the release of hydrogen is also predicted to be possible from the products by reaction of Li₂B₁₂H₁₂ with CaH₂; but the initial step above must occur first. No clear predictions were made regarding the kinetics or reversibility of this reaction, hence our interest in testing it experimentally.

Approach

Borohydrides in Mesoporous Silicate

Mesoporous silicate MCM-48 was synthesized in a pressure vessel by hydrothermal methods as described elsewhere [13]. Me₄NBH₄ and Et₄NBH₄ were prepared by wet chemical methods; purity was verified by Fourier transform infrared (FTIR) and XRD. Silicates were loaded with borohydride by incipient wetness methods (see 3rd quarter 2009 report for further preparation details). Loaded compounds were subsequently characterized by differential scanning calorimetry (DSC)/thermal gravimetric analysis (TGA) for thermal analyses, FTIR for general composition and validation, XRD for structural analyses, Brunauer-Emmett-Teller (BET) surface area determination, residual gas analysis to determine the gas product composition and inelastic neutron scattering (INS) to probe the chemical environment inside the pores. INS spectra were collected on the filter difference spectrometer at the Manuel Lujan, Jr. Neutron Scattering Center at Los Alamos National Laboratory.

Calcium Borohydride Destabilization

The theoretically predicted destabilization reaction between Ca(BH₄)₂ and LiBH₄ was investigated in solid state by ball milling of a stoichiometric mixture of commercially obtained calcium and lithium borohydrides and pressing a pellet of the mixture. DSC/TGA were performed on several pellet samples during heating. Volumetric analyses were also performed on larger samples (~300 mg) of loose ballmilled powder. The sample was heated in a sealed reactor of known volume which was purged by vacuum and backfilled with a small amount of Ar. All preparations were carried out in a helium glove box.

Results and Discussion

Borohydrides in Mesoporous Silicate

The combined results of XRD, FTIR and BET analyses revealed that Me₄NBH₄ and Et₄NBH₄ were...
each successfully loaded into mesoporous silicates in uniform fashion (see 3rd quarter 2009 report for further details). TGA analyses revealed that both Me₄NBH₄ and Et₄NBH₄ decompose at lower temperatures when loaded in MCM-48. Figures 5(a) and 5(b) show TGA data for pure R₄NBH₄ and R₄NBH₄ loaded in MCM-48 for R=Me and R=Et respectively. It should be noted that host MCM-48 (not shown) displays no measurable mass loss until temperatures well above 500°C. The thermal analyses in Figures 5(a) and 5(b) reveal that temperature for the onset of decomposition is lowered significantly for both borohydrides when loaded in MCM-48. Mass spectrometry reveals that the primary product of both decomposition reactions is hydrogen. However, the mass spectrum also indicates that a significant quantity of diborane is present in the decomposition gas stream of both R₄NBH₄ compounds. Diborane was present in the bulk decomposition products as well.

INS analyses indicated shifts in frequency and changes in intensity of the vibrational modes of both [R₄N⁺] and [BH₄⁻] ions after loading in MCM-48. These changes indicate that the ions are adsorbed onto the silica surface, and that the silica surface changes the chemical environment of these borohydrides slightly. Comparisons of the INS spectra of the bulk and loaded compounds of Me₄NBH₄ are shown in Figure 6(a). The spectra of Et₄NBH₄ and its porous silicate loaded counterpart are shown in Figure 6(b). Further evidence of surface interaction is indicated by the formation of surface hydride compounds which occur during vacuum decomposition of Me₄NBH₄. This surface compound was verified to contain a surface Si-H bond by comparison with the INS spectrum of amorphous silica gel with gaseous hydrogen. INS spectra of MCM-48 loaded

FIGURE 5. (a) TGA 5K/min. heating performed under light Ar flow [1]. Bulk Me₄NBH₄ [2]. MCM-48 loaded with Me₄NBH₄. (b) TGA 5K/min. heating performed under light Ar flow [1]. Bulk Et₄NBH₄ [2]. MCM-48 loaded with Et₄NBH₄.

FIGURE 6. (a) INS spectra of bulk Me₄NBH₄ and MCM-48 loaded with Me₄NBH₄. Adsorption is apparent from the shifts in frequency of numerous vibrational modes and broadening of spectral features, particularly at low frequencies. (b) INS spectra of bulk Et₄NBH₄ and MCM-48 loaded with Et₄NBH₄. Adsorption is apparent from the shifts in frequency of numerous vibrational modes and broadening of spectral features, particularly at low frequencies.
with Me$_4$NBH$_4$ after decomposition and the hydrogen exposed silica can be seen in Figure 7(a) and 7(b) respectively. It should be noted that this surface Si-H bond does not form on the decomposition of Et$_4$NBH$_4$ adsorbed on MCM-48 nor did it occur in samples of Me$_4$NBH$_4$ adsorbed on nickel-doped MCM-48.

Zr(BH$_4$)$_4$ also adsorbs on MCM-48 with alterations in its chemical environment as observed by INS spectroscopy. Several low frequency normal modes of Zr(BH$_4$)$_4$ were shifted by significant amounts; with higher frequency modes less affected. Currently Zr(BH$_4$)$_4$ has been essentially ruled out as a hydrogen storage medium because it becomes volatile upon melting at ~30°C, and decomposes in gas state at ~160°C [14]. This volatility renders the compound unusable in most hydrogen storage systems. TGA data reveal that the Zr(BH$_4$)$_4$ is retained by the MCM-48 during heating, mitigating the volatility issue. Zirconium was verified to be retained by comparison of the Si:Zr ratio as measured by XRF. The severe sensitivity to moisture of Zr(BH$_4$)$_4$ in MCM-48 is also apparently reduced somewhat from the bulk compound.

### Calcium Borohydride Destabilization

The TGA/DSC curves for the LiBH$_4$/Ca(BH$_4$)$_2$ mixture (heated under Ar flow) are shown in Figure 8(a). Two notable endothermic events occur during the heating of the mixture. The endothermic peak at ~115°C coincides with the structural phase transition in LiBH$_4$. The second endothermic peak in the DSC curve of Figure 4b (labeled with a '?') onsets around 200°C. The melting of LiBH$_4$ typically occurs at 285°C, and is greater in total enthalpy change than the structural phase transition at ~120°C and is thus non-consistent with this feature. No melting was evident in the sample upon visual inspection after heating. At higher temperatures, the melting of LiBH$_4$ is notably absent from the DSC curve. There is no such feature in the DSC curve of Ca(BH$_4$)$_2$, which only begins to decompose at ~350°C [15]. The pressure and temperature data from the volumetric analysis of the Ca(BH$_4$)$_2$/LiBH$_4$ mixture is plotted in Figure 8(b). A reaction releasing gas (presumably hydrogen) begins around 220°C. These data are consistent with a thermal destabilization effect from the ballmilling of Ca(BH$_4$)$_2$ and LiBH$_4$. However, it is unclear if the reaction proceeds as Ozolins et al. [5] predict. FTIR showed the resultant solid residue to be free of the Li$_2$B$_{12}$H$_{12}$ product which is the cause of the predicted thermal destabilization (see 4th quarter 2010 report for more details; residual BH$_4$ was clearly present as well). Also the observed reaction released only 39% of the expected gas emissions that would account for the theoretical reaction of Ozolins et al. This implies partial reaction, or a separate destabilization mechanism.
**Conclusions and Future Directions**

**Borohydrides in Mesoporous Silicate**

We have demonstrated that adsorption of the borohydrides within the MCM-48 pores provides various utilitarian effects. In Me$_x$NBH$_4$ and Et$_x$NBH$_4$ a significant reduction (>50°C decrease) in decomposition temperature was observed in TGA for each compound respectively. Rates of thermal decomposition are also improved in the adsorbed compound vs. bulk. Preliminary results indicate that MCM-48 adsorbed Zr(BH$_4$)$_4$ is retained by the MCM-48 during heating, mitigating the volatility issue. Additionally, the air sensitivity of Zr(BH$_4$)$_4$ is significantly reduced when adsorbed on MCM-48.

Inelastic neutron scattering has revealed that the surface chemically interacts with pore encapsulated borohydrides, and plays some role in decomposition of adsorbed borohydrides. We have also demonstrated that doping of this network with transition metals can alter the decomposition chemistry.

**Calcium Borohydride Destabilization**

We have verified a destabilization effect caused by mechanical mixing of LiBH$_4$ and Ca(BH$_4$)$_2$. The mechanism of this reaction does not appear thus far to be consistent with the theoretically reaction producing Li$_2$B$_{12}$H$_{12}$. However, we have not conclusively verified a separate mechanism, and subsequent reaction to decompose the Li$_2$B$_{12}$H$_{12}$ may occur. While the observed destabilization is an improvement versus either bulk Ca(BH$_4$)$_2$ or LiBH$_4$, the reaction temperature, hydrogen yield and kinetics of the observed destabilized decomposition reaction are still require further improvement to be directly usable in hydrogen storage.

**Plan for Future Studies**

- The effects of surface sites on dehydrogenation of borohydrides may prove useful to future researchers investigating borohydrides for hydrogen storage. The impact on storage capacity and reversibility associated with the use of hydride complexes in porous networks is yet unknown.
- The destabilization of CaBH$_4$ and LiBH$_4$ by solid state mixture has not yet been optimized, and may be viable if it can be further catalyzed by addition of dopants. The products and reversibility are yet unknown.

IV.I.1 Standardized Testing Program for Solid-State Hydrogen Storage Technologies

Objectives

Overall

• Support DOE’s Hydrogen Storage sub-program by operating an independent, national-level reference laboratory aimed at assessing and validating the performance of novel and emerging solid-state hydrogen storage materials and full-scale systems.

• Conduct measurements using established protocols to derive performance metrics: capacity, kinetics, thermodynamics, and cycle life.

• Support parallel efforts underway within the international community, in Europe and Japan, to assess and validate the performance of related solid-state materials for hydrogen storage.

Current

• Evaluate and validate the effects of piezo-induced charge on the sorption capacity of nano-porous carbon.

• Evaluate and validate hydrogen sorption capacity in polyether ether ketone (PEEK)-derived carbon material.

• Assess hydrogen spillover effects and kinetics in AuAl$_2$ and AuLi-intercalated isoreticular metal organic framework (IRMOF)-16.

Technical Barriers

The technical barriers associated with the operational objectives of the laboratory are:

• Standardization of methods suitable to a wide variety of compositions of matter.

• Development and implementation of “Gold Standard” measurement techniques.

Moreover, this project addresses the following technical barriers from the Storage section (3.3.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

• Verification of material performance

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

(Q) Reproducibility of Performance

• Verification of system performance

(K) System Life-Cycle Assessment

(Q) Reproducibility of Performance

(F) Codes and Standards

Technical Targets

This project addresses the fundamental need for establishing a national-level laboratory whose core mission is to study and independently verify the intrinsic sorption characteristics of novel and emerging materials for hydrogen storage, including such activities as they pertain to their use in full-scale storage systems. As a fully qualified laboratory under the purview of the DOE, the laboratory plays a central role in down-selecting materials and systems that emerge from the Centers of Excellence and outside entities by:

• Providing in-depth analysis and understanding of hydrogen physisorption and chemisorption mechanistic behavior.

• Determining and validating material and system storage capacities.

• Determining material and system kinetics (charging/discharging rates), thermodynamics, and cycle-life durability.
Accomplishments

- Contributing to the testing requirements for codes and standards of full-scale systems.
- Providing listing and labeling services for full-scale systems such as fire safety performance.

- Evaluated the effect of piezo-induced charge on hydrogen adsorption in nanoporous carbon at 77 and 298 K, using materials provided by Michigan Tech University, and observed that piezo-induced charge accumulation did not lead to a measurable increase in hydrogen uptake via hydrogen-charge binding interactions.
- Validated the hydrogen sorption capacity in PEEK-derived carbon at 77 and 298 K using material provided by Duke University. Experimental measurements showed:
  - Maximum excess concentration of 5.4 wt% at 77 K and 55 bar.
  - Absolute volumetric capacity approaching 30 g/L at 77 K and 70 bar.
- By leveraging SwRI’s parallel research activities, IRMOF-16 compounds entrapping nanoparticles of AuAl₂ and AuLi (i.e., metal intercalated IRMOF-16) were successfully synthesized and characterized. Experimental measurements showed:
  - Excess concentration of 1.1 wt% at 80 bar and room temperature for the AuAl₂-IRMOF-16 compound, which can be attributed to hydrogen spillover, with relatively fast kinetics (15 min for equilibration).
  - Total loading of intercalated AuAl₂ in IRMOF-16 sample was only 0.13 wt%.
  - Total loading of intercalated Ti in previously-reported Ti-IRMOF-16 compound (showing 1.3 wt% uptake at room temperature and 80 bar) was only 0.04 wt%.

Introduction

Promising classes of materials being developed for reversible on-board hydrogen storage have emerged, thus compelling a rigorous and independent evaluation of their storage capacity, thermodynamics, and kinetics. Occasionally, entirely new chemistries or structural motifs are discovered that yield unexpected properties which must be further studied or validated. Notably, metal organic frameworks (MOFs) [1], destabilized nitrogen-based metal borohydrides [2], and spillover compounds of MOFs, nanoporous carbon materials [3,4], and silica nanosprings, are examples of materials exhibiting surprisingly favorable storage properties which approach the sought-after material targets for on-board storage (Figure 1).

The laboratory has proceeded to evaluate new materials of importance whose validation of hydrogen storage properties is regarded as a high-priority within the solid-state storage community and the DOE. The most recent priorities for the laboratory have concentrated on evaluating piezo-induced charging effects on hydrogen binding interactions in nanoporous carbon, and hydrogen sorption in PEEK-derived nanoporous carbon. In addition to these DOE directives for validation, internally-sponsored materials development activities have been undertaken to evaluate whether chemisorptive strategies for hydrogen storage predicated on spillover can be elicited in AuAl₂ and AuLi-intercalated IRMOF-16 compounds. These efforts were principally motivated by the need to overcome the diffusion-limited kinetics associated with hydrogen spillover in surface catalyzed MOF and carbon materials previously studied [3-5].

Approach

Validating the sorption behavior of storage materials and uncovering the mechanisms involved are approached through close collaboration with researchers among the Materials Centers of Excellence (e.g., the Physisorption Center of Excellence), the international community, and SwRI’s Internal Research & Development Program (IR&D). The laboratory employs a “best practices” approach based on standard operating procedure-documented analytical methods to critically evaluate novel storage materials of potential impact to the sought-after storage goals. By leveraging SwRI’s IR&D program, fundamental aspects of materials research are addressed where critical knowledge or physical matter is presently lacking. This element of...
the program provides a venue for the discovery of new materials and the elucidation of unknown mechanisms.

Results

Effects of Piezo-Induced Excess Charge on Hydrogen Binding

The results of our studies over the past year are highlighted in Table 1. An important directive this year was to independently determine whether or not hydrogen uptake could be enhanced by injecting excess charge into a conductive, porous sorbent, such as nanoporous carbon, and thereby provide the means by which the binding energy between dihydrogen and the localized charge on the sorbent could be increased. This idea, which was conceived at Michigan Technological University (MTU) [6], required that we design and construct a highly-modified sample vessel for low-temperature (77 K) sorption measurements. In this modified vessel, the sample was electrically isolated from the assembly via a thin-walled glass insert, while two piezoelectric elements of the lead magnesium niobate-lead titanate type were embedded in the sample at a fixed distance from each other. One pole (i.e., face) of each piezoelectric element was also electrically insulated so that the face of the conductive pole could emit a local excess-charge into the surrounding carbon sample as hydrogen gas pressure was increased.

While the premise of this concept would seem intuitively sound, our laboratory failed to demonstrate a measurable difference in hydrogen uptake between piezo-induced charge generation in nanoporous carbon and the same carbon sample in the uncharged state under identical analytical conditions of the volumetric technique (Table 1 and Figure 2). This difference between hydrogen-charge binding interactions in the charged and uncharged states, however, may have been so subtle due to the experimental conditions employed, such as a low ratio of total charge to sorbent surface area, that the desired effect could not be effectively realized. Indeed, other passive or active modalities of injecting excess charge into a conductive sorbent may be more effective in enhancing hydrogen uptake or increasing the sorption temperature, or both.

PEEK-Derived Carbon

High-pressure volumetric analysis of PEEK-derived carbon was encumbered by this material’s propensity to absorb helium, thus invalidating the use of a helium calibration for determining the skeletal density of the sample (or free volume of the system). To overcome this analytical challenge, the high-pressure gravimetric technique was employed to measure the hydrogen isotherm at room temperature. In this case, the simplified local density (SLD) model combined with the Bender equation of state were used in a fitting algorithm to derive the hydrogen skeletal density and the pore volume of the sample by treating these characteristic properties as fitting parameters [7].

LTDMS = laser induced thermal desorption mass spectrometry
The corrected hydrogen isotherms at 77 K measured by the volumetric technique are shown in Figure 3. Here the maximum excess concentration for hydrogen uptake was 5.39 wt% at 55 bar with no measureable hysteresis in the desorption path. Using the pore volume derived from the SLD model and fitting algorithm, the profile for absolute volumetric capacity was computed as shown in Figure 4. The absolute volumetric capacity for this material approached 30 g/L at 70 bar and, while this is a remarkable result, it is less than the current benchmark of 40 g/L at 70 bar for MOF-177.

Metal-Intercalated IRMOF-16

Storage materials predicated on hydrogen spillover effects are under intensive study in our laboratory. However, spillover materials exhibiting enhanced uptake at room temperature have been consistently plagued by exceedingly slow kinetics, principally because doping of these materials with a catalyst (and bridging compounds) has been limited to the surface of the porous receptor (e.g., carbon or MOF) [3-5]. A better than present strategy for engineering an “ideal” spillover material has been envisaged in which metal clusters are intercalated into (or rather encapsulated by) a three-dimensional nano-architecture. MOFs are particularly attractive in this regard because the pores of the crystalline framework could potentially lead to entrapment of metal particles or clusters within the framework, thereby forming a network of such particles with long-range periodicity and in close proximity to receptor sites for binding of atomic hydrogen following catalytic dissociation.

In pursuit of unique spillover motifs with improved kinetics, we have expanded our work on the synthesis and characterization of IRMOF-16 [Zn₄O(1,4-di(4-carboxyphenyl)benzene)] compounds entrapping nanoparticles of metal catalysts (i.e., metal intercalated IRMOF-16) by preparing the AuLi-IRMOF-16 and AuAl₂-IRMOF-16 intercalated compounds [8]. These were successfully synthesized using an ionic liquid (IL) as a co-solvent and in situ entrapment of the catalyst particles. The catalyst compounds used here were previously prepared in our laboratory by depositing each metal alloy into IL in vacuo under conditions of plasma magnetron sputtering. In each case, the gravimetric technique was employed to measure hydrogen isotherms at room temperature. The catalyst loading in each compound was also quantified using inductively coupled plasma mass spectrometry (ICP-MS).

The AuAl₂-IRMOF-16 intercalated compound demonstrated higher than expected hydrogen uptake at room temperature (1.1 wt% excess at 80 bar) (Figure 5), achieving steady-state conditions at each pressure point within 15 min (as compared with 600 min for surface-catalyzed spillover materials evaluated in our laboratory). Surprisingly, the AuLi-IRMOF-16 compound yielded only 0.5 wt% excess at 67 bar. In both cases, however, hydrogen uptake via spillover occurred with only 0.1 wt% loading of catalyst in the voids of the MOF as determined by the ICP-MS analysis.

Overall, we have demonstrated that structural motifs of this kind can dramatically improve the kinetics associated with hydrogen spillover effects by encapsulating catalyst particles within framework voids and distributed therein throughout the bulk framework. This close proximity of catalytic centers to the structural moieties of the receptor shortens the diffusion length associated with the transport of atomic hydrogen to chemisorptive binding sites on the receptor following dissociative spillover.
Conclusions and Future Directions

The passive (or active) injection of excess charge into a nanoporous carbon is in principle an attractive means of increasing physisorption binding interactions of dihydrogen for enhanced storage, which is deserving of exploration. However, our laboratory has failed thus far to observe experimentally meaningful differences in hydrogen uptake between carbon samples in contact with half-insulated piezoelectric elements for charge generation and the same material in its uncharged state. The lack of supporting results notwithstanding, future work in this area should first seek to calculate the ratio of the total charge theoretically generated by piezoelectric elements (or other means) to the surface area of the carbon material. Such rudimentary calculations would provide the information needed to effectively scale the experimental setup so that differences in hydrogen uptake between the charged- and uncharged states, if they occur, are most likely to fall within the known limits of detection of the sorption technique.

In the search for novel forms and sources of active carbon materials for physisorption storage, robust materials have emerged with remarkably high surface areas. Nanoporous carbon derived from PEEK exhibits promising characteristics for hydrogen storage in terms of specific surface area and chemical stability. We observed excess gravimetric and absolute volumetric capacities at 77 K that are approximately 70% of those values for the current benchmark, MOF-177 [1]. Further gains in performance are possible as processing methods for the source PEEK polymer are refined.

The potential for chemisorptive strategies via spillover in catalytically-doped nanostructures points to promising opportunities in meeting the DOE on-board storage targets. In expanding our work on metal-doped MOFs as spillover materials, we have shown that entrapping the catalyst in the periodic voids of the framework effectively shortens the diffusion lengths between catalytic centers and chemisorptive sites that lie in close proximity. As was intended, this arrangement manifests in a dramatic improvement in sorption kinetics at room temperature. Future work should concentrate on refining the structural purity of these sorts of structural motifs so that additional gains in room temperature uptake can be realized.

V. FUEL CELLS
V.0 Fuel Cells Sub-Program Overview

Introduction

The Fuel Cells sub-program supports research, development, and demonstration of fuel cell technologies, focusing on the development of fuel cells and fuel cell systems for use in a variety of stationary, portable and transportation applications, with a primary focus on reducing cost and improving durability. Efforts are balanced to achieve a comprehensive approach to fuel cells for near-, mid-, and longer-term applications. Early market penetration is targeted through the development of fuel cell technologies and systems for portable-power applications, auxiliary power units (APUs), and specialty applications such as material handling equipment. Fuel cell technologies already provide sufficient performance and durability to be competitive with alternative technologies in some of these applications, while in others relatively modest improvements are required. The expansion of fuel cells into applications and markets that have more stringent technical and cost requirements is also being pursued. The sub-program pursues the development of fuel cell technologies and systems for distributed power generation—including combined heat and power (CHP) for residential and commercial applications—and for light-duty vehicles, in the longer-term, to allow fuel cell technologies to have significant economic, energy security, and environmental benefits on a national scale.

The sub-program’s portfolio of projects covers a broad range of technologies including polymer electrolyte membrane fuel cells (PEMFCs), direct methanol fuel cells, alkaline fuel cells, and solid oxide fuel cells (SOFCs). Efforts support research and development (R&D) of fuel cell stack components, fuel processors for stationary and off-road transportation applications, and system balance of plant (BOP) components. Along with ongoing efforts, funding allowed for nine new projects, following a 2008 solicitation/lab call, to be initiated in Fiscal Year (FY) 2010. These projects include R&D of catalysts and membrane electrode assembly (MEA) structures with reduced platinum group metal (PGM) content, PGM-free catalysts, portable power, as well as degradation and durability studies, and fuel cell mass transport studies. The DOE funding for these projects is approximately $33 million.

Goal

Develop and demonstrate fuel cell power system technologies for stationary, portable, and transportation applications.

Objectives

• Develop a 60% peak-efficient, durable, direct hydrogen fuel cell power system for transportation at a cost of $45/kW, by 2010; and at a cost of $30/kW, by 2015.\

• Develop a fuel cell system for consumer electronics (<50 W) with an energy density of 1,000 Wh/L, by 2010.\

• Develop a distributed-generation PEMFC system operating on natural gas or liquefied petroleum gas that achieves 40% electrical efficiency and 40,000 hours durability at $750/kW, by 2011.\

• Develop a fuel cell system for APUs with specific power of 40 W/kg and power density of 35 W/L, by 2015.\

FY 2010 Technology Status

Major challenges in the advancement of fuel cell technology are reduction of cost and improvement of durability. Air, thermal, and water management are also key issues for enhancing fuel cell performance. Fuel cells are approaching their targets for power density and specific power, but further progress is required to achieve system packaging requirements necessary for commercialization. Efforts continue to evaluate, understand, and mitigate degradation mechanisms through modeling and experimental validation by the national laboratories, universities, and fuel cell developers. While

[1] Objectives are from the Multi-Year Research, Development and Demonstration Plan, which is under review.
hydrogen is the fuel of choice for automotive applications, stationary applications would benefit from technology improvements permitting fuel flexibility.

The tasks in the *Multi-Year Research, Development and Demonstration Plan*, to be updated in 2010, are organized around components (membranes, electrodes, MEAs, gas diffusion layers, bipolar plates, seals, and BOP components), supporting analysis, and benchmarking and characterization activities. Task areas for fuel cell system and fuel processor sub-system development for stationary power generation applications are included, as are those for early market fuel cell applications, such as portable power, and for the development of innovative concepts for fuel cell systems.

The Fuel Cells sub-program maintains a portfolio of R&D projects specifically aimed at meeting technical and cost targets that will allow fuel cells to compete in the marketplace. With cost a prime driver, analysis of the cost status on an annual basis is required for progress to be gauged. As shown in Figure 1, the cost of a hydrogen-fueled 80-kW fuel cell power system projected for high volume production (500,000 units/year) has been estimated to be $51/kW (assuming 2010 technology), a $22/kW (30%) reduction from the 2008 cost of $73/kW and $10/kW (16%) reduction from the 2009 cost of $61/kW. Cost reductions resulted from simplified architecture and reduction in stack component costs through ongoing R&D efforts. The cost of the fuel cell stack has been estimated to be $25/kW.

**FY 2010 Accomplishments**

Continued progress was made toward meeting 2010 and 2015 technical and cost targets during FY 2010. Notable technological advances in several component areas have led to significant improvements in performance and durability, with decreased cost.

**Advanced Catalysts Enable Reduction in Precious Metal Loading**

The high cost of catalysts based on platinum (Pt) and other PGMs presents a major impediment to widespread commercialization of fuel cell technology. Reducing the loading of Pt and other PGMs, without compromising performance, is therefore a key path to decreasing system cost.

3M continues to develop advanced cathode catalysts based on nanostructured thin film (NSTF) technology. In late FY 2009, 3M reported results from testing of 400 cm² short stacks with NSTF-based PtCoMn catalysts with total PGM content as low as 0.19 gPGM/kW. In FY 2010, 3M increased PtCoMn mass activity 30%, reaching 0.24 A/mg₉₉ for Pt₃Ni, alloy with mass activity of 0.40 A/mg₉₉. 3M developed a post-fabrication treatment process that is roll-good compatible and increases oxygen reduction reaction mass activity up to 50% for PtCoMn and the Pt₃Ni alloy. Further

---

work promises to yield even greater improvements, allowing NSTF catalysts to approach activity levels observed with idealized model catalysts.\(^3\)

3M operated a membrane over 5,000 hours with load cycling with an MEA based on a non-stabilized 20-μm membrane and catalyst loading of 0.15 mg\(_{\text{PGM}}\)/cm\(^2\), meeting the DOE 2010/2015 durability target of 5,000 hours. (The 7,300 hours reported previously was with a higher PGM loading.) With the use of chemical stabilizers in the membrane, 3M exceeded the 200-hour DOE target for stability under open-circuit voltage hold in H\(_2\)/air by more than 300%.\(^3\)

Development of novel core-shell catalysts at Brookhaven National Laboratory (BNL) has contributed to efforts to decrease PGM loading. In FY 2010, BNL improved its core-shell catalyst by using an interlayer of gold (Au) to separate the Pt shell from the PdCo core. Rotating disk electrode testing of the new catalyst has demonstrated mass activity as high as 1.10 A/mg\(_{\text{PGM}}\) and specific activity as high as 1,170 μA/cm\(^2\) at 0.9 V,\(^4\) suggesting a high probability of meeting DOE MEA-level and stack-level targets of 0.44 A/mg\(_{\text{PGM}}\) and 720 μA/cm\(^2\). Scale-up of core-shell catalysts has also been demonstrated, with production of a Pt/Pd core-shell catalyst in batches up to 20 g at Cabot Fuel Cells.

These and other advancements in PGM-based catalysts represent significant progress in FY 2010 toward improvement of fuel cell performance and reduction in fuel cell cost through minimization of PGM loading.

**Non-Precious Metal Catalysts Demonstrate Potential for High-Performance, Low-Cost Fuel Cells**

Continued work at Los Alamos National Laboratory (LANL) on PGM-free catalysts yielded significant performance improvements in FY 2010, with volumetric current density as high as 60 A/cm\(^3\) measured at 0.80 V (iR-free) during fuel cell testing with Fe-cyanamide-C catalyst, representing a 64x improvement over the past two years.\(^4\) Extrapolation to correct for mass-transport limitations suggests that current density as high as 165 A/cm\(^3\) is achievable with this catalyst, in excess of the DOE 2010 target of 130 A/cm\(^3\). Progress also continues on PGM-free polyaniline-based catalysts at LANL, with activity as high as 31 A/cm\(^3\) measured at 0.80 V, a 36x improvement over the past two years.\(^4\)

**Innovative Polymer Chemistry Produces New Membrane Materials for Hot and Dry Conditions**

3M developed new polymer electrolyte membranes with higher proton conductivity and improved durability under hotter and dryer conditions compared with previously produced membranes, as shown in Figure 2.\(^5\) The new multi-acid side-chain polymer membranes have better mechanical properties than conventional single acid side chain perfluorosulfonic acid (PFSA) membranes. In FY 2010, 3M developed innovative polymers in which side chains contain both sulfonic acid and sulfonamide groups. These new perfluoroimide acid (PFIA) polymers have higher tetrafluoroethylene backbone crystallinity than PFSA of the same equivalent weight, and thus have better mechanical properties, including lower swelling and lower water uptake.

---

solubility. Efforts continue to produce PFIA membranes of lower equivalent weight and higher conductivity under dry conditions.

Degradation Studies Reveal Pathways to Increased Durability

Improvements in durability of fuel cell systems will facilitate user acceptance of fuel cells to replace conventional power generation technology. Argonne National Laboratory is investigating the role of electrocatalyst degradation in fuel cell durability, and has thus far highlighted the effect of catalyst particle size on degradation rates, revealing that performance of catalysts with small initial particle size moves toward that of larger particles during operation with cycling, as shown in Figure 3. Work at LANL has demonstrated the critical role of electrode processing on durability. Electrodes formed by an ink-painting technique are strongly sensitive to the nature of the solvent used in the ink. Electrodes prepared from glycerol-based inks demonstrated excellent durability (less than 30 mV loss at 0.8 A/cm² after 70,000 cycles, (exceeding the DOE target of 30,000 cycles), while electrodes prepared from water/alcohol-based inks suffer from severe degradation.

Metal Bipolar Plate Development Demonstrates Corrosion Resistance at Low Cost

Since bipolar plate corrosion and high cost have a negative impact on fuel cell stack cost and durability, sub-program activities support development of novel materials and fabrication methods for bipolar plates. TreadStone Technologies demonstrated coating approaches that allow for the development of low-cost, corrosion-resistant, metal bipolar plates, with an FY 2010 cost estimate well below $5/kW, achieving the FY 2010 target. The approach relies on the use of small, conductive, corrosion-resistant materials as conductive points to cover a small portion of metal surface, together with the use of non-conductive, corrosion-resistant materials to cover the majority of the surface of the metal plates.

CHP Operation Demonstrates Capability for Energy and Cost Savings

DOE is developing distributed energy and CHP systems based on several technologies. Acumentrics Corporation is funded to develop micro-CHP systems based on tubular SOFC technology. In FY 2010, Acumentrics achieved a 24% increase in system power density, enabling a 33% reduction in stack volume and a 15% reduction in stack weight. A low degradation rate of 0.86%/1,000 hours during 1,500 hours of testing was demonstrated.9

Budget

The President’s FY 2011 budget request calls for approximately $67 million for the Fuel Cells sub-program, with emphasis on R&D of materials, fuel cell stack components, and system BOP components, targeting lower cost and enhanced durability for stationary, portable, and transportation applications. Further emphasis is placed on R&D for integrated fuel cell systems for distributed power, including CHP applications, where a ‘technology-neutral’ approach is pursued. The FY 2011 request also includes approximately $19.5 million for a potential solicitation, subject to approval and congressional appropriations. The figure below shows the budget breakdown by sub-program R&D area for the FY 2010 congressional appropriation and the FY 2011 budget request.

FY 2011 Plans

In FY 2011, the Fuel Cells sub-program will continue R&D efforts on fuel cells and fuel cell systems for several key applications, with a focus on further developing multiple fuel cell technologies using various fuels, which involves improving component properties. Support will continue for R&D that addresses critical issues with membranes, catalysts, electrodes, and modes of operation. The sub-program will continue to place emphasis on the science and engineering at the cell and stack level and, from a systems perspective, on integration and component interactions.

The sub-program will also place significant emphasis on BOP component R&D (such as water transport, sensors, and air compression) that can lead to lower cost and lower parasitic losses. Continued support of modeling will guide component R&D, to benchmark complete systems before

they are built and explore alternate system components and configurations. Cost analysis efforts will be expanded to include distributed power generation systems (including CHP) for a variety of fuel cell technologies.

FY 2011 will see the continuation of existing projects and of those awarded in FY 2010, as well as a new initiative. A planned solicitation, subject to approval and congressional appropriations, is expected to lead to the awarding of new projects in FY 2011.

Project Start Date:  October 1, 2003
Project End Date:  Project continuation and direction determined annually by DOE

Objectives

• Develop a validated model for automotive fuel cell systems, and use it to assess the status of the technology.
• Conduct studies to improve performance and packaging, to reduce cost, and to identify key research and development issues.
• Compare and assess alternative configurations and systems for transportation and stationary applications.
• Support DOE/FreedomCAR automotive fuel cell development efforts.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cells section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(B) Cost
(C) Performance
(E) System Thermal and Water Management
(F) Air Management
(G) Start-up and Shut-down Time and Energy/Transient Operation

Technical Targets

This project is conducting system level analyses to address the following DOE 2010 and 2015 technical targets for automotive fuel cell power systems operating on direct hydrogen:

• Energy efficiency:  50%-60% (55%-65% for stack) at 100%-25% of rated power
• Power density:  650 W/L for system, 2,000 W/L for stack
• Specific power:  650 W/kg for system, 2,000 W/kg for stack
• Transient response: 1 s from 10% to 90% of rated power
• Start-up time: 30 s from –20°C and 5 s from +20°C ambient temperature
• Precious metal content: 0.3 g/kW (2010), 0.2 g/kW (2015)

Accomplishments

• Determined the performance of nanostructured thin film catalyst (NSTFC) stacks with 0.15 mg/cm² Pt loading and supported 20-µm membranes.
• Evaluated the performance of the Honeywell integrated compressor-expander-motor module (CEMM) for 1.5-atm operation.
• Analyzed the performance of parallel ejector-pump hybrids for fuel management.
• Constructed performance maps for planar membrane humidifiers.
• Collaborated with Honeywell to evaluate the performance of advanced microchannel automotive radiators.
• Conducted drive cycle simulations to determine the fuel economy of hybrid fuel cell vehicles for different rated-power efficiencies.

Introduction

While different developers are addressing improvements in individual components and subsystems in automotive fuel cell propulsion systems (i.e., cells, stacks, balance-of-plant components), we are using modeling and analysis to address issues of thermal and water management, design-point and part-load operation, and component-, system-, and vehicle-level efficiencies and fuel economies. Such analyses are essential for effective system integration.

Approach

Two sets of models are being developed. The GCtool software is a stand-alone code with capabilities for design, off-design, steady-state, transient, and constrained optimization analyses of fuel cell systems.
In Fiscal Year (FY) 2010, we changed our reference FCS configuration (see Figure 1) to eliminate the anode humidifier, switched to a single stack (with metal bipolar plates) that produces the gross power required for 80-kW, net power, and expanded the system configurations to include the low-pressure option. We evaluated the performance of three systems: S1 – the reference pressurized FCS with 2.5-atm stack pressure at rated power, S2 – a low-pressure FCS with 1.5-atm stack inlet pressure at rated power, and S3, which is S2 without a cathode humidifier [1].

**Air Management**

We modeled the performance of the Honeywell CEMM originally designed for 2.5-atm peak pressure (S1 conditions). We determined the optimum operating points of the mixed axial flow compressor, variable area nozzle turbine, 3-phase brushless direct current motor, and the liquid-cooled motor controller. We found that the CEMM component efficiencies are quite comparable under S1 and S2 conditions. The main difference is that the peak shaft speed is 85,000 rpm under S2 conditions compared to 110,000 rpm under S1 conditions. Thus, it may be possible to improve the performance of the CEMM for S2 conditions by redesigning it for a higher speed at 1.5-atm and full flow.

Our analysis indicates that the maximum turndown may be limited by compressor surge for shaft speeds less than 45,000 rpm. We estimate that at rated power, the CEMM consumes ~10 kW, in S1 and <6 kW, in S2. At idling conditions, the estimated power consumption is 250–400 W, depending on the allowable minimum shaft.
speed. The minimum shaft speed, if lower than the lift speed, will affect the durability of the airfoil bearings.

Fuel Cell Stack

In FY 2009, we had developed a cell and stack model for 3M’s NSTFC-based membrane electrode assemblies (MEAs) using data for electrochemically active surface area, specific activity, short and crossover currents, high-frequency resistance and polarization curves over a wide range of temperatures and inlet relative humidities [2]. In FY 2010, we used the model to determine the optimum stack operating conditions for S1, S2 and S3 scenarios. With fixed air and fuel stoichiometry (50% oxygen and 50% per-pass hydrogen utilization) and rise in coolant temperature (10°C), at rated power, we calculated the optimum stack temperature (i.e., coolant exit temperature) and the inlet cathode and anode dew point temperatures as 85°C/64°C/59°C for S1, 75°C/61°C/53°C for S2, and 65°C/22°C/22°C for S3, respectively. These results clearly show the role of pressurization and air humidification in determining the optimum stack temperature.

Figure 2a shows a comparison of the power density and the Pt content of the FY 2009 (0.1(a)/0.15(c) mg-Pt/cm², 35-µm 850 equivalent weight [EW] membrane) and FY 2010 (0.05(a)/0.1(c) mg-Pt/cm², 20-µm 850 EW supported membrane) reference S1 systems. We estimate that the power density for the 2010 system is 20% lower at 50% system efficiency due to lower Pt loading (0.8-1 A/cm²) but is about 6% higher at 40% system efficiency because of the thinner membrane (>2 A/cm²). Lower Pt loading and thinner membrane combine to produce a 30-45% reduction in Pt content for the 2010 systems (0.12-0.30 g-Pt/kWe-net).

Figure 2b compares the performance of the FY 2010 S1 and S2 systems. The cell voltage in S1 is 25-35 mV higher to achieve the same system efficiency by compensating for the greater CEMM parasitic power. In spite of the higher cell voltage, S1 can have higher power density because of the positive effect of the system pressure on the current density. Depending on the system efficiency, we project up to 12% higher Pt content for the S2 scenario.

Fuel Management

We analyzed the performance of the parallel ejector-pump hybrid in the fuel management system. Figure 3 shows the entrainment by a supersonic ejector [3] in which the motive gas is pure hydrogen from the compressed gas tank and the suction gas is spent hydrogen at the stack outlet. We consider that the motive gas is available at pressure less than 15 atm (regarded as the empty tank pressure) and that the suction gas is saturated with water vapor (molecular weight of 3-7) at 1-1.15 atm (S2 scenario). The desired lift pressure is 3 psi at rated power and the recirculation ratio (suction to primary mass flow rate) is 2.5. In our terminology, entrainment expresses the ratio of the suction flow rate established by the ejector to the flow rate required for 50% hydrogen utilization.
Figure 3 shows the entrainment and the motive gas pressure as functions of the normalized stack power. A single ejector alone can recirculate hydrogen for stack power down to 43% of rated power (Figure 3a). Between 28 and 43% stack power, a blower is needed to assist in recirculating the hydrogen; below 28% stack power, the motive gas pressure is too low to achieve the required lift pressure and the blower alone recirculates hydrogen. The ejector-only portion of the operating map can be expanded by including a second ejector that is parallel to and smaller than the first ejector (Figure 3b); however, the blower is still needed for stack power less than 24%. Alternately, a variable throat-area ejector can be employed to expand the ejector-only operating window to 36-100% stack power (Figure 3c).

Our model indicates that, without an ejector, a 400-W (mechanical power) blower is needed to recirculate hydrogen in the S2 scenario. A single fixed-area ejector reduces the blower power by more than 90%. Although the blower power can be reduced considerably with a variable-geometry ejector (to 25 W) or a dual-ejector arrangement (to 10 W), additional complexity may be difficult to justify [4].

**Water Management**

We received and analyzed Honeywell and PermaPure data for full-scale, half-scale and one-tenth-scale membrane humidifiers [5]. We derived permeance for the units (aggregate, not local values) and showed that the permeance can be represented in terms of the operating temperatures and the relative humidity of the dry air exiting the humidifier. We also constructed a map for mass-transfer effectiveness factors that, together with the permeance chart, can be used as nomographs for sizing such membrane humidifiers.

We used the data to develop and validate a model to determine the heat and mass transfer between the counterflowing wet and dry streams separated by a Nafion® membrane. The model considers water uptake from the wet stream, diffusion through the Nafion® membrane, and desorption into the dry stream. Figure 4 shows the model results for mass flux of water from a saturated wet stream at 2.5 atm and 80°C to dry air at different inlet temperatures. The flux is a strong function of the dew-point approach temperatures ($T_{dp}$), the difference between the inlet wet-air $T_{dp}$ and the outlet dry-air $T_{dp}$. Figure 4 indicates the existence of an
optimum dry air inlet temperature ($T_{in}$) for maximum flux. The flux decreases for dry air inlet temperature ($T_{in}$) higher than $T_m$ because of the low water uptake in the membrane (too dry). The flux decreases for $T_d$ lower than $T_m$ because the humidified air approaches saturation. Also, $T_m$ is a function of the dew-point approach temperature. The lower the approach $T_{dp}$, the lower the $T_{sat}$ and the smaller is the maximum water flux.

Our simulations show that the water mass transfer flux is also a strong function of the membrane thickness, temperature of the wet air and the operating pressure. For a given approach $T_{dp}$, the flux increases if the membrane is made thinner, the pressure is increased, or the wet-air temperature (i.e., the stack temperature) is raised.

The results in Figure 4 confirm the importance of including the pre-cooler that lowers the temperature of the compressor discharge air to 55-60°C before entering the humidifier. Without the pre-cooler, the cathode humidifier will need five- to ten-times larger mass-transfer area.

Thermal Management

We received and analyzed the thermal and fluid mechanics data from Honeywell for 25 cm x 25 cm x 3.3 cm sub-scale and 70 cm x 45 cm x 5.5 cm full-scale radiators with 18 and 24 louver fins per inch (fpi) and 40 and 50 fpi plain microchannel fins. We derived the friction factor ($f$) and heat transfer ($j$) coefficients from the data, formulated correlations for the $f$ and $j$ factors, and incorporated these correlations in our automotive radiator model. We compared the relative performance of the four fin geometries tested and concluded that the 40 fpi microchannel fins are superior to the 18 fpi louver fins in the full-scale design. We also concluded that the fuel cell powertrains may need to be derated for ambient temperatures higher than 40°C since the fan power doubles for every 5°C increase in ambient temperature.

We conducted a study to assess heat rejection in fuel cell vehicles as a function of the FCS efficiency and stack temperature. We considered that the air conditioning condenser (9 kW heat load) and the low-temperature radiator (13-17 kW heat load) are stacked in front of the high-temperature radiator that rejects waste heat generated in the fuel cell stack. Our results show that for a given fan power, the system S2 with 40% efficiency at rated power must be capable of operating at 5-10°C higher stack temperature than the same system with 50% efficiency. Also, from the standpoint of heat rejection, the 40%-efficiency FCS may be acceptable if it can be operated at stack temperatures exceeding 95°C.

We evaluated the prospect of raising the stack temperatures to 95°C under transient conditions (e.g., hill climbing at 55 mph) where high heat rejection may be required for several minutes. We determined that the maximum stack temperature is limited by the system pressure and the dew-point temperature of the cathode air at stack inlet. The CEMM motor power may limit the ability to pressurize adequately if the CEMM does not include an expander. Similarly, the stack temperature cannot be raised if the system does not include a humidifier. We concluded, therefore, that the S3 configuration may not be viable for transportation applications.

System Performance

We analyzed the part-load performance of the S2 system configurations and found that the system efficiencies peak at about 10% of the rated power. Reducing the rated power efficiency from 50% to 45% results in less than a 1% difference in peak efficiency. We also found an inverse relationship between the rated-power efficiency and the system efficiency for power less than 10%; because of hydrogen crossover, the efficiency is marginally higher for the system with 40% rated-power efficiency than the system with 50% rated-power efficiency. We conducted battery-FCS hybrid vehicle simulations to establish the relationship between the rated power efficiency and the system efficiency over drive cycles. The simulations were run for two modes of operation, one in which the FCS is operated primarily as a battery charger and the second in which it is operated in the load-following mode (LFM). The fuel economy is higher in the battery-charging mode (BCM) but the FCS durability may be an issue because of the excessive number of starts and stops. On the Urban Dynamometer Driving Schedule (UDDS), our battery power management strategy produces 58 fuel cell start-stops in BCM and only four in LFM. FCS start-stops can be eliminated altogether if the fuel cell is allowed to idle at low loads. Our LFM simulations indicate that reducing the rated-power efficiency from 50% to 40% results in just 2% difference in system efficiencies over the UDDS, <3% over the Highway Fuel Economy Test (HWFET) cycle, and >9% on the Los Angeles drive cycle (LA92). The corresponding differences in fuel economy are ~2% over the UDDS, <6% over the HWFET, >9% over the LA92, and <7% over the combined cycle used for fuel economy certification. We conclude that reducing the system efficiency at rated power from 50% to 40% results in >50% reduction in Pt content and >40% reduction in cost of stacks manufactured at high volumes while decreasing the peak efficiency by <1% and fuel economy by <7%.

Conclusions and Future Directions

- The variable-area nozzle turbine allows the CEMM to be adapted to different design pressures without significant losses in component efficiencies. The parasitic CEMM power can be reduced by 40% if the compressor discharge pressure is lowered from...
2.6 atm (S1 scenario) to 1.6 atm (S2 scenario) at the rated power design point.

- The Pt content can be potentially decreased by 30-45% by reducing the Pt loading from 0.25 mg/cm² (2009 status) to 0.15 mg/cm² (2010 status) and using a thinner supported membrane (20 µm vs. 35 µm). Depending on the system efficiency at the design point, we project the Pt content (2010 status) to be between 0.12 and 0.30 g/kWe (net), with the potential to meet the ultimate DOE target.

- Our analysis of the different arrangements of the fuel management system indicates that the recirculation blower power can be decreased by 90% by using a parallel ejector for metering the fuel and entraining the depleted hydrogen from stack outlet. The blower power can be further decreased with dual ejectors or a variable-geometry ejector, but the system complexity may be difficult to justify.

- A pre-cooler between the air compressor and the membrane humidifier can lead to a more than five-fold increase in mass transfer flux of water in the humidifier. Besides the dry air inlet temperature, the water flux is also a strong function of the membrane thickness, temperature of the wet air from the fuel cell stack and the operating pressure.

- From the standpoint of heat rejection, a lower efficiency FCS may be acceptable, provided that the stack temperature can be allowed to increase under certain transient conditions. The maximum stack temperature may be limited by the operating pressure and air humidification.

- In FY 2011, we will investigate the effects of alternative system configurations, rated power efficiency (Pt content) and system operating points on the high-volume manufacturing cost, dynamic drive-cycle performance and component durability.

V.A.2 Mass-Production Cost Estimation for Automotive Fuel Cell Systems

Objectives

- Identify the lowest cost system design and manufacturing methods for an 80 kW, direct-H₂ automotive proton exchange membrane (PEM) fuel cell system based on three (now two) technology levels:
  - Current status
  - 2010 projected performance (replaced by “current status” for 2010 update)
  - 2015 projected performance
- Determine costs for these three technology level systems at five production rates:
  - 1,000 vehicles per year
  - 30,000 vehicles per year
  - 80,000 vehicles per year
  - 150,000 vehicles per year
  - 500,000 vehicles per year
- Analyze, quantify and document the impact of fuel cell system performance on cost
  - Use cost results to guide future component development

Technical Barriers

This project addresses the following technical barriers from the Fuel Cells section (3.4.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

| DOE Targets/DTI Estimates in $/kWₑ (at 500,000 Systems/Year Manufacturing Rate) |
|-----------------|-------|------|------|------|
| Stack Cost
| DOE Target      | $65   | -    | $25  | $15  |
| DTI 2006 Estimate (Year 1) | -   | $66  | $30  | $25  |
| DTI 2007 Estimate (Year 2) | -   | $50  | $27  | $23  |
| DTI 2008 Estimate (Year 3) | -   | $38  | $29  | $25  |
| DTI 2009 Estimate (Year 4) | -   | $26  | $24  | $22  |
| DTI 2010 Estimate (Year 5) | -   | $25  | $21  |
| System Cost
| DOE Target      | $125  | -    | $45  | $30  |
| DTI 2006 Estimate (Year 1) | -   | $108 | $70  | $59  |
| DTI 2007 Estimate (Year 2) | -   | $94  | $66  | $53  |
| DTI 2008 Estimate (Year 3) | -   | $72  | $65  | $51  |
| DTI 2009 Estimate (Year 4) | -   | $61  | $56  | $51  |
| DTI 2010 Estimate (Year 5) | -   | $51  | $39  |

Accomplishments

- DTI 2009 Cost Estimate:
  - Improved existing conceptual design and component specification of complete fuel cell power systems at three technology levels (2009, 2010, and 2015).
  - Determined final 2009 cost status.

- Performed detailed sensitivity analysis using tornado charts and Monte Carlo techniques.
- Analyzed new technologies and manufacturing alternatives.
- Identified components and systems that warrant further research.

**DTI 2010 Cost Estimate:**
- Improved existing conceptual design and component specification of complete fuel cell power systems at two technology levels (2010 and 2015).
- Determined final 2010 cost status.

**Introduction**

In this project, DTI has built on previous analyses to estimate the cost of 80 kWₑₓₚₜₑₜₜ PEM fuel cell vehicular power systems at five annual production rates (1,000, 30,000, 80,000, 130,000, and 500,000 systems per year) and three levels of projected fuel cell and manufacturing technology (current, 2010, and 2015). During the first year of the project, we investigated state-of-the-art PEM fuel cell technology and prepared system cost models to reflect 2006, 2010, and 2015 estimates. Each ensuing year, the cost model was updated to reflect advances in technology and the evolving cost analysis. During the most recent reporting period, an adjustment in funding led to a compression of the project timeline, and the 2010 update was completed earlier than originally scheduled. As such, this annual progress report covers the fourth year and part of the fifth year of the DTI project, reflecting updates and advances in technology from both 2009 and 2010. Since the current year is 2010, the “current” technology and the 2010 projected technology have merged, leaving only two technology levels to examine: the current status (2010) and the 2015 projection.

A Design for Manufacturing and Assembly (DFMA®) methodology is employed to obtain the fuel cell system cost estimates. DFMA® is a methodology created by Boothroyd Dewhurst, Inc. to systematically estimate the total manufacturing cost of a component or system and then to conduct a comparative cost analysis so as to allow a redesign to achieve the lowest system cost. Typically, a markup factor is applied to the costs of general and administrative, scrap, research and development (R&D), and profit and is applied to all manufacturing entities contributing to the effort (original equipment manufacturer, Tier 1, Tier 2, etc.). However, per DOE directive for this project, a markup is only applied to lower-tier supplied materials and components, not to materials or operations conducted by the highest-tier fuel cell assembler. (Scrap costs are included at the component level but not at the system level.)

The costs reported in this document reflect the values from the 2010 status update.

**Approach**

There are four main steps to our approach: research, system modeling, component design, and application of DFMA®-style redesign and costing techniques. The first step, research, has been conducted continuously throughout the project. It encompasses the review of published materials and patents, as well as interviews with key researchers and manufacturers. This provides a common ground assessment of the system layout and technologies currently used or anticipated to be used by the fuel cell system community. After enough information was collected to move forward, a preliminary system concept and mechanical/piping layout were developed to meet the technical requirements for the different technology levels. Excel spreadsheet-based performance models were used to determine heat loads, mass flows, compositions, and pressure levels throughout the systems. The flow diagrams were then iteratively modified to obtain a projected optimal configuration and performance.

Armed with the preliminary system concepts and layouts, we designed each of the main components that make up the system. This involved specifying the detailed geometries of the flow plates, gaskets, membrane electrode assemblies (MEAs), etc., and determining which materials to use. The most appropriate manufacturing processes to use for each component were then selected based primarily on cost, but with consideration of the performance and durability parameters. When it was unclear which approach was best, several different methods were analyzed, and the component designs were adjusted to suit the manufacturing method. For each component, we defined a manufacturing process train, and then applied our costing methodologies to it. Using a comprehensive DFMA®-style approach, we calculated the manufacturing process costs, setup costs, material costs, and assembly costs, and then summed them to determine the total costs for the stack and the system. Amortization of the machinery capital costs and expendable tooling, as well as labor costs (including indirect labor costs for fringe benefits) were included in the cost estimates. The costs of some non-stack components such as radiators, pumps, blowers, controllers, sensors, etc. were calculated by a simplified DFMA®-style methodology, or were based on price quotations from vendors.
Results

The cost differences between the two different technology levels (see Table 2) are driven primarily by expected improvements in stack power density (833 to 1,000 mW/cm²), operating pressure (1.69 to 1.5 atm), and peak stack temperature (90 to 99°C). Of these, increased power density is most responsible for stack cost reduction. Balance-of-plant (BOP) cost reductions stem primarily from system simplifications (i.e. reduced or eliminate components). For example, the current technology system uses a Nafion® membrane air humidification system with an air precooler, and the 2015 has no humidification system at all. Simplifications of the air, humidification and coolant systems yield the majority of technology improvement savings.

The stack cost decreases with advancing technology level due to both power density improvement and reduction of the parasitic electrical loads. Major cost reductions are not currently projected as a result of manufacturing method change or material selection. Rather, future improvements in stack power density (as a result of expected improved MEA performance) result in a reduction of cell active area and a corresponding decrease in material cost.

Unsurprisingly, the stack cost is the largest and most important contributor to the system cost. While most of the BOP components are based on modifications of proven, existing technology, the stack designs are comparatively immature. The impact of this is twofold: the stack has the most room for technological improvement and the component production methods are less refined. Therefore, most of our analysis in previous years of the project has been focused on the stack, since it provided the most potential for cost improvement. Since the 2008 status update however, the focus has shifted towards the BOP. With the exception of the nanostructured thin-film (NSTF) catalyst application process, the changes to the stack analysis are mostly adjustments of operating parameters rather than the addition of new components or changes in design. Also, the number of stacks per system is cut from two to one based on suggestions from industry and the United States Council for Automotive Research Fuel Cell Technical Team (FCCT).

The NSTF catalyst application process is a major technological improvement on the previous VertiCoater die-slot application method, and facilitates large improvements in power density and catalyst loading while simultaneously improving durability. The previously-modeled VertiCoater method had the advantage of being one of the least-costly application techniques judged adequate for high production rates and reasonably high MEA performance. However, it became increasingly clear that further increases in power density with simultaneously lower Pt loading were probably not possible with this technique. Consequently, the switch was made to the NSTF method, which has shown remarkable recent improvements in power density and durability at low Pt loadings. Developed at 3M, the NSTF deposition process begins with the sublimation of a layer of crystalline finger-like projections, or “whiskers”, that create a high surface area substrate on which the active catalysts may be deposited. Next, vapor deposition methods are utilized to deposit a very thin layer of a ternary catalyst alloy coating onto the whiskers in a very precise and even manner. The resulting catalyst-coated whiskers can then be hot pressed into the fuel cell membrane to form a porous mat electrode intimately bonded to the membrane. 3M has

recently demonstrated significant improvements in the durability and the power-density-to-catalyst-loading ratio that surpass the 2010 DOE performance targets.

When compared to the previous method of catalyst application considered (die-slot application based on the Coatema VertiCoater), the total NSTF catalyst system and application is only slightly more expensive for a given power density and catalyst loading. However, the NSTF method facilitates a lower catalyst loading and improved power density that cannot be otherwise achieved. Consequently, taking power density and catalyst loading into consideration, a net savings of $10.28/kW_{net} is obtained by switching from a die-slot catalyst application to the NSTF catalyst system.

A central theme of the past year’s work has been the integration of performance-parameter-based scaling into the cost model. Although the previous cost model included performance parameters, we have enhanced the level of detail and interaction to better reflect the actual performance. Integration between all of the components (in both the stack and the BOP) has been greatly increased, such that geometries and costs now scale dynamically based on a variety of parameters (e.g. operating pressure, air mass flow, and cooling and power requirements).

In past years of the analysis, the power density and catalyst loading values used in the model were specified by the DOE and the FCTT, and reflected the average performance of several different technologies. Now that the NSTF process has been implemented in the model, the power density and catalyst loading values are based on experimental data polarization curves that correspond to NSTF MEAs under specified operating conditions. Interpolation between polarization curves is used to determine power density at the model-specified operating pressure.

Almost all of the BOP components were re-examined in greater detail, with extra emphasis on those with the largest contribution to cost. The system schematics were refined, and components were added and subtracted. Detailed analyses were conducted of the wiring and piping/tubing requirements, with consideration for flow rates, cooling and power requirements, and the physical distances between components.

The most substantial cost analysis improvement relates to the new compressor/expander motor (CEM) analysis, for which an all-new cost estimate was conducted in collaboration with Honeywell. It is a bottom-up cost analysis based directly on the blueprints from an existing Honeywell design, utilizing a combination of DFMA® methodology and price quotes from established Honeywell vendors. Current and future CEM designs were analyzed, and a detailed model was developed to scale the size, cost, and power draw of the CEM based on rotational speed, air mass flow, pressure ratio, and the inclusion or exclusion of an expander. For current technology, the CEM cost shrinks from $8.51/kW_{net} in 2008 to $8.07/kW_{net} in 2010. For 2015 technology, it increases from $5.37/kW_{net} to $6.31/kW_{net}.

Numerous other small changes were made to the fuel cell system cost model, the result of which yields a small cumulative net savings. While their net effect is comparatively small, the improvements enhance the analysis appreciably and lead to greater confidence in the cost estimates.

At 500,000 systems per year, the total cost for the stacks, including assembly and stack conditioning, comes to $25/kW_{net} and $21/kW_{net}, for the 2010 and 2015 technology year cost projections respectively (see Figure 1). These should be compared to the 2010 and 2015 DOE stack targets of $25/kW_{net} and $15/kW_{net}. When accounting for the BOP items, the system costs are roughly double that of the stacks alone and sum to $51/kW_{net} and $39/kW_{net} for 2010 and 2015, respectively (see Figure 2).
Conclusions and Future Directions

Key conclusions from the past year of the project include:

- 2010 stack cost estimate (at 500,000 systems/year) meets the DOE target of $25/kW_{net}, and 2015 cost is predicted to be $6/kW higher than DOE target for 2015.
- The 2010 and 2015 system cost estimates (at 500,000 systems/year) are $6/kW and $9/kW higher than DOE targets, respectively.
- Significant technical breakthroughs will be required in order to achieve the 2015 DOE system cost targets.
- NSTF catalyst application method represents current state-of-the-art, shows great promise.
- Switch from die-slot catalyst coating to the NSTF method yielded savings of $10.28/kW_{net}, due primarily to enhanced power density made possible by NSTF MEA.
- Though not as dominating as in previous years, catalyst cost (especially Pt) remains largest single stack cost contributor.
- Pt catalyst reduction remains a potential pathway to appreciable cost savings.
- Although detailed new CEM cost analysis resulted in only minor cost changes, new estimate is much more robust, scales with system performance parameters.
- Substantial cost reductions (factors of 3-5) are achieved by increasing manufacturing volume from 1,000 to 500,000 systems per year production rate.
- BOP component costs are comparable to stack costs, so R&D to reduce, simplify, or eliminate BOP components is needed for significant overall system cost reduction.

When compared to the DOE’s 2005 status values and our estimates from the previous four years, it’s clear that the significant technology advances of the last several years have resulted in substantial cost reductions (see Figure 3). Still, there is a substantial predicted overage in meeting 2015 targets: $6/kW on the stack and $9/kW for the total system. Further R&D or system configuration advances are needed to close these gaps.

During the coming year, DTI will address the following topics:

- Documentation of the 2010 update in the Year 5 annual report update.
- Updating of the 2010 technology system to reflect 2011 technology.
- Identification of capital equipment and R&D needs.
- Optimization study of stack operating pressure.
- Lifecycle cost analysis.

FY 2010 Publications/Presentations

1. July 15th, 2009 - Hartford, CT: HTAC Open Meeting
2. August 12th, 2009 - Detroit, MI: Presentation to Fuel Cell Tech Team
Objectives

The overall objective is to assess the high-volume (500,000 units/year) manufacturing cost for an 80 kW (net) direct-hydrogen polymer electrolyte membrane fuel cell (PEMFC) system for automotive applications. This past year’s (2009-2010) objectives were:

- Estimate the bottom-up manufactured cost of the 2009 PEMFC system, assuming a nano-structured thin film catalyst (NSTFC)-based membrane electrode assembly (MEA) and a 30 micron perfluorosulfonic acid (PFSA) membrane.
- Perform sensitivity analyses on key stack and system parameters, assuming high-volume production (500,000 units/year) of the 2009 PEMFC system.
- Update the bottom-up manufactured cost for the PEMFC system based on updated stack performance assumptions and system configuration for 2010 – preliminary costs reported.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cells section (3.4.4) of the

¹ Based on bottom-up high-volume manufacturing cost and an assumed 15% markup to the automotive original equipment manufacturer (OEM) for all major balance-of-plant (BOP) components.
² Assumes a vertically integrated stack manufacturing process by the OEM based on bottom-up, high-volume manufacturing cost and assumes no markup for all major stack components.

Accomplishments

- Updated the bottom-up manufacturing cost for the 2009 PEMFC system configuration assuming current technology status, and high-volume production (500,000 units/year).
- Performed single-variable and multi-variable (Monte Carlo) sensitivity analyses on key stack and system parameters, for high-volume production (500,000 units/year).
• Participated in an independent peer review of our 2008 cost analysis methodology, assumptions and resulting cost projections.
• Developed preliminary bottom-up, high-volume manufacturing cost estimate for the 2010 PEMFC stack, assuming current technology status.

Introduction

The DOE seeks to develop a durable fuel cell power system for transportation applications. Cost is a major challenge to the commercialization of automotive fuel cell power systems. The cost of fuel cell power systems must be reduced to less than $50/kWe for the technology to be competitive with automotive internal combustion engine power plants, which currently cost about $25-35/kWe.

A rigorous, bottom-up analysis of projected high-volume manufacturing cost is required to accurately gauge the status and potential of fuel cell technology to meet the FreedomCAR and Fuel Partnership goals. TIAX LLC (formerly the Technology and Innovation group within Arthur D. Little) has assisted DOE with the development of cost projections for PEM fuel cells for transportation since 1999, analyzing reformate-based systems through 2004, followed by direct-hydrogen systems from 2005 through 2010.

Approach

We have applied an internally developed technology costing methodology that has been customized to accurately analyze and quantify the processes used in the manufacture of PEMFC stack and BOP components. TIAX has developed a proprietary, bottom-up, technology-based cost model which is used in conjunction with the Boothroyd-Dewhurst Design for Manufacturing and Assembly (DFMA®) software.

The approach starts with a technology assessment of the system configuration and components. Argonne National Laboratory (ANL) develops a fuel cell stack/system configuration and performance models that would represent the state-of-the-art for fuel cell vehicle technology in the current year. We perform a literature and patent search to explicate the component parts, specifications, material type and manufacturing process. Subsequently for each component, we develop a bill of materials based on the system specification/performance modeling provided by ANL, determine material costs at the assumed production volume, break down manufacturing processes into unit operations, and identify appropriate manufacturing equipment. We also perform single-variable and multi-variable (Monte Carlo) sensitivity analyses to identify the major cost drivers and the impact of material price and process assumptions on the high-volume PEMFC system cost results. Finally, we solicit feedback from the Fuel Cell Tech Team, developers and vendors on the key performance assumptions, process parameters, and material cost assumptions; we calibrate our model using this feedback.

Results

Throughout this document, we report a “factory cost”, which is a bottom-up estimate of the high-volume manufacturing cost based on an 80 kW net power PEMFC system, and an “OEM cost”, which assumes a 15% markup (over the factory cost) to the automotive OEM for the BOP components. We assumed a vertically integrated process for the manufacture of the PEMFC stack by the automotive OEM, so no markup is included on the major stack components. Raw materials and purchased components implicitly include supplier markup.

In 2009, we updated the PEMFC system configuration, materials, processes, performance assumptions and component specifications [1,2]. Figure 1 shows the ANL 2009 PEMFC system configuration chosen for costing [1-3]. Table 2 is a summary of the stack performance assumptions and resultant high-volume manufactured cost of the 2009 PEMFC stack cost for six different scenarios modeled by ANL [3,4]. We assumed a baseline Pt cost of $1,100/tr.oz., and captured the impact of variability in Pt cost through the sensitivity analyses.

The high-volume 2009 PEMFC stack cost for six scenarios ranges from $19/kWe to $40/kWe [4]. Using S5 as the 2009 baseline scenario, the updated assumptions lowered the stack cost from $29/kWe in 2008 to $22.3/kWe in 2009. The low Pt loading with high power density is attributed to novel catalyst and support structure (i.e. NSTFC on organic whisker support). We based our cost assessment on ANL’s single-cell modeling which is calibrated using data from an NSTFC-based short stack. The electrodes, primarily due to the Pt material, represent ~48% of the ~$22/kWe fuel cell stack manufactured cost in 2009.

We developed bottom-up manufacturing costs for the cathode and anode planar membrane humidifier, high-temperature (HT) and low-temperature (LT) radiators, hydrogen blower and CEM based on ANL specifications [3] and other patents [1,4]. We scaled vendor/catalog quotes for the air precooler, radiator fan, HT and LT coolant pumps, hydrogen demister, air demister, solenoid valves, flow orifice, and air/H₂ mixer. Table 3 is a summary of the projected high-volume OEM cost for the 2009 BOP subsystems and individual components [4].

Figure 2 shows the component/subsystem cost breakout for the 2009 PEMFC stack and system. BOP,

\(^1\) Based on bottom-up high-volume manufacturing cost and an assumed 15% markup to the automotive OEM for all major BOP components.

\(^2\) Assumes a vertically integrated stack manufacturing process by the OEM-based on bottom-up, high-volume manufacturing cost and assumes no markup for all major stack components.

---

![FIGURE 2. TIAX 2009 PEMFC Stack and System Cost [4]](image-url)
balance of system, and system assembly costs together represent ~60% of the PEMFC system cost in 2009, compared to ~38% in 2005. The projected high-volume OEM cost of the CEM at $790/unit (~$10/kWe) is the largest contributor to the combined BOP and assembly cost of $33/kWe in 2009.

We performed single- and multi-variable sensitivity analyses to examine the impact of major stack and BOP parameters on the high-volume 2009 PEMFC system cost. As seen in Figure 3, Pt loading, power density, and Pt cost are the top three drivers of the PEMFC system OEM cost. The results of a multi-variable (Monte Carlo) analysis are shown in Figure 4; the high-volume 2009 PEMFC system OEM cost ranges between $45/kWe and $97/kWe (± 2σ), with the mean of the distribution being $71/kWe.

We are currently working on updating our cost projections to the ANL 2010 PEMFC system configuration, stack performance assumptions, and stack and BOP component specifications. Figure 5 shows a preliminary layout of the 2010 PEMFC system [4,5]. The key features are: NSTFC MEA with 20 μm reinforced PFSA membrane, thermal nitrided metal bipolar plates, non-woven carbon paper gas diffusion layer (GDL), pleated planar membrane humidifier for cathode air humidification, and no anode fuel humidifier.

Table 4 is a summary of the stack performance assumptions and resultant high-volume manufactured cost of the 2010 PEMFC stack cost for six different scenarios modeled by ANL [4,5]. Our preliminary estimates show that the high-volume 2010 PEMFC stack cost for six scenarios ranges between $17/kWe, and $33/kWe [4]. These initial estimates will be finalized by the next reporting period.

Table 5 is a summary of the high-volume system OEM cost of the 2010 PEMFC system for six different scenarios modeled by ANL [4,5]. The preliminary 2010 PEMFC system OEM cost is estimated to range from $49/kWe, to $65/kWe [4]. These initial estimates will be finalized by the next reporting period.

**Conclusions and Future Directions**

- The 2009 PEMFC stack cost was estimated to range between $19/kWe and $40/kWe over six different scenarios.
- The PEMFC stack and system costs were estimated to be $22/kWe and $55/kWe, respectively for the 2009 baseline scenario.
- BOP, balance of system and system assembly costs together represented ~60% of the projected PEMFC system cost, for the 2009 baseline scenario.
Monte Carlo analysis shows that the 2009 PEMFC system OEM cost ranges between $45/kWe and $97/kWe (± 2σ), with a mean cost of $71/kWe. Preliminary estimates for the manufactured cost of the 2010 PEMFC stack range between $17/kWe and $33/kWe, while preliminary estimates for the OEM cost of the 2010 PEMFC system range from $49/kWe to $65/kWe over six different scenarios.

The projected high-volume OEM cost of the CEM at $790/unit (~$10/kWe) is the largest contributor to the combined BOP and assembly cost of $33/kWe in 2009.

Platinum loading, power density, platinum cost, membrane cost and CEM cost are the top five drivers of the PEMFC system cost in 2009.

Monte Carlo analysis shows that the 2009 PEMFC system OEM cost ranges between $45/kWe and $97/kWe (± 2σ), with a mean cost of $71/kWe.

Preliminary estimates for the manufactured cost of the 2010 PEMFC stack range between $17/kWe and $33/kWe, while preliminary estimates for the OEM cost of the 2010 PEMFC system range from $49/kWe to $65/kWe over six different scenarios.

V.A.4 Characterization of Fuel Cell Materials

Objectives

- Develop new, innovative microanalysis and imaging techniques to characterize fuel cell material constituents before, during, and after electrochemical aging.
- Elucidate membrane electrode assembly (MEA) degradation and/or failure mechanisms by conducting extensive microstructural characterization using advanced electron microscopy techniques (comparing as-processed and electrochemically-aged MEAs).
- Develop correlations between MEA structure/composition and durability/performance.
- Collaborate with fuel cell component developers and manufacturers, university researchers, and other national laboratories, to evaluate materials using electron microscopy and complimentary microstructural/compositional analysis techniques; provide feedback for optimization.

Technical Targets

This project is focused on conducting fundamental characterization studies on the stability of individual constituents comprising fuel cell MEAs. Of primary importance is relating MEA microstructural changes during aging to fuel cell durability and performance. Long-term MEA aging studies are being conducted in collaboration with numerous external partners, including MEA manufacturers, proton exchange (or polymer electrolyte) membrane fuel cell (PEMFC) stack manufacturers, universities, and national laboratories. ORNL research is focused not only on the pre- and post-mortem analysis of powders, membranes, and MEAs, but also on the development and application of in situ microscopy techniques to elucidate degradation mechanisms that contribute to limiting the life of PEM fuel cells. Insights gained will be applied toward the design and manufacture of fuel cell materials that meet the following DOE 2015 MEA targets:

- Cost: ≤$5/kW
- Durability with cycling: ≤80°C – 5,000 h; >80°C – 5,000 h
- Operating temperatures: ≤120°C
- Total catalyst loading (for both electrodes): 0.2 g/kW (rated)
- Extent of performance degradation over lifetime: 5%

Accomplishments

- Investigated microstructural and compositional contributions to cathode carbon-support corrosion mechanisms in electrochemically-aged MEAs.
- Conducted detailed microstructural studies of Pt migration as a function of changing aging protocols.
- Applied advanced statistical analysis techniques to evaluate Å-scale elemental and compositional analyses and segregation within catalyst nanoparticles (multivariate statistical analysis – principal component analysis).
- Continued ‘proof-of-principle’ testing of ORNL’s specialized liquid cell holder for in situ electrochemical testing of fuel cell materials in the Hitachi HF-3300 transmission and scanning transmission electron microscopy (TEM/STEM).
- Established several new research collaborations in FY 2010 with industry (3M, UTC Power), other laboratories (Naval Research Laboratory, Jet Propulsion Laboratory) and universities (University of Texas at Austin, Brown University).
- Supported a full-time graduate student from Rensselaer Polytechnic Institute working on microstructural characterization of PA-PBI.
membranes (Kelly Perry received her Ph.D. from Rensselaer Polytechnic Institute in December 2009 and now works at ORNL on fuel cell characterization).

- Continued extensive alloy catalyst nanoparticle characterization studies using sub-Å resolution high angle annular dark field scanning transmission electron microscopy (HAADF-STEM).

Introduction

PEMFCs are being developed for future use as efficient, zero-emission power sources. However, the performance of PEMFCs degrades rapidly with time at elevated temperature during electrochemical aging. Performance degradation can be attributed to the durability of individual components comprising the MEA, such as the electrocatalyst, catalyst support, and/or the proton-conducting polymer membrane. However, many of the mechanisms contributing to decreased stability within the MEA during long-term electrochemical aging are not fully understood.

During the past several years, the Microstructural Characterization Program at ORNL has been focused on forming collaborative relationships with numerous industrial PEMFC developers/manufacturers, universities, and national laboratories, to utilize advanced microscopy techniques to evaluate as-fabricated and electrochemically-aged PEMFC MEAs and to characterize individual PEMFC material components. These studies are used to establish critical processing-microstructure-performance relationships and to elucidate MEA degradation and failure mechanisms. Understanding the structural and compositional changes to the materials comprising the MEA during electrochemical aging will allow for the implementation of processing changes and critical materials development that are required for optimized PEMFC durability and performance.

The techniques developed as part of this “baseline” research project are also being applied to other fuel cell systems.

Approach

The microstructural characterization task utilizes advanced electron microscopy analysis techniques to characterize the individual material components comprising PEMFCs, before and after incorporation into an MEA and after electrochemical aging. Our approach is focused on identifying and optimizing novel high-resolution imaging and compositional/chemical analysis techniques, and developing unique specimen preparation methodologies, for the mm-Å-scale characterization of the material constituents of fuel cells (electrocatalyst, support, membrane, etc.). ORNL applies these advanced analytical and imaging techniques for the evaluation of the microstructural and microchemical changes of each material constituent and correlating these observations with fuel cell performance (aging studies are conducted at collaborators laboratories). These studies are designed to elucidate the microstructure-related degradation mechanisms contributing to fuel cell performance loss. Most importantly, ORNL is making the techniques and expertise available to fuel cell researchers outside of ORNL via several mechanisms – (1) Work for others (proprietary) research, (2) ORNL User Facilities (Shared Research Equipment, Center for Nanophase Materials Science, and High Temperature Materials Laboratory), and (3) collaborative non-proprietary research via the Microstructural Characterization Project that is in line with ORNL’s “baseline” research activities.

The research effort in FY 2010 was focused on establishing two primary characterization focus areas for the evaluation of the degradation of fuel cell materials as a function of aging protocol; (1) understanding the mechanisms of cathode carbon support corrosion and (2) performing the in-depth characterization of Pt migration and re-precipitation during PEMFC aging. In addition, the application of statistical data analysis techniques, in particular multivariate statistical analysis and principal component analysis to the compositional analysis (energy dispersive spectroscopy and electron energy loss spectroscopy spectrum imaging) of nanoparticles (bi- and ternary-alloy catalysts) has been optimized (not discussed). Significant progress has been made in each of these focus areas.

Results

Carbon Corrosion

Carbon support corrosion is a well-recognized degradation problem during the operation of PEM fuel cells, and is particularly problematic at the cathode. While the rate of carbon corrosion is relatively low during “normal” fuel cell operation, the oxidation of the carbon support is severe during fuel (H₂) starvation and under open circuit voltage conditions experienced during start-up/shut-down cycling (cathode potentials >1.2 V). There are several recent studies that have focused on the kinetics of carbon support corrosion under adverse fuel cell operating conditions [1-5] and several mechanisms for electrochemical carbon oxidation have been postulated. At the center of these mechanisms is the permanent loss of carbon in the cathode layers due to oxidation via the reaction:

\[
C + 2H_2O \rightarrow CO_2 + 4H^+ + 4e^- 
\]

This mechanism has been confirmed (at least to some degree) by the direct observation of collapsed cathode layers and the measurement of the CO₂ (and
CO) evolution during operation. Carbon loss at the cathode has been associated with decreased catalyst utilization in the cathode due to Pt agglomeration and Pt detachment from the carbon support, thereby decreasing the electrochemically active surface area (EASA). While it is clear that there is increased carbon corrosion during fuel cell operation under high potential-cycling conditions, the actual structural reasons for, and mechanism of, carbon corrosion have yet to be unambiguously identified.

Recently, several electrochemically-aged MEAs that have experienced significant cathode corrosion (most of these MEAs are at end-of-life, EOL), have been evaluated using high-resolution electron microscopy imaging and analysis techniques to elucidate the microstructural and compositional factors that play a role in (1) the observed structural collapse/compression of the cathode layer(s) and (2) changes/growth of Pt cathode catalyst nanoparticles contributing to loss of EASA. For example, a “typical” thinned/compressed cathode (composed of Pt-supported on Vulcan XC72) observed after 1,500 0.1-1.2 V (10 mV/sec) cycles is shown in Figure 1. The high-resolution (HR)-TEM images shown in Figure 2 compare the structure of the as-processed (Pt loaded) Vulcan XC72 carbon support (2a) and the same material after potential cycling (2b) in an MEA. There was a significant amount of carbon remaining in the cathode structure after aging, however, the crystalline structure of the Vulcan changed dramatically during potential cycling. The graphitic nature of the starting Vulcan support (2a) was completely amorphous after aging (2b) and these amorphous (glassy) carbon particles were tightly bound (sintered) and densified together, resulting in extensive densification (compression) of the cathode. This graphitic-to-amorphous transformation was confirmed by electron energy loss spectroscopy, as shown in

![Figure 1: Typical Cross-Section of a “Collapsed” EOL Cathode](image1)

![Figure 2: TEM images of (a) Pt nanoparticles on Vulcan XC72 carbon particle and (b) Pt nanoparticles on Vulcan carbon particle after aging.](image2)
Figure 3, which also indicated relatively high oxygen contents within the amorphous carbon regions. The Pt particles clearly coalesce during potential cycling, but this phenomenon is exacerbated by the enhanced carbon oxidation due to the presence of Pt and the sintering together of the carbon particles. The Pt particles do not become detached from the carbon support (as previously reported by other research groups), but experience significant growth and remain attached to a non-conductive, amorphous, O-enriched carbon support structure. The combination of these major degradation events will have a detrimental impact on fuel cell life.

These results are typical of the types of structures found in compressed/collapsed cathodes after electrochemical aging – in FY 2011, additional (and systematically aged using different aging protocols) examples will be analyzed to establish carbon-corrosion mechanisms and to directly correlate microstructural degradation with durability (extent of performance loss).

Pt Migration

The migration of Pt\textsuperscript{2+} from the cathode layer into the membrane during fuel cell operation, and the consequent re-precipitation of Pt nanoparticles at different locations in the membrane (related directly to H\textsubscript{2} and O\textsubscript{2} gas cross-over), which is relatively easy to observe/image in a microscope (optical of scanning electron microscope, SEM) at low magnifications. However, extensive evaluation of aged MEAs during the past year has shown that the re-precipitation of Pt at the cathode/membrane interface AND within the membrane is significantly more complicated than the formation of a simple Pt-band.

To understand the Pt migration as a function of aging protocol, numerous aged cross-sectioned (intact) MEAs have been characterized via TEM/STEM in terms of size, crystalline nature, and distribution (distance from cathode layer) within the membrane (from cathode/membrane interface to anode/membrane interface), the results of which will be directly correlated with performance loss. In addition, the amount of Pt loss from the cathode layer will be quantified. These analyses will be extended to include Pt-alloy catalysts to determine leaching effects and the stability of alloy catalysts during aging.

Figure 4 shows an example of the measurements being made via TEM/STEM, where the MEAs evaluated (Pt loaded on both cathode and anode layers) were subjected to a low number (4-5) of freeze-thaw cycles. In this case, the only differences between the cells evaluated (cell #1 and cell #2) were the type of membrane used (Nafion\textsuperscript{®} 111 vs. 211) and the type of gas diffusion layer (GDL) used (paper vs. cloth). Figure 4(a) shows a cross-section SEM image of a typical Pt-band. Figure 4(b) shows the typical size and morphology of the Pt-nanoparticles from two separate areas of the membrane; within the Pt-band (single-crystal cuboctahedron-shaped Pt particles ranging in size from ~30-70 nm) and away from the Pt-band (closer to the anode, single-crystal Pt particles ranging in size from ~3-10 nm). The Pt particle distribution profiles were completely different, as shown in Figure 4(c), where cell #2 (Nafion\textsuperscript{®} 211 membrane and cloth GDL) exhibited significantly larger (and fewer) Pt particles distributed across the entire membrane and a well-defined Pt-band at a distance between 15-30 µm from the cathode, and cell #1 (Nafion\textsuperscript{®} 111 membrane and paper GDL) exhibited a linear decrease in Pt nanoparticle size from the cathode side (from 15 nm to 5 nm, cathode to anode) and a less distinct Pt-band at a distance between 30-40 µm from the cathode layer. The reasons for such dramatic differences in Pt migration are not fully understood, but additional data from other aged MEAs will permit the correlation of such behavior with performance. This work will continue in FY 2011.

Conclusions and Future Directions

- Several new collaborations have been established during the past year that have accessed the unique imaging (microscopy) capabilities at ORNL via:
  - Work for others (proprietary research).
We will continue to establish new collaborations with industries, universities, and national laboratories (including access via ORNL User Facilities) to facilitate “transfer” of unique capabilities. We will also continue to support new DOE fuel cell projects with microstructural characterization and advanced characterization techniques.

- Progress to date to develop in situ liquid TEM/STEM as a viable technique to monitor the degradation of fuel cell materials has been hampered in FY 2010 for one primary reason – while we have been able to meet all program milestones for FY 2010 regarding optimizing the holder design and windows/chips, we are still delayed because of unreliable delivery of “working” windows/chips for the cell. Addressing this issue will be a priority in FY 2011.

- Initiated microstructural and microchemical characterization of EOL PEMFC MEAs to assess cathode carbon-support degradation mechanisms. Several collaborations have recently been pursued (General Motors and UTC Power) to systematically evaluate the progression of carbon corrosion as a function of aging conditions (via durability studies) rather than using EOL MEAs, which will be a primary focus of research in FY 2011.

- The migration and re-precipitation of Pt into and within has been studied in greater detail. Detailed studies to evaluate the amount, particle shape, size distributions, etc. of Pt from the cathode and into the membrane are being correlated with EASA losses and extent of carbon corrosion to fully interpret degradation behavior as a specific function of aging protocol. These correlative studies will be continued in FY 2011.

E-mail: Nancy.Garland@ee.doe.gov

Contract Number: DE-AI-01-01EE50660
Project Start Date: Fiscal Year (FY) 2001
Project End Date: Project continuation and direction determined annually by DOE

Objectives
- Provide neutron imaging-based research and testing infrastructure to enable the fuel cell industry to design, test, and optimize prototype to commercial grade fuel cells.
- Provide a secure facility for proprietary research by industry. Make open research data available for beneficial use by the general fuel cell community.
- Continually improve and develop methods and technology to accommodate rapidly changing industry/academia needs.

Technical Barriers
This project addresses the following technical barriers from the Fuel Cells section (3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:
(A) Durability
(C) Performance
(D) Water Transport within the Stack

2015 System Targets
- Unassisted start from low temperature: -40°C
- Durability with cycling at operating temperature of ≤80°C: 5,000 h
- System energy density: 650 W/L
- System specific power: 650 Watt/kg

- Energy efficiency: 65% at 25% rated power, 55% at 100% rated power
- Cost: $35/kW
- Start-up time to 50% power: 50 seconds from -20°C, 5 seconds from 20°C
- Freeze start operation: unassisted start from -40°C
- Durability with cycling: 5,000 hrs

Accomplishments
- Improve spatial resolution of the measurement of the through-plane water content of an operating proton exchange membrane fuel cell (PEMFC). Develop stable, high resolution charge-coupled device (CCD)-scintillator detector system.
  - New high resolution neutron imaging system deployed and in use.
  - Measured spatial resolution is 13 μm.
  - High resolution system using scintillator coupled to CCD achieves sub 20 μm spatial resolution
- Measure fundamental through-plane transport properties of diffusion media (DM) and membranes that incorporates improved measurement uncertainty analysis. Transfer new data analysis suite to fuel cell industry and national labs. Prepare for publication in a peer reviewed journal article demonstrated use of new analysis tools with established models and data.
  - Measured gas diffusion in DM as a function of saturation and electroosmotic drag in hydrogen pumping experiments.
  - In collaboration with Los Alamos National Laboratory (LANL), have studied a range of membrane histories and compositions; results and analysis are being prepared for publication.
  - The measured water content in the DM has been compared to models of the saturation using NIST-developed analysis tools.
- Search for systematic errors in neutron radiography:
  - Determined systematic underestimation of water content due to unaccounted residual water in dry membrane images and beam hardening.
  - Developed experimental method to overcome this systematic undercounting of water.
- Improvements to the Neutron Imaging Facility and fuel cell support infrastructure:
  - Improved the facility fuel cell test stand humidification system allowing for more
accurate humidification of fuel cells designed for high resolution testing.
- Improved the high resolution freeze testing capabilities of the facility.

Introduction

At NIST, we maintain the premier fuel cell neutron imaging facility in the world and continually seek to improve its capabilities. This facility provides researchers a powerful and effective tool to visualize and quantify water transport inside operating fuel cells. Imaging the water dynamics of a PEMFC is carried out in real time with the required spatial resolution needed for fuel cells that are being developed today. From these images, with freely available NIST-developed image analysis routines, PEMFC industry personnel and researchers can obtain in situ, non-destructive, quantitative measurements of the water content of an operating PEMFC. Neutron imaging is the only in situ method for visualizing the water distribution in a “real-world” PEMFC. Unlike X-rays, whose interaction with materials increases with the number density of electrons, neutrons interact via the nuclear force, which varies somewhat randomly across the periodic table, and is isotopically sensitive. For instance, a neutron’s interaction with hydrogen is approximately 100 times greater than that with aluminum, and 10 times greater than that with deuterium. It is this sensitivity to hydrogen (and insensitivity to many other materials) that is exploited in neutron imaging studies of water transport in operating fuel cells.

Approach

The typical length scales of interest in a PEMFC are: channels approximately 1 mm wide and 1 mm deep, the DM is 0.1 mm to 0.3 mm thick, the membrane is 0.01 mm to 0.05 mm thick, and the active area is 2 cm² to 500 cm². Thus, to nondestructively study in situ the water and hydrogen transport in PEMFCs while in operation we will develop new facilities and improve existing capability for obtaining high spatial and temporal resolution neutron images. Employing the mathematical models of neutron scattering, we will develop a software suite that enables users to obtain quantitative measurements of the water content in an operating PEMFC. Due to the complexity of PEMFCs and the large number of open questions regarding water transport in PEMFCs, we will develop partnerships with industry, academia, and national laboratories to train them in the use of the facility, collaborate with them on research projects, and seek their feedback to pursue future technical breakthroughs.

Results

We have worked in close collaboration with LANL to develop a fundamental understanding of the water uptake by the membrane, a critical materials characterization for modeling the through-plane water transport in PEMFCs. This collaborative effort explored multiple sources of measurement uncertainty, both in the neutron imaging system and in the fuel cell operation and assembly; a full journal article is in preparation that will detail the effort summarized here. The most important advancement impacting these measurements has been the recent introduction of the new high resolution microchannel plate detector, with a measured spatial resolution of about 13 μm. The impact of this detector on the measurement of PEMFC through-plane water content can be seen in Figure 1, where images of a test section viewed edge on are imaged at three different spatial resolutions. The right-most image shows the current detector spatial resolution, which is a factor of 20 improvement over the spatial resolution at the start of this project.

Another important refinement that was recently made to the neutron image analysis is the proper accounting of the residual water content of the membrane (both in the active area and under the gaskets) in the dry reference image. For the new detector, the measured neutron attenuation is not linear in water thickness, a known effect called beam hardening. Beam hardening can be modeled by a quadratic function allowing the water content to be accurately estimated from the radiographs. Accounting for the beam hardening effect and the residual water in the membrane modifies the calibration of neutron intensity versus water thickness. Shown in Figure 2a is a comparison of the membrane hydration with and without incorporating the residual water. This
The neutron imaging facility staff facilitates and collaborates with a broad group of neutron imaging users with experiments that support the DOE Hydrogen Program. In the past year, neutron imaging data from this unique facility has been used by researchers from six companies, eight universities, three national laboratories, and has been a part of the thesis research of 12 graduate students. Among these projects researchers from General Motors, Rochester Institute of Technology, and the Michigan Technological University used the imaging facility to study a wide range of purge conditions and the impacts of varying thermal properties of the DM on water management. These studies are critical to develop a fuel cell robust enough to withstand the stresses of freeze and achieve the DOE cold start targets. A cell was designed for this work that closely parallels publicly known details of automotive fuel cell designs. This allows the cell to be more representative of commercial automotive designs yet the details of cell operation can be publicly shared. Coupled with neutron imaging measurement of the water content, the design incorporates in situ current, temperature, and high frequency impedance distribution measurements, enabling precise, local correlations between water mass, current density, temperature and high frequency resistance (HFR) (Figure 3a). While HFR measurements probe the state of hydration of the fuel cell membrane, they are not capable of determining the actual amount of water in the fuel cell membrane. Using neutron imaging, which allows quantification of the water content, a correlation between the local HFR and local water content in the fuel cell during a purge can be made (Figure 3b). Here the sensitivity of neutron imaging to water is clearly shown to be as low as 4 micrometers corresponding to a water mass of about $6.5 \times 10^{-8}$ g per pixel. The correlation clearly shows a marked change in HFR when the amount of water in the cell is roughly equal to the membrane thickness. With this information, accurate models of the dry purge can be derived that aim to reduce the amount of input energy needed to purge the fuel cell stack at shutdown and still start under freeze conditions.

In addition to studying the effects of purge on cold-start, this cell was used to study the effects of varying the properties of the DM on water management, in particular the thermal conductivity. During operation of the cell, the waste heat from the cathode reaction results in a temperature gradient between the membrane and the flow fields, with the membrane at a higher temperature; thus the water saturation pressure at the membrane is higher than at the flow fields. Changing the temperature profile can therefore reduce or increase the amount of water that condenses in the DM. As shown in Figure 4, by raising the thermal conductivity of the DM the temperature gradient decreases, resulting in more condensed water in the DM. Conversely by lowering the thermal conductivity of the DM the temperature gradient increases, resulting in less condensed water in the DM. Overall more condensed water was observed in diffusion media with higher thermal conductivity than ones with lower thermal conductivity. From this data, one can create structured DM, shown in Figure 4d, to optimize the water transport along the length of the active area seen in Figure 4e.
FIGURE 3. Shown here in a) is the fuel cell with representative images of the separate in situ characterizations that were performed at once. The second image from the top shows the neutron image and how it correlates to all the other in situ measurements. Here the water distribution is peaked where the current peaks along with the minimized HFR and a maximum in temperature due to waste heat from the chemical reaction. In b) the local HFR is shown as a function of water mass measured using neutron imaging. The neutron method is capable of measuring the local water content with 4 micrometer uncertainty.

FIGURE 4. Shown in a) are the neutron images of the water distribution of a DM with low thermal conductivity for various current densities and b) a DM with high thermal conductivity. The amount of retained water is plotted in c) for the various current densities for the DMs of varying thermal conductivity. A graded DM is shown in d) where high thermal conductivity DMs are used near the dry inlets to improve membrane hydration seen in e), while low thermally conductive DMs are used in the middle wetter region to reduce flooding in the DM.
Researchers from Pennsylvania State University used the NIST high-resolution detector to image a cell from the edge and varied the hydrophobicity of the flow fields to determine where the retained water was between the anode and cathode [1]. A previous study of the in-plane water distribution showed the surprising result that the cell retains more water with hydrophobic flow fields at lower current densities [2]. The present study observed that the hydrophobic lands result in small unconnected droplets, preventing the capillary wicking that occurs with the laminar sheets formed on hydrophilic surfaces. Therefore less water was pulled out of the DM into the channel, and more water was present on the anode due to increased back diffusion. This excess water in the DM formed large, connected regions under the flow channels, increasing the likelihood of flooding in the channels, and could have adverse affects on the cell operation during shutdown and startup under sub-zero conditions.

Conclusions

- High-resolution imaging is playing a key role in understanding the through-plane water transport in fuel cells:
  - Current resolution of 13 μm represents a factor of 20 improvement in spatial resolution over a four year period.
  - Fundamental water transport measurements in the DM provide:
    - Understanding of transport in fuel cells with hydrophobic channels.
    - Understanding of the role of phase change induced flow.
  - In situ membrane hydration measurements are critical for accurate models of water transport:
    - Worked with LANL in understanding the hydration of membranes as a function of water activity, membrane compression, and protonation.
    - Determined an experimental method to account for undercounting of water and eliminate this systematic from neutron imaging.
    - Combined results from thermo gravimetric analysis and neutron imaging to correctly analyze data.
- Neutron user program successfully provides users with unique access to neutrons:
  - In the past year, neutron imaging data from this unique facility has been used by researchers from six companies, eight universities, three national laboratories, and has been a part of the thesis research of 12 graduate students.

Future Directions

- Study transport and dynamics in four cell stacks designed for neutron radiography.
- Study water transport in the microporous layer and compare with realistic models of the microporous layer.
- Work with modelers to correlate models and experimental data in an operating fuel cell.
- Develop large area detectors (10 cm by 10 cm) with spatial resolution of less than 15 μm.
- Investigate neutron optical techniques to improve the spatial resolution to less than 10 μm.

FY 2010 Publications/Presentations

Objectives

The overarching objectives of the project are to assist the DOE in developing fuel cell systems by analyzing the technical, economic, and market drivers of direct hydrogen polymer electrolyte membrane fuel cell (H-PEMFC) adoption.

In 2010, Battelle’s major task focused on developing a manufacturing cost analysis and associated technical targets for a 5 kW backup power fuel cell system operating on direct hydrogen. The cost analysis was performed at three technology levels and production volumes:

- Current Status (2,000 Units)
- 2012 (10,000 Units)
- 2015 (100,000 Units)

Preliminary analysis of the manufacturing costs is presented in this report. Final review and refinement are expected to be complete after the deadline for submission of this report.
in fuel cell technology. This information was used to determine the preliminary design of the H-PEMFC stack and system for the years of interest (2010, 2012, and 2015). The overall system design was used to design the main components of the system, like the membrane electrode assembly, bipolar plate etc. The system design and configuration was then iterated multiple times based on further input from industry and insights provided by the simultaneous cost analysis. Manufacturing methods were then selected based on the industry practices and considerations for achieving desired durability and costs. These methods were further refined based on feedback from industry and based on cost modeling. Once the system configuration was defined, the system cost was determined. The system cost is comprised of capital equipment, stack production, balance of plant (BOP), and assembly/test costs. Capital equipment and BOP costs are determined using estimates and quotations from vendors of suitable hardware. Whenever possible, multiple vendors were solicited for pricing information to gain confidence in the validity of the costs used in the analysis. The cost of production of the stack and the system assembly and testing was estimated using models developed from the manufacturing process definitions, implemented in the Boothroyd-Dewhurst DFMA™ software.

**System Design and Assumptions**

An air-cooled system was chosen for the analysis. This is reflective of many commercially available H-PEMFC systems for backup power applications. Compared to a water-cooled system, an air-cooled system offers a reduction in BOP components and advantages in reliability, transport, and durability. An air-cooled system is generally operated at a lower current density than a water-cooled system which in turn requires more membrane active area. Due to equipment limitations, an air-cooled system also is limited on the stack size. The system schematic is shown in Figure 1.

The operational characteristics for the system are listed in Table 1. Stack construction details are summarized in Table 2. Primary changes considered for systems in 2012 and 2015 are an increase in current density, an increase in the membrane utilization, and a decrease in the number of bipolar plates. The increase in current density is expected to come from research advances in membranes and catalysts. The increase in membrane utilization is attributed to improvements in the design and manufacturing capabilities. The reduction in bipolar plates is realized by combining the cathode air and cooling air process streams into a single process air flow and thereby eliminating the need for separate cooling air channels.

Battelle approached manufacturing by defining a business model where the fuel cell stack components, stack assembly, system assembly, and test and conditioning are all performed in-house. Doing so means acquiring and operating all necessary machinery as well as buildings and associated infrastructure such as electric distribution, heating and cooling, cleanliness control, lifting and transportation of materials, and storage. System components falling outside the defined core will be purchased or outsourced. As a result, no equipment or facilities are included for production of commercially available off-the-shelf items, such as blowers and pressure regulators, nor are any resources allocated to commercially common processes like metal machining or plastic molding.

Since a transition to high production volumes was anticipated well before the lifetime of the manufacturing equipment, high-volume equipment was identified and used at the outset. The manufacturing processes utilize roll-to-roll style processing (instead of batch processing). This approach results in excess manufacturing capacity initially, but as production volumes increase over time...
the capacity is eventually exceeded. More equipment is bought as those limits are reached, phasing the cost of manufacturing capital expenditures.

Cost estimates were developed for each piece of machinery in the manufacturing process. Quotes were gathered from vendors when possible, from published pricing information, resale listings, internet searches, and by engineering estimate when necessary. The same price was used across the various manufacturing line itemizations if a machine appears in multiple process lines.

Any capital expenditures are amortized over a 20-year period and the annual amortized cost is distributed over production volume for that year. For example, if total capital financing costs in year 1 are $2,000,000 with a production volume of 10,000 units, each unit’s price will reflect $200 of capital cost. This approach results in capital costs representing a diminishing portion of the fuel cell system cost with increasing production volume. In all three of the forecast years, manufacturing capital costs are a minority contributor to the overall cost of a fuel cell system.

The cost of production was estimated using models developed from the manufacturing process definitions, implemented in the Boothroyd-Dewhurst DFMA™ software. Standard models for processes or machinery existing in the software were used whenever possible. A custom model was programmed, using fundamental mechanical principles and published machinery specifications or data gathered from vendors.
when a standard model was not available. Basic cost assumptions are detailed in Table 3.

Assumptions were developed from previously published information, discussions with vendors, using standard values defined in the software, and by engineering estimates.

Scrap rates for the stack manufacturing processes vary and in some cases represent a tangible portion of the process’s cost. As with the manufacturing process definition itself, much of this information is considered proprietary in industry. The values used for the Battelle analysis are representative of ranges documented in previously published information. When such data was not available, engineering estimates were made based on Battelle’s manufacturing knowledge. Table 4 delineates the scrap rates, which were held constant over all the forecasted years. These rates capture not only scrap resulting from initial production of material, but also excess material consumed during stack rework as part of test and conditioning.

The remainder of the fuel cell system components, including BOP and structure (frame) and enclosure, are purchased or outsourced. The assembly, integration, testing, and conditioning of all these items are done in-house. Stack assembly and test costs are included in the stack estimate while the cost of system assembly and test is included at that level.

### Results

The system cost breakdown and total system costs are shown in Table 5. According to the Battelle analysis, in 2010 with an annual production volume of 2,000 units, cost of a 5 kW H-PEMFC system is $6,986 or $1,379 per kW. This cost declines by 26% to $5,084 or $1,017 per kW in 2012, and by 39% to $4,221 or $844 per kW in 2015. Approximately 60% of the reduction to $844/kW in 2015 is achieved through reduction in costs of the stack components, particularly the bipolar plates and the MEA. The remaining 40% is equally split between reductions in the BOP component cost and the lower assessment of capital costs on a per unit basis. The modest decrease in BOP costs is due to many of them already being produced in high quantities with limited margin for cost reduction. Approximately 50% of the source for reduction in cost for both the 2012 and 2015 cases is due to technology advances while the other half is due to increased production volume.

In general, materials represent the most significant cost of fuel cell stack production, evident in Figure 2. In the case of the bipolar plates; production cost is split more uniformly across all three of tooling, processing, and raw materials. The cost production breakdown is similar for 2012 and 2015.

At initial and low volume production, much of the capacity of the manufacturing equipment goes unused. In some cases, the entire year’s worth of production can be run in a few calendar days. However, by business model definition, the equipment purchase at the beginning is justified by the rapidly increasing production quantities over the five year period of study. Despite much of the machinery’s production capacity potentially going unused in the first few years, the unused capacity represents, by way of capital costs allocated to each unit, a small portion of the system cost.

Considering line utilization is useful for identifying process bottlenecks. Battelle defined line utilization as a percentage calculated as the number of machine hours necessary to produce the annual quantity divided by the total number of annual machine hours available.
The annual machine hours available are the number of machines times 24 hours (3, 8-hour shifts) in a day. The results of this are tabulated in Table 6.

The bottlenecks in production are identified by these tables and include the bipolar plate forming, stack assembly, and test and conditioning. Despite having limitations to productivity, the system cost impact of these bottlenecks is mostly low since raw material costs are the predominant expense in stack production. Of the group, eliminating the bipolar plate forming bottleneck will have the most impact on stack cost. The elimination of the bipolar plate bottleneck can be achieved by emerging technologies, like flat/unformed sheet metal or foils. Industry expects test and conditioning time to decrease significantly over the next five years, providing a modest opportunity for cost reduction.

**Conclusions and Future Directions**

System costs and stack costs are expected to decline to $847 per kW and $203 per kW, respectively with annual volumes of 100,000 units. Major contributors to the system cost are the bipolar plates, MEA, and the DC/DC converter. The main drivers to MEA cost are the raw materials, most specifically catalyst. Additional research in alternative material-based bipolar plates and lower-catalyst MEAs could reduce these costs. The lack of a suitable off-the-shelf DC/DC converter is a significant obstacle. Further work to understand the
application requirements and the drivers for DC/DC converter cost is recommended.

Next steps on the project are to complete a sensitivity analysis of the cost drivers likely to most impact the cost of the system and incorporate the feedback from industry and the peer reviewers and publish final results.

**FY 2010 Publications/Presentations**

Objectives

- Provide DOE with an independent assessment of the performance of fuel cell systems and components developed under DOE contracts.
- Characterize and benchmark the performance of state-of-the-art commercial fuel cell technology available in the market.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cells section (3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Durability
(C) Performance
(D) Water Transport within the Stack
(G) Start-up and Shut-down Time and Energy/Transient Operation

Contribution to Achievement of DOE Fuel Cells Milestones

This project will contribute to achievement of the following DOE milestones from the Fuel Cells section of the Fuel Cell Technologies Program Multi-Year Research, Development, and Demonstration Plan:

- **Milestone 86**: Evaluate short stack against 2011 targets for operation over the full operating temperature range. (4Q, 2010)
  - We are testing stacks from different developers and documenting their performance according to well-defined test protocols for comparison of the measured performance against DOE targets.

Accomplishments

- Characterized two 5-kW complete systems.
- Characterized one 12-kW complete system.
- Began characterization of a 2-kW stack which contains bipolar plates designed for high-temperature operation.
- Participated in and made technical presentations at meetings of the International Organization for Standardization Working Group 11 under Technical Committee 105 of the International Electrotechnical Commission, held on February 8-9, 2010, in Milan, Italy. The goal of this international group is to draft the technical specification of a single-cell test protocol. Representatives from six countries attended. The technical specification has been published.
- Initiated collaborative effort to compare the test protocols developed by the European Fuel Cell Testing and Standardization Network (FCTESTNET)/fuel cell testing, safety, and quality assurance (FCTESQA) and by DOE to characterize and age fuel cell stacks. The objective of the effort is to determine if the results depend on the protocol used or if the results are protocol-independent.

Introduction

This project helps DOE determine and document progress toward achieving its technical targets by providing an independent assessment of evolving
fuel cell technology. In addition, in this project we develop standardized fuel cell testing procedures to aid in the evaluation of different stack technologies on a common basis. The procedures and methods used at the Argonne Fuel Cell Test Facility do not depend on the technology being tested, that is, they are transparent to the technology being tested; thus, they provide a means for easy comparison of the performance and expected life of the technology from many different developers. In these procedures, the stack is characterized in terms of initial performance, durability, and room-temperature performance. To further accelerate fuel cell technology developments, these procedures are compared with similar procedures developed by other national and international organizations.

The initial performance establishes a baseline for comparison as the fuel cell ages. The aging process is accelerated to yield a reasonable projection of life at constant power and under driving duty cycles in a reasonable amount of testing time. Periodically during the aging test, the test is interrupted and the stack performance is re-characterized. A life projection is then made by comparing the most recent performance characteristics with those measured earlier.

**Approach**

We have developed standardized fuel cell and stack test procedures to aid in the evaluation of different stack technologies. These test procedures characterize the stack in terms of initial performance (e.g., power and voltage vs. current, efficiency, hydrogen crossover), durability, and low-temperature performance. The testing is repeated during and after defined aging under steady-state and cycling operations to determine performance decay over time.

The test facility is flexible enough to accommodate the unique needs of different fuel cell technologies. Modification and upgrading of the test facility is an ongoing process that is carried out in consultation with fuel cell developers and DOE.

**Results**

The performance of two 5-kW, direct hydrogen fuel cell systems was characterized in terms of polarization behavior (sequential and random polarization curves) of the fuel cell stack. For these tests, the system was cycled using the dynamic stress test (DST) profile shown in Figure 1 to simulate accelerated aging of the stack. The DST profile consists of several steps representing different current levels ranging from 0 A to current values where the average cell voltage in the stack is 0.6 V/cell. After every ~100 h (1,000 DST cycles) of this accelerated aging protocol, the DST cycling was interrupted and the stack performance was characterized by measuring a sequential polarization curve.

The performance and aging characteristics of the two 5-kW stacks were very similar; the results from one will be used in the following discussion. The stack-only polarization data from this accelerated aging test are shown in Figure 2. The initial performance was in very good agreement with the rated performance of the stack. Further, the data in Figure 2 indicate that there was very little change in the performance of the stack over the first about ~1,200 h of the accelerated aging under the DST cycling conditions. After that, however,
there was a significant decrease in the measured performance of the stack.

The power vs. current density curves were calculated from these data (see Figure 3). As expected, very little change in these curves was seen during the first ~1,200 h of DST aging.

There is interest in the U.S. and in the European Union (EU) to standardize testing protocols. It is hoped that with standardized protocols, fuel cell development will be accelerated and information exchange will be increased. Under the FCTESTNET framework program, the EU has developed a set of protocols it is proposing as standards. These protocols are being validated under the FCTESQA program in a number of EU laboratories.

As part of our collaboration with FCTESQA, we compared the performance of a previously-tested, hydrogen-fueled, 15-kW stack using the sequential polarization protocols developed by FCTESTNET and by DOE. The major differences between the two polarization protocols are the sequence of currents used and the portion of the polarization experiment that is reported as the resulting data. Figure 4 shows that the DOE protocol starts at open circuit, and then increases and decreases the stack current in turn. The FCTESTNET protocol, on the other hand, can start at almost any current setting. In the example shown in Figure 4, the test protocol starts at about 50% of the rated current; the current then increases, decreases, and finally increases again. The DOE protocol reports data from both the current-increasing and the current-decreasing sections; for the FCTESTNET protocol, only the results from the current-decreasing portion are reported. Figure 5 shows the current-decreasing portion of the polarization curves obtained from the 15-kW stack using the two protocols; there was no significant difference between the two curves.

Based on the genesis of the protocols, differences in the levels and profiles of stress placed on the fuel cell or stack may be expected to affect how the cell or stack ages during a durability test. The U.S. durability protocol was based on the accelerated testing of automotive-class traction batteries (Figure 1). Those used by the EU were based on different assumptions, such as a smooth power increase followed by power off (Figure 6a) or on-off cycling (Figure 6b). Aging experiments were conducted to measure the relative stress imposed by the test profile. Here, the DST and FCTESTNET Profile B were used to age the stack; each aging test lasted about 75 h. The change in performance of the stack with aging profile was gauged by polarization curves (see Figure 7). As can be seen from Figure 7, the DST profile produced a 7.4% decrease in performance at the maximum current density. The FCTESTNET Profile B produced an additional 2.0% decrease in performance. Thus, the DST profile seems to age the stack faster. FCTESTNET Profile A will be used next to complete the study as well.
as to investigate whether the order in which the tests are performed affects the results (path dependency).

**Conclusions and Future Directions**

- We have characterized the performance of two identical 5-kW systems, a 12-kW system, and a 2-kW stack, the last containing bipolar plates designed for high-temperature operation.
- The performance of the two 5-kW stacks was observed to be essentially identical and representative of this particular fuel cell technology.
- Testing of the stacks under an accelerated aging regime of current and potential cycling showed little change in performance over the first ~1,200 h (12,000 DST cycles); however, the stack performance degraded rapidly after 1,200 h.
- We are collaborating with the EU’s FCTESTNET program to compare and validate the fuel cell test protocols being developed by the EU and the DOE. Preliminary results from the testing of a 15-kW stack of circa 2002 technology showed that there was no significant difference between the polarization curves obtained under these two different protocols. More detailed work is still needed to confirm these early results for the state-of-the-art fuel cell technology, and to evaluate the effects of accelerated aging schedules under the two testing protocols.
- In future work we will continue to characterize DOE fuel cell contract deliverables, as well as benchmark other fuel cell technologies.
- We will continue to collaborate with other fuel cell testing laboratories, such as the Institute for Energy (Netherlands), and we will begin the maintenance of the technical specification that Working Group 11 has produced (single-cell test protocol).

V.A.8 Technical Assistance to Developers

Objectives

- Assist technically, as directed by DOE, fuel cell component and system developers.
- Test materials and components and provide feedback to customers.
- Support the development and testing of durability protocols with the US Fuel Cell Council (USFCC).
- Provide support to the U.S. Council for Automotive Research (USCAR) and the USCAR/DOE Freedom Cooperative Automotive Research (FreedomCAR) Fuel Cell Technical Team.
- Validate technical findings as directed by DOE.

Technical Barriers

This project can be directed to address any of technical barriers from the Fuel Cells section (3.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (MYRDDP), however it principally addresses:

(A) Durability
(B) Cost
(C) Performance

Technical Targets

In this particular task, any of the technical targets in the MYRDDP Table 3.4.4 may be addressed at any given time. Specifically, select tasks that apply to the technical targets in this project are listed below, while their status is listed in the ‘Accomplishment’ section.

- Provide continued testing insight and advice to DOE principal investigators.
- Testing of materials and participation in the further development and validation of durability test protocols with the USFCC.
- Offering technical assistance to USCAR and the USCAR/FreedomCAR Fuel Cell Technical Team.
- Participating in working groups and review meetings.

Approach

Our approach has consistently focused on collaborative-type interactions as guided by DOE. A large portion of this effort goes unpublished, for proprietary reasons. However in this fiscal year, we have continued to provide testing support and actively participated in developing test protocols. In addition, LANL has provided hands-on short courses on several fuel cell topics.

Accomplishments

- Honored several invited presentations.
- Hosted numerous visitors to LANL.
- Collaborated with multiple industrial, university, or laboratory partners.
- Provided test insight and/or results to several DOE principal investigators.
- Participated in the review and development of USFCC durability protocols.
- Held Hands-On Fuel Cell Short Course.

Highlights

Figures 1-5 show some highlights of the technical assistance task for the 2010 Fiscal Year.
FIGURE 1. Hardware designed at LANL, to provide National Institute of Standards and Technology (NIST) beam line scientists (Hussey and Jacobson) support in conducting beam hardening experiments.

FIGURE 2. Los Alamos measured water profiles and performance of dead-ended anode to help University of Michigan develop and validate simple control oriented models and simulate the dynamics of large fuel cell stack systems operating with a dead-ended anode, which do not rely on anode humidification or re-circulation systems.

FIGURE 3. Cyclic voltammetry was run on a sample provide by NIST before running subsequent experiments such as hydrogen crossover measurements, break-in procedure, and polarization curves.

**Objectives**

- Develop understanding of water transport in polymer electrolyte membrane (PEM) fuel cells.
- Evaluate properties of materials affecting water transport and fuel cell performance.
- Develop (enable) new components and operating methods.
- Accurately model water transport within the fuel cell.
- Develop a better understanding of freeze/thaw cycles and sub-freezing operation.

**Technical Barriers**

**Accomplishments**

**Gas Diffusion Layer (GDL) Materials**

- Demonstrated better water removal characteristics with modified microporous layer (MPL) properties.
- Demonstrated performance improvement by optimizing GDL properties and in-plane GDL type in relation to its flow-field position.

**Membrane Water Content Measurements (by Neutron Imaging)**

- Measured compression effect on water content in membranes.
- Made reversible in situ measurements of membrane water content to examine Schroeder’s paradox.

**Freeze**

- Measured durability of various cell configurations and the location of frozen water (ice) for various operating conditions.

**Modeling**

- Created modeling simulations of oxygen partial pressure in the cathode catalyst layer as a function of channel liquid pressure for various types of GDLs.
- Modeled the dynamic behavior of water in response to various step-changes in current density.

---

**Introduction**

Ineffective control of water distribution can be a major impediment to implementation of PEM fuel cells (PEMFCs). Several important parameters, including membrane conductivity and mass transfer resistance within porous electrodes, are intimately linked to water distribution, requiring effective management of water in...
order to maximize fuel cell performance. Components such as the PEMs and electrode layers require sufficient water to be present in order to allow adequate proton conductivity. Conversely, excess water within the system leads to mass transfer losses and can require additional balance-of-plant costs (extra energy or weight for increased humidification). The range of conditions under which the system is required to operate makes meeting all these requirements at the same time even more difficult. The conditional extremes provide the biggest challenges: maintaining hydration under hot/dry conditions and preventing flooding/dealing with ice formation under cold/wet conditions. In order to address these challenges there is a need for increased understanding of water transport and phase change within fuel cell components. This requires that the structure and properties of fuel cell materials be fully understood. The materials ultimately employed will need durability under normal and transient operations while allowing effective water management under any environmentally-relevant condition.

Approach

Our approach to understanding water transport within fuel cells is structured in three areas: fuel cell studies, characterization of component water transport properties, and modeling of water transport. These areas have aspects that can be considered free-standing, but each benefit greatly from work performed in the other areas. The modeling studies tie together what is learned during component characterization and allow better interpretation of the fuel cell studies. This approach and our team give us the greatest chance to increase the understanding of water transport in fuel cells and to develop and employ materials that will overcome water-related limitations in fuel cell systems.

Results

Effect of Hydrophilic Treatment of Microporous Layer on Fuel Cell Performance

The GDL in a PEMFC is the component primarily responsible for effective water management under a wide variety of conditions. Optimal GDL performance is obtained when the MPL has enough hydrophobic pores for gas access and enough hydrophilic pores for water wicking [1]. To optimize the water transport properties of the GDL, SGL Technologies has developed new GDLs that incorporate aluminosilicate fibers to create hydrophilic pathways in the MPL to facilitate liquid water removal from the cathode catalyst layer [2]. Figure 1a shows the performance of fuel cells using the GDL with the hydrophilic fibers in the MPL (25BL) is significantly better than the baseline hydrophobic GDL (25BC). The cell with the 25BL GDL shows a 150 mV improvement in the voltage at a current density of 2 A cm\(^{-2}\). However when the cathode gas was changed to HelOx, the performance of the two cells were almost identical. This indicates that the improvement in the performance is primarily due to better mass transport characteristics of the 25BL GDL with the hydrophilic fibers in the MPL.

The improvement in mass transport was verified with alternating current impedance spectra of the two cells which confirms the better mass transport for the 25BL GDL and is illustrated in Figure 1b. The high frequency resistance (HFR) of both these cells is the same (≈0.04 Ω cm\(^{-2}\)), however, the low frequency (0.1 Hz) resistance of the cell with the 25BL GDL is ≈40% lower. Moreover, the impedance spectra in HelOx of these two cells is identical, indicating that the improved performance of the 25BL GDL is due to better water removal resulting in improved oxygen diffusion kinetics. The decreased mass transport resistance in HelOx when compared to air is directly attributed to the 3.7 times better diffusion of O\(_2\) in He vs N\(_2\) [3].
Neutron Imaging of MEA Water Profiles

In order to further investigate the origin of the mass transport improvement, the water profiles of two cells with 24BC and 25BL GDLs were obtained via neutron radiography with the newly installed 13 µm resolution detector at NIST. The 25BC cell is expected to behave similar to the 24BC one (based on the performance data). Figure 2 shows the water profiles obtained in the cross-section view of these cells. The baseline GDL (24BC) shows a typical profile where a peak in water content is seen close to the location of the cathode catalyst layer. Moreover the MPL (≈50 µm thick) exhibits low liquid water content as illustrated by the steep drop in water content as one moves away from the membrane electrode assembly (MEA). In contrast, the cell with the 25BL GDL shows significant liquid water in the MPL region as evidenced by the steady water content profile as one moves across the MPL. This figure also indicates that the liquid water saturation in the cathode catalyst layer is lower when using the 25BL GDL. Both GDLs show significant water accumulation in the substrate with the 25BL GDL having greater water saturation. The water content indicates a maximum saturation of only 15% in the GDL substrate for the 25BL GDL. Although the absolute water content in the thin catalyst layers and membranes is difficult to obtain due to the smearing of the water content based on the 13 mm detector resolution, these results indicate that the mass transport losses are predominantly due to liquid water in the catalyst layer pores.

Modeling of GDL Properties Effect

Modeling simulations examined various GDL properties to evaluate the mass-transfer limiting current as a function of inlet water flux. Results show that there are high limiting currents and the water flux is flat in the practical fuel cell operating range. The modeling results agree with the experimental results, showing that bulk transport (convection) does not lead to mass-transfer limitations because the effective permeability remains too high. These results indicate that once a water pathway is established, it can sustain practical liquid-water fluxes. The effect of variations in GDL properties on mass transport can be summarized in Figure 3, which shows the oxygen partial pressure as a function of the channel water pressure. At high channel water pressures, the GDL with hydrophilic pores retains the highest oxygen partial pressures at the catalyst layer.

Neutron Imaging of Membrane Water Content

Water transport in the Nafion® ionomic membrane has profound influence on the performance of the polymer electrolyte fuel cell, in terms of internal resistance and overall water balance. We conducted high resolution neutron imaging of Nafion® membranes in order to measure water content in situ with varied compression on the membrane. Figure 4 shows the measured membrane water content ($\lambda = \# \text{ water molecules per sulfonic acid group}$) for various cell compressions, including a restricted membrane (low membrane compression, <140 psi) and a highly compressed membrane (>400 psi). Restricted and compressed membranes have identical water content with the exception of when the membrane was in contact with liquid H$_2$O. In contact with liquid water, the highly compressed membrane had substantially less water ($\lambda = 17.5$) than the membrane that had lower compressions ($\lambda = 21.5$), indicated that compression can limit the membrane water uptake, but only at high water contents. When comparing the constrained
and compressed cases, it is interesting that additional membrane compression did not cause significant reduction in water uptake. A possible explanation may be that the compression of the GDL mitigates the pressure exerted on the membrane itself. The in situ measurement ability of neutron imaging was also used to examine Schroeder’s paradox, which addresses the inconsistency between the measured membrane water content at 100% RH and in contact with liquid water, which is inconsistent with thermodynamics because the chemical potential of saturated water vapor is equal to that of liquid water at the same temperature. For this measurement, the membrane RH was increased from 50% RH to 100% RH to liquid, then reversed. The membrane water content at 100% RH was identical in the forward and reverse directions at $\lambda = 10$, compared with the liquid $\lambda = 21.5$, thus proving the validity of Schroeder’s paradox.

**Conclusions**

**GDL Materials**
- Modified MPL properties show better water removal characteristics and performance.
- Performance improvement can be realized by varying the in-plane GDL type in relation to its flow-field position.
- Mass transport losses are predominantly due to liquid water in the catalyst layer pores, not due to water saturation levels in the GDL substrate.

**Membrane Water Content Measurements by Neutron Imaging**
- Cell compression influences membrane water content at high levels of water.
- Reversible in situ measurements of membrane water content verified existence of Schroeder’s paradox in Nafion® fuel cell MEAs.

**Freeze**
- Membrane hydration due to the generated current and back diffusion is dominant at sub-freezing temperatures.
- Freeze operation/cycling can result in loss of catalyst surface area, increase in porosity of catalyst layer and mass transfer limitations.
- High Teflon® content in the MPL results in better durability during freeze/thaw cycling and operation.
- Ice formation location depends on temperature, current density, cell configuration.

**Future Directions**

**Experimental and Characterization**
- Segmented cell measurements of new optimized GDL materials (25BL).
- Pneumatic pressure control to change in situ GDL compression and measure GDL compression effect on water transport.
- X-ray radiography/tomography of GDLs measuring water movement through pores.

**Modeling**
- Modeling of through-plane water distribution and transport in MEA-GDL regions by simulating water profile measurements with varying conditions and GDL hydrophobicity.

**Transport Projects**
- Support new transport projects and distribute measurements to 2008-funded projects.

Project Start Date: June 1, 2007
Project End Date: May 31, 2011

Objectives

• Develop advanced physical models for water transport and generation, and conduct material and cell characterization experiments.
• Improve understanding of the effect of various cell component properties and structure on the gas and water transport in a proton exchange membrane (PEM) fuel cell.
• Encapsulate the developed models in a modeling and analysis tool for cell design and future application.
• Demonstrate improvements in water management in cells and short stacks.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cells section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) Durability
(D) Water Transport within Stack
(E) System Thermal and Water Management
(G) Start-up and Shut-down Time and Energy/Transient Operation

Technical Targets

This project is addressing fundamental issues in water transport within the fuel cell stack. The resulting understanding will be applied toward the design of stack components and operating strategies that enable meeting the 2010/2015 targets for transportation fuel cell stacks operating on direct hydrogen:

• Stack power density: 2,000 W/L
• Cold start-up time to 50% rated power @ 20°C: 5 secs
• Unassisted start from low temperature: -40°C

Accomplishments

• Generated flow regime map from experimental studies of droplet emergence at a gas diffusion layer (GDL)-channel interface studies; demonstrated improved model agreement with the transition from film flow to droplet regime;
• Implemented experimental setup for collecting wet pressure drop and transient pressure signatures in two-phase flows in channels and cells; improved agreement of model predictions and observed wet pressure drop;
• Integrated electrochemistry, heat transfer, and phase change with the computational fluid dynamics (CFD) two-phase flow models and demonstrated improvement in current density distribution for initial validation test case; and
• Identified materials and design modifications to focus on for improved water management.

☆☆☆☆☆☆☆☆☆
Introduction

Water management in PEM fuel cells is challenging because of the inherent conflicts among the needs for: (1) supplying adequate water to establish and maintain the membrane electrical conductivity, (2) removing the water produced by the electrochemical reactions at the cathode, and (3) uniformly distributing the gaseous reactants at catalyst surfaces near the membrane to effectively utilize these costly catalysts. As power density of the cells increases, more water will be generated within the same cell volume. Therefore, increasing power density requirements will drive a greater need for design tools incorporating an improved understanding of how liquid water is transported within fuel cells. An additional barrier to widespread use of fuel cells for automotive power is the performance degradation caused when liquid water freezes within the cells. Optimizing water management to influence where the liquid water remains at shutdown is a promising path to improving cold starting capabilities and freeze-thaw reliability.

This project is intended to improve the fundamental understanding of water transport within a PEM fuel cell, and capture that knowledge in design tools capable of assisting the industry to meet targets for increased power densities and improved cold-start performance. To achieve these objectives, the project is focused on developing predictive models for water transport in GDL materials, characterizing materials for model inputs and verification, implementing the resulting understanding in engineering design tools, and validating the resulting design tools against fuel cell performance data and in situ diagnostics of water distribution within operating fuel cells.

Approach

The overall approach of the project team is integrated experimental characterization with model development and application to meet the high level objectives of improving fundamental understanding of water transport in PEM fuel cells and demonstrating improved performance. The initial focus of the experimental characterization was on measuring relevant physical and transport properties of the GDL materials typically placed between the catalyst and reactant flow channels. Diagnostic and characterization studies progressed from water and two-phase (water and air) fluid transport properties of GDL materials, to analysis of water transport in non-operational and operational fuel cells. The related modeling studies have followed a similar progression, with initial emphasis on microscale simulations of single fluid and two-phase transport within GDL materials. The knowledge gained from the materials characterization and microscale simulations was used to develop models suitable for incorporation into an engineering design tool for fuel cell scale analysis of reactant and water transport coupled with power generation. The verification of these models, and the resulting design tool, is in progress and will be accomplished by comparing predicted and measured effects of material and operating conditions on cell performance and water distribution within the cell. Applying our models to screen and improve water management strategies, then testing the resulting concepts in prototype fuel cells, will further demonstrate our improved fundamental understanding and validate the resulting design tools.

Results

In this third year of research, the emphasis has been on completing experimental studies and model evaluation for water transport in fuel cell components such as GDLs and channels, and on completing integration of the water transport models with electrochemistry and heat transfer for modeling of operational cells. We have also begun to apply the gathered data and developed models to screening concepts for improving fuel cell performance through better water management.

Ex situ studies completed this year included two-phase, i.e. liquid water and air, experiments in fuel cell microchannels and channel-GDL assemblies. A flow regime map for the two-phase system arising from liquid water injection into microchannels was generated from controlled experiments designed to model water emergence phenomena in a PEM fuel cell cathode gas microchannel. The microchannel was 250 μm square in cross-section, with a single 50 μm square opening in the bottom for water injection. In general, higher air flow velocities resulted in decreased contact angle hysteresis so that the leading and trailing edges of the droplets had similar contact angles. Higher air flows also promoted droplet detachment in surface tension controlled regimes, as shown in Figure 1. The Weber number scales on the top and right axes of Figure 1 correspond to the relative values of the droplet inertial forces and surface tension forces. With increasing water velocity, the region corresponding to droplet flow regime becomes smaller. At some point, while increasing the superficial water velocity, the slug and film regime will intersect and thus the flow pattern might turn into an intermittent quasi single-phase liquid flow. The desirable operating states are expected to be at the higher air flows within the droplet regime. In this operating region, droplets are formed and more easily removed from the GDL surface, as opposed to the water forming liquid films that would prevent reactants from reaching the fuel cell catalyst or the water accumulating in slugs that would large pressure drops and pressure variations along the channels.

The capabilities of the developed two-phase flow models to predict trends from the droplet injection in microchannel experiments have been improved by
refining the treatment of surface tension. Simulations of experiments such as these are typically performed using the volume of fluid approach, VOF, which provides better resolution of liquid-vapor interface movement and better captures surface tension effects but assumes a no-slip interface at the liquid-vapor surface. The principal disadvantage of the VOF technique is the computational time requirement, since it is inherently a transient technique requiring limited time steps and a relatively fine computational grid to capture surface tension effects accurately. The computation of surface tension forces for liquid-vapor interfaces in channels has recently been improved in the developed two-fluid, two momentum equation solution approach, and initial tests indicate that this new algorithm improves the ability to identify the onset of droplet formation and surface-tension dominated flows. Although the two-phase multiplier is still slightly underestimated for ‘wet’ to dry pressure drop ratios, the improved surface tension algorithm does result in droplet and slug formation for steady state simulations enabling faster screening of design concepts.

Techverse experimentally studied two-phase flow regimes in the cathode channels of a non-operational cell as a function of air flow rates, water flow rates, and cell orientation to analyze transport in channel-GDL assemblies. The apparatus was prepared by using a GDL to separate a liquid water reservoir from transparent serpentine cathode channels. Visualization and image analysis were used to identify the flow regimes, and pressure drop measurements were performed. In general, a horizontal cell with water entering from above the flow channels exhibited the least two-phase flow pressure drop, while a vertical cell with air flowing up had the largest pressure drop for the same air and water flow rates. Analysis of photographs at steady operation indicated that a horizontal cell orientation with water flowing up into the channels, and a vertical cell orientation with air flowing up, were most likely to form water films blocking open GDL surface area. Several operating points from the experiments for the vertical orientation of the channels, Figure 2, were simulated using the developed two-fluid models for water transport through porous GDL materials and in the channels. The model predictions were qualitatively consistent with the experimental observation of film formation at these conditions, and the predicted variation in channel pressure drop with water flow rate was in good agreement with the experimental measurements.
