THE MEASUREMENT OF RADIATION EXPOSURE OF
ASTRONAUTS BY RADIOCHEMICAL TECHNIQUES

January 4, 1971 Through April 4, 1971

R. L. Brodzinski

ABSTRACT

The concentrations of the radioisotopes observed in the feces from the Apollo 12 and 13 missions were normalized to the weight of the respective stable element in the specimens. These newly normalized concentrations confirmed all prior conclusions regarding assignment and identification of samples, anomalously high and low concentrations of radionuclides, and cosmic radiation dose.

The concentrations of 23 major, minor, and trace elements in the fecal samples from the Apollo 12 and 13 astronauts are reported. Most elemental excretion rates are comparable to rates reported for earlier missions. Exceptions are noted for calcium, iron, and tin. Body calcium and iron losses appear to be reduced during the Apollo 12 and 13 missions such that losses now seem to be insignificant. Refined measurements of tin excretion rates agree with normal dietary intakes. Earlier reported tin values are in error.

A new passive dosimetry canister has been designed which contains foils of tantalum, copper, titanium, iron, cobalt, aluminum, and scandium. This unit weighs only ~ 11 g more than the original design. By measuring the concentrations of the various products of nuclear reactions in these metals after space exposure, the characteristics of the incident cosmic particles can be determined.

A ^{210}Po concentration of $(2.58 \pm 0.41) \cdot 10^{-4} \text{ d/m/cm}^2$ has been measured in a blank foil of the Solar Wind Composition experiment material exposed to the lunar atmosphere during the Apollo 12 landing. Analysis of the actual exposed foil is proceeding. A net increase in ^{210}Po activity, attributable to lunar exposure, can be correlated with the radon concentration of the lunar atmosphere. (At time of writing a real net activity attributable to lunar radon has been observed - the first such measurement of lunar atmosphere.)

The text of a paper entitled, "The Measurement of Radiation Exposure of Astronauts by Radiochemical Techniques" is included as an appendix.

TASK - DETERMINATION OF THE RADIONUCLIDE CONTENT OF FECES AND URINE
FROM ASTRONAUTS ENGAGED IN SPACE FLIGHT

Astronauts engaged in space flight are subjected to cosmic radiation which induces radioactive isotopes in their bodies. The radiation dose received from cosmic particles can be determined from the quantities of these induced radionuclides.⁽¹⁾ The concentrations of the induced radioactivities can be determined by direct whole body counting of the astronaut or by indirect measurement, such as counting that fraction of the radionuclides excreted in the feces and urine. This latter approach was used for evaluation of radiation activation during the course of the Apollo 12 and 13 missions. In addition, some fallout and naturally occurring radioisotopes have been measured, and variations in their concentrations may serve as tracers of changes in the biological life processes occasioned by the space environment.

The concentrations of the radioisotopes listed in Tables I and II have been normalized by dividing the decay corrected disintegration rate by the weight of the respective stable element in the sample determined by a technique of instrumental neutron activation analysis.⁽²⁻⁴⁾ The specific activities for urine specimens should be very nearly the same as those present in the astronaut's body at the time of sampling since all elements excreted in the urine must have been previously metabolized. The data for feces is not quite so clear cut, however, since the quantities of inert elements excreted can be perturbed by unmetabolized elements passing through the gastrointestinal tract or by external addition, as is the case with the sodium salt bactericide. This more precise method of normalizing the data does not change any of the original conclusions^(4, 5) regarding assignment and identification of samples, anomalously high and low

concentrations of radionuclides, and cosmic radiation dose.

A paper entitled, "The Measurement of Radiation Exposure of Astronauts by Radiochemical Techniques," which is based on the measurements of the quantities of the cosmogenic radionuclides found in the feces and urine of the Apollo 7 through 13 astronauts, was presented on March 1, 1971 at the National Symposium on Natural and Manmade Radiations in Space. The text of this paper, which will be published in the proceedings of this symposium, is reproduced in Appendix A of this report.

TASK - NEUTRON ACTIVATION ANALYSIS OF FECES AND URINE FROM ASTRONAUTS ENGAGED IN SPACE FLIGHT ---

This program has been instituted in an attempt to foresee any possible metabolic changes in astronauts caused by conditions of weightlessness and prolonged physical inactivity which are manifested by an uptake or loss of an element or elements by their bodies. The primary concern is the terrestrially observed phenomenon of osteoporosis (loss of skeletal calcium), although changes in the uptake and excretion rates of other essential microconstituents of the body, such as cobalt, iron, selenium, and the alkali metals, are also important.

A previously described technique of instrumental neutron activation analysis (1, 2, 4) was used to determine the concentrations of Ca, Na, K, Rb, Cs, Fe, Co, Zn, Cr, Sc, Br, Se, Hg, Ag, Sb, Au, Sn, As, Eu, Tb, Th, Hf, and Ta in the returned Apollo 12 and 13 fecal samples. These concentrations are reported in Tables III through VI.

Calcium and the Alkali Metals

The functional responsibility and biological importance of calcium and the alkali metals in the body is well known and has been discussed previously⁽⁴⁾. The fecal excretion rates of these elements are calculated from the data in Table III by dividing the total weight of each element by the number of man days of the mission.

Calcium fecal excretion rates of 0.302 and 0.39 g/man day for the Apollo 12 and 13 missions respectively are significantly lower than the rates observed for previous missions⁽⁴⁾. These low excretion rates indicate a negligible body calcium loss for these astronauts if they are ingesting a reasonable amount of calcium in their food (such as that ingested on the earlier manned Apollo missions).

Sodium fecal excretion rates of 58 and 78 mg/man day for the Apollo 12 and 13 missions seem to indicate that the specimens were not contaminated with a sodium salt bactericide. Assuming 2.76% of the excreted sodium is in the feces,⁽⁶⁾ total loss rates of 2.1 and 2.8 g/man day are calculated which are similar to other determinations obtained for astronauts⁽⁴⁾ and to normal dietary intakes⁽⁶⁾.

The respective potassium fecal excretion rates are 250 and 304 mg/man day for the Apollo 12 and 13 astronauts. A potassium fecal excretion of 16.5%⁽⁶⁾ leads to a total loss of 1.5 and 1.84 g/man day which is similar to intake and excretion values obtained for earlier missions⁽⁷⁾.

Rubidium fecal excretion rates of 379 and 667 μ g/man day become total body excretion rates of 1.65 and 2.90 mg/man day when divided by a 23%⁽⁸⁾ fecal excretion. These values compare favorably with a normal daily intake of 2.53 mg^(6, 9)

The cesium fecal excretion rates are 0.945 and 1.16 μ g/man day for the Apollo 12 and 13 missions respectively. These are the lowest values yet observed for manned Apollo missions^(3, 4)

Elemental Groups IB, IIB, VIA, and VIII

The physiological functions of the metals located in the center of the periodic table have been discussed in an earlier report⁽⁴⁾. While not all of these elements have known uses in the body, some have suspected essential properties and others are known to be toxic. The concentrations of the elements of this group which were measured are given in Table IV.

The chromium fecal excretion rates observed for Apollo 12 and 13 are 28.9 and 43.8 μ g/man day respectively. These values are also the lowest yet observed^(3, 4) and are considerably less than a normal intake of 150 μ g/day⁽⁹⁾. This may be a reflection of dietary intake.

Iron fecal excretion rates for these latter two missions are 5.26 and 7.90 mg/man day. These values are in accord with the intake values for previous missions and indicate that the large loss of body iron observed for the Apollo 7 through 11 missions⁽⁷⁾ has apparently been curtailed.

The measured cobalt fecal excretion rates are 4.79 and 6.25 $\mu\text{g}/\text{man day}$ for the Apollo 12 and 13 missions. These values are much lower than rates observed for earlier missions⁽⁴⁾ and are more nearly that which would be expected from normal dietary intake values^(6, 9). Intake values and urinary excretion rates should be checked to adequately evaluate the gain or loss of this element.

Silver fecal excretion rates of 17.7 and 12.6 $\mu\text{g}/\text{man day}$ are calculated for the Apollo 12 and 13 missions and are the lowest values yet observed.

Respective gold losses are 165 and 21.7 $\mu\text{g}/\text{man day}$. The large difference between the two missions and the extremely high concentrations of gold in the three samples listed in Table IV as the Command Module Pilot, indicate the presence of this element in the astronauts' bodies is largely a very individual matter.

Zinc fecal excretion rates of 3.70 and 8.33 $\mu\text{g}/\text{man day}$ for Apollo 12 and 13 astronauts respectively are the lowest values yet observed⁽²⁻⁴⁾ although 8.33 $\mu\text{g}/\text{day}$ is still within the expected range based on normal dietary intakes.

Elimination rates for mercury are calculated to be 13.7 and 21.3 $\mu\text{g}/\text{man day}$ for these two missions which are comparable to normal dietary intakes. These mercury elimination rates are lower than previously observed rates^(3, 4) by factors of 2-12.

Elemental Groups IV B, V B, VI B, and VII B

The body chemistry and/or toxic properties of these elements from the right side of the periodic chart has also been discussed elsewhere⁽⁴⁾. The concentrations and total weights of the measured elements in this category are given in Table V.

The tin fecal excretion rates are 1.41 and 16.2 mg/man day respectively for the Apollo 12 and 13 missions. These values are about three orders of magnitude higher than those reported for previous missions^(3, 4) and are more compatible with normal dietary intakes of 17 to 22 mg/day^(6, 9). Discovery of a procedural error indicates that previously reported values of tin concentrations are incorrect. Corrected values will be given in a later report.

Arsenic has not been previously reported. However, the Apollo 12 and 13 mission fecal excretion rates are calculated to be <27 μ g/man day and 2.85-13 μ g/man day respectively. These values are considerably lower than the reported normal value of 2.3 mg/day⁽⁶⁾.

Calculated antimony fecal excretion rates of 11.0 and 8.28 μ g/man day for the Apollo 12 and 13 missions respectively are very similar to those observed on previous missions^(3, 4). One specimen (Apollo 12 CMP 225 hrs.) has an unprecedented high concentration of antimony.

Selenium fecal excretion rates of 14.7 and 20.4 μ g/man day for the latter two missions are the lowest ever observed, but the significance of this fact is uncertain.

Fecal excretion of bromine, a minor path of elimination for this element, proceeded at the rate of 304 and 66.8 μ g/man day for the Apollo 12 and 13 missions respectively. These rates are comparable to those previously observed^(3, 4). Three samples from the Apollo 12 mission have unusually high

bromine concentrations, and this circumstance may be sufficient to fingerprint the unlabeled specimen as coming from the LMP.

The Lanthanides, Actinides, and Groups III A, IV A, and V A

While the metabolic functions of these elements are not yet known, the data are reported in the hopes that they will prove useful in the future. Perhaps the concentrations and ratios of concentrations of these elements would be useful in the identification of samples. Of the elements reported in Table VI, only scandium has appeared previously. The fecal excretion rates calculated for the Apollo 12 and 13 missions for this element are 446 and 409 ng/man day, which are only slightly lower than previously observed values⁽⁴⁾. Normal daily intakes or excretion rates are not known for any of these reported elements. The measured fecal excretion rates are 136 and 128 ng europium/man day, (105-350) and (136-380) ng terbium/man day, 1.94 and (1.05-1.2) μ g thorium/man day, 1.37 and 1.75 μ g hafnium/man day, and 1.16 and 1.33 μ g tantalum/man day.

Summary

The concentrations of 23 elements were measured in the fecal samples collected during the Apollo 12 and 13 missions. Most elemental excretion rates are comparable to those reported for earlier missions and with expected excretion rates based on normal dietary intakes where known. Major differences are observed in these latter two missions for calcium, iron, and tin. The excretion rate of calcium is lower than previously observed, and any body calcium loss is expected to be even less significant than it was for the earlier missions. The excretion of iron is greatly reduced in the Apollo 12 and 13 specimens to the point where loss of body iron by astronauts may no longer be a concern. The tin excretion rates reported for the latter missions

are about three orders of magnitude higher than reported for the earlier missions. The higher values are more nearly those expected on the basis of normal dietary intake, and the lower values reported earlier are felt to be incorrect due to a procedural error. There is a possibility that not all inflight fecal specimens from the Apollo 12 mission were returned since some could' have been jettisoned with the lunar excursion module. If this were the case, the actual excretion rates for this mission would be higher than those reported by an amount which would be dependent on the quantity of specimens jettisoned. Due to the similarity of the reported excretion rates for this mission with other Apollo missions, it is likely that all samples were indeed returned.

TASK - INDUCED RADIONUCLIDES IN SPACECRAFT

In order to more accurately determine the cosmic-ray flux and energy spectrum incident on astronauts during space flight, which is responsible for and relatable to the radiation dose received by them, an assembly of pure monitor foils has been developed. When these pure metals are exposed to the cosmic particle flux, various nuclear reactions will take place which are representative of the target element and the quantity and energy of incident particles. By measuring the concentrations of the various products and knowing the probability (cross section) for each observed reaction, the number and energy of incident particles can be calculated.

The assembly of metal foils was incorporated into the passive dosimetry cannister. A new cannister was designed with positive sealing screw caps and a thin (0.0075") side wall to reduce the attenuation of cosmic particles entering the can. The can was then lined with concentric sleeves of 0.003" tantalum, 0.001" copper, 0.001" titanium, 0.002" iron and 0.003" cobalt side by side as a single sleeve, and 0.004" aluminum foils. The standard dosimeter cluster, with the addition of about a 1/2" length of 0.020" diameter scandium wire sealed in glass, completes the cannister assembly. The entire unit only weighs ~11 g (7%) more than the original system. An exploded view of the new design is shown in Figure 1. The tantalum, copper, titanium, iron, and aluminum foils are intended as proton flux monitors, and the excitation functions for the production of many of the spallation products anticipated to be present in these foils after space exposure are well known. The cobalt foil and the scandium wire are intended as thermal and epithermal neutron monitors since the capture cross sections and decay characteristics of the products are ideally suited for measurement after extended space missions.

TASK - SEARCH FOR LUNAR ATMOSPHERE

Radon decay product analysis of the Solar Wind Composition (SWC) foils exposed to the lunar atmosphere by the Apollo 12 astronauts is presently in progress. The radon atoms present in the lunar atmosphere from the decay of surface uranium should embed themselves in the SWC foil and, through several rapid radioactive decays, be transformed into long-lived ^{210}Pb . By measuring the concentration of ^{210}Po (granddaughter of ^{210}Pb) in the returned SWC foils, it should be possible to characterize the radon concentration in the lunar atmosphere and, therefore, the uranium concentration in the lunar soil.

In order to obtain maximum sensitivity, a new low level Ortec 325S alpha counting system is being calibrated for the determination of ^{210}Po . The system has an absolute efficiency of 31.3% for this isotope and a background of 0.0002 counts per minute. The ^{210}Po in the SWC foils is separated by dissolution of the foil and autoplating onto a silver disc which is then counted. The silver disc and the reagents used in the process contribute a negligible amount to the measured ^{210}Po activity. Blank SWC foil G 30-11 (0.2118g, 53.24 cm^2) has been processed, and an activity of $(2.58 \pm 0.41) \cdot 10^{-4} \text{d/m/cm}^2$ was observed. This can be compared to a ^{210}Po activity of $(2.9-6.6) \cdot 10^{-4} \text{d/m/cm}^2$ observed previously in a similar blank foil measured on a less sensitive counting system. The Apollo 12 SWC foil exposed to the lunar atmosphere, G 17-7-6-7, will be analyzed for ^{210}Po content in the near future.

EXPENDITURES

The following table documents the expenditures according to task and total cost incurred from January 4, 1971 through April 4, 1971 for the work reported herein.

<u>TASK</u>	<u>EXPENDITURES</u>
Determination of the Radionuclide Content of Feces and Urine From Astronauts Engaged in Space Flight	\$ 4,062

APPENDIX A

THE MEASUREMENT OF RADIATION EXPOSURE OF
ASTRONAUTS BY RADIOCHEMICAL TECHNIQUES

R. L. Brodzinski
Battelle Memorial Institute, Pacific Northwest Laboratories
P. O. Box 999
Richland, Washington 99352

ABSTRACT

The principal gamma-ray-emitting radioisotopes produced in the body of astronauts by cosmic-ray bombardment which have half-lives long enough to be useful for radiation dose evaluation are ^7Be , ^{22}Na , and ^{24}Na . The sodium isotopes were measured in the preflight and postflight urine and feces, and those feces specimens collected during the manned Apollo missions, by analysis of the urine salts and the raw feces in large crystal multidimensional gamma-ray spectrometers. The ^7Be was chemically separated, and its concentration measured in an all NaI(Tl), anticoincidence shielded, scintillation well crystal.

The overall sensitivity of the experiment was reduced by almost all variables such as low concentrations of excreted cosmogenic radionuclides, high concentrations of injected radionuclides, low sample sizes, long delay periods before analysis, and uncertain excretion rates. The astronaut radiation dose in millirads, as determined by this technique, for the Apollo 7, 8, 9, 10, 11, 12, and 13 missions was 330, 160, <315, 870 ± 550 , 31, 110, and <250 respectively. In view of these limitations this technique would be best applied to cases of unusually high exposures, such as that encountered from solar flares.

INTRODUCTION

With the advent of space flight, it has become necessary to determine the radiation dose to man from exposure to the galactic, Van Allen, and solar flare particles. The high-energy galactic portion of the spectrum is fairly constant and has a relatively low intensity. The high intensity Van Allen radiation is of medium energy and localized in space. However, the solar radiation is not so predictable, and the flux and energy of particles from the sun can vary tremendously depending on solar activity. Since high levels of radiation exposure are possible, radiation dosimetry which will properly define radiation exposures is essential in space research programs. Dosimetry methods employed thus far, such as nuclear emulsion films, thermoluminescent dosimeters, and ionization gauges provide very useful indirect methods for estimating radiation dose but are subject to limitations. They measure only a surface exposure at a specific point(s) in the spacecraft or on the astronaut's body rather than an integral whole body exposure, and they have a limited sensitivity to large variations in particle energy. Some of the inherent limitations of these external dosimeters are avoided by using the induced radioactivity in the body of an astronaut as a measure of his radiation exposure. During a space flight, radionuclides are produced throughout the entire body of an astronaut, and the production rates are related directly to the cosmic particle flux within the body. The absolute and relative amounts of the various radionuclides bear a direct relationship to the intensity and energy spectrum of the particles which are doing the biological damage.

The radiation dose received from the cosmic particles can be determined from the quantities of induced radionuclides⁽¹⁻⁴⁾. The amounts of these induced activities can be determined by direct measurement, i.e., whole body counting of the astronaut, or by indirect measurement, such as counting the

radionuclides excreted in the feces and urine. The latter approach was used for evaluation of radiation activation during the course of the manned Apollo missions.

The principal gamma-ray-emitting radioisotopes produced in the body by cosmic-ray bombardment are ^7Be ($t_{1/2} = 53$ day), ^{11}C ($t_{1/2} = 20.5$ min), ^{13}N ($t_{1/2} = 9.96$ min), ^{22}Na ($t_{1/2} = 2.60$ yr), and ^{24}Na ($t_{1/2} = 15.0$ hr). The primary mode of production of ^7Be and ^{11}C is the spallation of carbon, nitrogen, and oxygen in the body. The ^{13}N comes principally from the spallation of nitrogen and oxygen, the ^{22}Na from the spallation of sodium, phosphorus, and calcium, and the ^{24}Na from the neutron activation of natural sodium. Of these, ^{11}C and ^{13}N are too short-lived to be measured by any method other than a direct determination, and this direct counting would have to be done as soon as possible after recovery. This is unfortunate, since these radioisotopes are produced in the largest abundance. The radionuclides ^7Be , ^{22}Na , and ^{24}Na are, however, sufficiently long-lived to facilitate their use in making dose estimates from measurement of their quantities in urine and fecal samples.

Other radioisotopes were also expected to be present in the bioassay samples. In addition to the aforementioned cosmogenic radionuclides, measurements of naturally present ^{40}K ; normally occurring ^7Be , ^{22}Na , and ^{137}Cs ; and ^{51}Cr and ^{59}Fe which were injected for medical studies were also made. Another radioisotope, ^{60}Co , was detected and quantitatively measured in some of the specimens. Corrections to the cosmogenic ^7Be and ^{22}Na must be made to account for the quantities of these radioisotopes normally occurring in the body because of fallout, food intake, and other ingestion processes. The quantities of the naturally occurring ^{40}K and the injected ^{51}Cr and ^{59}Fe in the bioassay samples could serve as biological tracers of various changes of metabolic processes during the course of a mission.

In previous studies, induced radioactivity to radiation dose relationships have been established for the radionuclides ^7Be , ^{22}Na , and ^{24}Na as a function of energy for proton bombardment of muscle tissue⁽²⁾. From these relationships and from the ratios in which these radionuclides are produced, the "effective proton energy" of cosmic radiation incident on an astronaut can be determined. This allows the direct estimation of the whole body radiation exposure received by astronauts from measurements of the radionuclides produced in their bodies.

EXPERIMENTAL

Preflight and postflight urine and feces and those feces specimens collected in flight were analyzed. Due to the quarantine period following lunar landing missions, all samples were not immediately available for analyses, thus allowing the short-lived radionuclides to decay. The urine specimens which were of small volume were solidified prior to analysis by the addition of CaSO_4 to 25 ml or less of the raw urine in order to form a standard counting geometry. Any samples of initial volume greater than 25 ml were treated by repeatedly boiling to dryness with nitric acid to destroy the organic matter present. The remaining salts were counted in large crystal multidimensional gamma-ray spectrometers⁽⁵⁻⁷⁾ for determination of ^{22}Na , ^{24}Na , ^{40}K , ^{51}Cr , ^{59}Fe , ^{60}Co , and ^{137}Cs . The salts were then redissolved in a weak HCl solution and diluted to known volume. An aliquot of this solution was taken for neutron activation analysis to determine the concentrations of stable elements in the sample. The remainder of the solution was reduced in volume to approximately 15 ml and transferred to a 100 ml polyethylene centrifuge tube. Approximately 5 mg of Be^{++} carrier and 20 mg of Fe^{+++} carrier were added, and the solution was neutralized with concentrated NH_4OH . After centrifugation the supernatant solution was discarded. Thirty-five ml of 3 N NaOH were added to the remaining precipitate and stirred vigorously until well mixed. After centrifugation the

supernatant liquid was transferred to a clear centrifuge tube, saturated with NH_4Cl , and heated in a water bath. If necessary, additional NH_4Cl was added until a $\text{Be}(\text{OH})_2$ precipitate settled from the solution. The solution was then centrifuged, and the supernatant fraction was discarded. The resulting quantitative precipitate containing the ^7Be activity was counted in an all NaI(Tl) anticoincidence shielded, 7-inch diameter scintillation well crystal in the absence of all interfering activities. This was necessary in order to measure the relatively small quantities of ^7Be present.

Fecal samples were thoroughly mixed in their collection bags to ensure homogeneity of the specimens. A small corner was cut off each bag and aliquots were extruded into standard counting geometry containers for measurements on multidimensional gamma-ray spectrometers of the radioisotopes ^{22}Na , ^{40}K , ^{51}Cr , ^{59}Fe , ^{60}Co , and ^{137}Cs . Separate aliquots were wet ashed with nitric acid and hydrogen peroxide to destroy the organic matter present. The resulting salts were dissolved in dilute nitric acid, and the same procedure as above was followed for separation of the ^7Be activity.

A luminous material composed of ^{147}Pm microspheres mixed with a scintillator is used extensively in the spacecraft in acrylic switch tips and sighting figures used in docking maneuvers. Because of the high rejection rate of switch tips caused by promethium leaks, there is some concern about the possible presence of ^{147}Pm in the weightless space capsule environment. For the later missions, approximately 10 mg of mixed rare earths were added to the feces prior to wet ashing. These were to serve as carriers for ^{147}Pm , which could possibly have been ingested by the crew members. This rare earth fraction was separated from the beryllium fraction after the initial NH_4OH precipitation by dissolving the precipitate in approximately 8 ml of 3M HCl and adding 2 ml of 49 percent HF . Centrifugation separated the rare earth

precipitate from the beryllium in the supernatant solution. The rare earth fraction was then dissolved in two parts concentrated HNO_3 and three parts saturated boric acid solution and reprecipitated with NH_4OH . After centrifugation and decantation, the precipitate was dissolved in dilute HCl ; and saturated oxalic acid solution was added to precipitate the rare earth oxalates. The solution was centrifuged; the supernatant solution was decanted; and the quantitative precipitate was washed with alcohol, transferred to a 1-inch diameter stainless steel dish and counted in an end window, gas flow beta counter for the measurement of ^{147}Pm .

RESULTS

The results of the individual determinations are given in Tables I through IV. All data have been normalized to a gram of feces, a milliliter of urine, or a gram of the respective stable element as determined by a technique of instrumental neutron activation analysis⁽⁸⁾. All data have been decay corrected to the time of splashdown of each respective mission. The results of all the radionuclide measurements in the excreta are given in the tables although only the concentrations of the cosmogenic radionuclides ^7Be , ^{22}Na , and ^{24}Na are of importance for the subject matter of this communication. The various samples in the tables are listed by the letters A, B, and C or LMP, CMP, and CDR to identify an individual astronaut. Those samples listed by numbers are unidentified and arbitrarily coded. The collection time for each specimen is given as Pre-, In-, or Post-flight unless more detail is known, in which case a number refers to elapsed time into the mission in hours, the letter F followed by a number indicates that number of days prior to flight, Post+0 refers to the first voiding after splashdown, Post+1 is the first 24 hour collection after splashdown and Day 2 is the following day after splashdown.

The average values of the cosmogenic radionuclide concentrations in each basic flight period are summarized in Table V according to the various methods of normalization. The increase in the activities from preflight to inflight and postflight periods should be indicative of the exposure to cosmic radiation. The concentrations of each radionuclide increase rather regularly for the Apollo 7 mission regardless of the method of normalization. However, the fecal data for the Apollo 8 mission are quite irregular, with only the urine data demonstrating increases in the cosmogenic radionuclides. The Apollo 9 and 13 missions show increases in the ^7Be concentration in the urine but demonstrate decreases in the ^{22}Na concentrations while the reverse is true for Apollo 11. Regular increases are shown for Apollo 10 and 12.

The increases in cosmogenic radioactivity from preflight levels to those after exposure to the space environment are almost certainly due to cosmic particle activation. Equating the magnitude of the increase with the radiation dose delivered by the particles is still fairly difficult, particularly when the dose is quite small as has been the case on all manned Apollo missions thus far. Concentrations normalized to the unit mass or volume of excreta are subject to variation in the biological dilution of the specimen. Concentrations normalized to the unit mass of stable element in the feces are also subject to variations in the quantities of unmetabolized elements passing through the gastrointestinal tract. Only the quantities of radionuclides in the urine normalized to the amount of stable element present can be expected to be reasonably representative of the specific activity in the whole body since the urine contains only metabolized material.

Indeed, it is necessary to make some assumptions regarding the percentages of the body burden of an element excreted in the feces or urine, the relative dilution factors of feces and urine, and the "contamination" of feces by unmetabolized elements in order to compare the data with the experimental

results for proton irradiated muscle tissue^(1, 2), proton irradiated radiotherapy patients⁽³⁾, and neutron irradiated radiotherapy patients⁽⁴⁾. In this manner, the average effective proton energy incident on the astronauts and the radiation dose received by them can be estimated. The details of these calculations will be omitted here since they are given elsewhere⁽⁹⁻¹²⁾. The results indicate an average effective proton energy of 38-40 MeV incident on the Apollo 7 mission astronauts and <38 MeV on the Apollo 8 mission astronauts. Radiation doses of 480 + 310, <315, 870 + 550, <480, and <250 millirads for the Apollo 7, 9, 10, 12, and 13 missions respectively are calculated.

Since the specific activity of the cosmogenic radionuclides in the urine should be a more accurate representation of the whole body burden of induced radioactivity, the specific activity of the ^{22}Na in the postflight urine of astronauts is compared to the specific activity of ^{22}Na in the urine of radiotherapy patients who have received a known radiation dose. This comparison leads to estimated cosmic radiation doses received by the astronauts on the Apollo 7, 8, 11, and 12 missions of 330, 160, 31, and 110 millirads respectively. It should be pointed out here that the uncertainty of the data given in Table V, and hence of these results, is quite large in some instances.

DISCUSSION

In principle the relationships between induced activity and radiation dose are straightforward. The probability for production of a certain isotope in the body of an astronaut is basically a function of the energy of the proton. Similarly, the radiation dose from a cosmic proton is also a function of its energy, and therefore, the induced activity is logically related to the radiation dose. Such relationships have been empirically determined for several different situations⁽¹⁻⁴⁾, and it remains only to measure the quantities of induced radionuclides in a particle irradiated person to determine the dose he received.

In practice, however, the procedure is not quite as simple as that just described. A calibrated whole-body counter is required to determine the quantities of induced radionuclides, and a high sensitivity-low background instrument would be required to measure the small quantities of radionuclides induced by the low levels of cosmic radiation encountered on a normal space flight. In lieu of the availability of a suitable whole-body counter, an indirect approach such as that used in this work can be applied. The principal limitations to this method have already been touched upon above. Only a small and uncertain fraction of the induced activity is eliminated in the excreta. Thus only the specific activity of an induced radioisotope in the urine can be extrapolated to the whole body burden with a reasonable degree of accuracy.

While the efficiency of low-level sample counters is routinely several orders of magnitude higher than whole-body counters, the small fraction of the total body activity in any bioassay sample reduces the sensitivity of a specimen measurement to the point where it is little better than that of a whole-body count. To complicate the situation in this work even further, there is a large demand for aliquots of post-flight urine specimens from the astronauts and typically only 10% or less of a 24-hour collection has been available for radionuclide concentration measurements. An additional complication in the case of non-lunar-landing missions (Apollo 13 excepted) was the injection of radioisotopes into the astronauts for medical studies. Although these isotopes were not the same as the cosmogenic radionuclides measured, their presence in the excreta lowered the overall accuracy of the measurements. Finally, the quarantine requirements of the lunar landing missions caused a delay in the analysis of postflight specimens which allowed substantial decay of the radionuclides present. These factors all contribute

to the reduced accuracy and sensitivity of the measurements reported herein. In an effort to improve the situation, a high sensitivity combination whole-body counter and sample counter has been proposed which could be rapidly utilized after a mission (even onboard the recovery vessel) to make accurate measurements of the whole body burden of radionuclides in the astronauts. The combination of direct measurement of whole body burdens of radionuclides and the early measurement of relatively large quantities of excreta should make much more accurate dose estimates possible.

This technique for measurement of radiation dose should be perfected during routine space missions so that in the event of an unusually high exposure, such as might be expected from a solar flare, an accurate determination of the radiation dose can be obtained. This situation would be analogous to those nuclear criticality accidents⁽¹³⁻¹⁵⁾ where conventional dosimetry techniques were extended and induced radioactivity was measured to interpret the radiation dose received by the exposed individuals.
