**1.0 Delaware Basin Drilling Surveillance Program**
The Delaware Basin Drilling Surveillance Program (DBDSP) is designed to monitor drilling activities in the vicinity of the Waste Isolation Pilot Plant (WIPP). This program is based on Environmental Protection Agency (EPA) requirements. EPA requires the Department of Energy (DOE) to demonstrate the expected performance of the disposal system using a probabilistic risk assessment or performance assessment (PA). This PA must show that the expected repository performance will not release radioactive material above limits set by the EPA’s standard and must consider inadvertent drilling into the repository at some future time.

The EPA provided criteria in 40 CFR 194.33 to address the consideration of future deep and shallow drilling in PA. These criteria led to the formulation of conceptual models that incorporate the effects of these activities. These conceptual models use parameter values drawn from the databases in Appendix DEL of the Compliance Certification Application (CCA). Examples of information of interest include the drilling rate of deep and shallow boreholes and data relating to the physical properties of drill holes such as diameter.

The EPA defined in 40 CFR Part 194.2 the area to be used for the historical rate of drilling for resources. It reads in part:

Delaware Basin means those surface and subsurface features which lie inside the boundary formed to the north, east and west of the [WIPP] disposal system, by the innermost edge of the Capitan Reef, and formed, to the south, by a straight line drawn from the southeastern point of the Davis Mountains to the most southwestern point of the Glass Mountains.

The Delaware Basin, depicted in Figure 1, includes all or part of Brewster, Culberson, Jeff Davis, Loving, Pecos, Reeves, Ward, and Winkler Counties in West Texas, and portions of Eddy and Lea Counties in southeastern New Mexico.

In accordance with these criteria, the DOE used the historical rate of drilling for resources in the Delaware Basin to calculate a future drilling rate. In particular, in calculating the frequency of future deep drilling, 40 CFR 194.33(b)(3)(i) (EPA 1996) provided the following guidance to the DOE:

Identify deep drilling that has occurred for each resource in the Delaware Basin over the past 100 years prior to the time at which a compliance application is prepared.

The DOE used the historical record of deep drilling for resources below 2,150 feet that has occurred over the past 100 years in the Delaware Basin. This was chosen because it is the depth of the repository, and the repository is not directly breached by boreholes less than this depth. In the past 100 years, deep drilling occurred for oil, gas, potash, and sulfur. These drilling events were used in calculating a rate for deep drilling for PA as discussed in Appendix DEL of the CCA. Historical drilling for purposes other than resource exploration and recovery (such as WIPP Site investigation) were excluded from the calculation in accordance with guidance provided in 40 CFR 194.33.
In calculating the frequency of future shallow drilling, 40 CFR 194.33(b)(4)(i) states that the DOE should:

Identify shallow drilling that has occurred for each resource in the Delaware Basin over the past 100 years prior to the time at which a compliance application is prepared.

An additional criterion for calculation of future shallow drilling rates is provided in 40 CFR 194.33(b)(4)(iii):

... in considering the historical rate of all shallow drilling, the Department may, if justified, consider only the historical rate of shallow drilling for resources of similar type and quality to those in the controlled area.

The only resources present at shallow depths (less than 2,150 feet below the surface) within the controlled area are water and potash. Thus, consistent with 40 CFR 194.33(b)(4), the DOE used the historical record of shallow drilling associated with water and potash extraction in the Delaware Basin to calculate the rate of shallow drilling within the controlled area. The controlled area is the 16 sections of land (16 square miles) within the WIPP Site boundary.
The EPA provides further criteria concerning the analysis of the consequences of future drilling events in performance assessments in 40 CFR 194.33(c)(EPA 1996). Consistent with these criteria, the following parameters regarding drilling were considered in the performance assessment as documented in Appendix DEL of the CCA:

- types of drilling fluids
- amounts of drilling fluids
- borehole depths
- borehole diameters
- borehole plugs
- fraction of each borehole that is plugged
- natural processes that will degrade borehole plugs
- instances of encountering pressurized brine in the Castile Formation

The DOE continues to provide surveillance of the drilling activity in the Delaware Basin in accordance with the criteria established in 40 CFR 194 during the operational phase and will continue until the DOE and the EPA agree no further benefit can be gained from continued surveillance. The results of this surveillance activity will be used to determine if a significant change has occurred that would be detrimental to the performance of the disposal system.

The Delaware Basin Drilling Surveillance Plan (WP 02-PC.02) places specific emphasis on the nine-township area that includes the WIPP Site and provides data to build on the data presented in Appendix DEL. The DBDSP supports the Compliance Monitoring Program, required by 40 CFR 191. Specifically, this program fulfills the Monitoring Assurance Requirement. Per the CCA, the DBDSP generated the data to assess the Compliance Monitoring Parameter (COMP) entitled Drilling Rate. The DBDSP is specifically defined in and authorized by the DOE Monitoring Implementation Plan (DOE/WIPP 99-3119). The output of the program is used to generate the Annual Compliance Monitoring Assessment Report (published by SNL) and is reported annually to EPA in the 40 CFR 194.4(b)(3) Report.

Surveillance of drilling activities within the Delaware Basin will continue after closure for 100 years or until the DOE can demonstrate to the EPA there are no significant concerns to be addressed by further surveillance (Section 7.1.4, DOE 1996b).
2.0 2001 Updates

PA is required by regulation to consider disturbed case scenarios that include intrusions into the repository by inadvertent and intermittent drilling for resources. The probability of these intrusions is based on a future drilling rate of 46.8 boreholes per square kilometer per 10,000 years. This rate is based on consideration of the past record of drilling events in the Delaware Basin. The DOE models multiple types of human intrusion scenarios in the PA. These include both single intrusion events and combinations of multiple boreholes.

Two different types of boreholes are considered: (1) those that penetrate a pressurized brine reservoir in the underlying Castile Formation and (2) those that do not. While the presence of pressurized brine under the repository is speculative, it cannot be completely ruled out based on available information. The primary consequence of contacting pressurized brine is the introduction of an additional source of brine beyond that which is assumed to be released to the repository from the Salado Formation. The human intrusion scenario models are based on extensive field data sets collected by the DOE. The DBDSP collects the drilling related data to be used for future PA calculations. The data have been collected from the time of the 1996 submittal of the CCA to the present and include specific wells drilled during the last year in the New Mexico portion of the Delaware Basin, specifically that of the nine-township area immediately surrounding the WIPP Site. These data are summarized in the following sections.

2.1 Drilling Techniques

The drilling techniques reported in Appendix DEL of the CCA are still being implemented by area drillers. There were a total of 105 wells spudded, not necessarily completed, in the New Mexico portion of the Delaware Basin from September 1, 2000 through August 23, 2001. This number is derived from the databases maintained by the DBDSP. In reality, the number of new wells is higher but the paperwork on some of the wells has not been filed with the State; therefore, the wells are not included in the count.

Rotary drilling rigs were used to drill all 105 wells. Some have been completed as oil wells, others as gas wells, while the rest are still in the process of being completed. All were conventionally drilled utilizing mud as a medium for circulation. Forty-one of these wells were in the nine-township area. The depths of the completed wells in the nine-township area range from 7,250 feet to 15,350 feet. Outside of the nine-township area the depths of the completed wells range from 3,092 feet to 17,296 feet.

A technique used by operators to increase production is to drill a well directionally or horizontally, which allows for more area of the wellbore to be in the production zone. As reported in Appendix DEL, this technique is not often used in this area because of the increased costs. The DBDSP monitors directional or horizontal drilled wells only in the nine-township area. Of the 41 new wells spudded in the last year in the nine-township area, none were directional or horizontal drilled wells. One well, spudded in 2000 and reported in last year’s report, was completed as a directionally drilled well. This well is located outside of the WIPP
Site but is drilled into a lease located on Section 31 underneath the WIPP Site.

2.1.1 Drilling Fluids

Employing a rotary rig for drilling involves the use of drilling fluids. Drilling fluid is commonly known as mud, which is the liquid circulated through the wellbore during rotary drilling and workover operations. In addition to its function of bringing cuttings to the surface, drilling mud cools and lubricates the bit and drill stem, protects against blowouts by holding back subsurface pressures, and deposits a mud cake on the wall of the borehole to prevent loss of fluids to the formation.

Typically, a driller will use fresh water and additives to drill the surface section of the hole which ends at the top of the Salado Formation. A change in drilling practices would necessitate a change in the application of drilling fluids. Within the Known Potash Lease Area (KPLA) of southeastern New Mexico, drillers are required under Title 19, Chapter 15, Order R-111-P of the New Mexico Administrative Code (NMAC) to use a saturated brine to drill through the salt formation which is usually called the intermediate section. This requirement is to keep the salt from washing out and making the hole larger than necessary and to protect the potash reserves that occur in this formation. Once this section has been drilled and cased, the driller again changes to fresh water and additives to finish drilling the hole to depth.

All the operators of new wells completed in the New Mexico portion of the Delaware Basin during the last year that reported mud weights listed weights of 8.4 to 10.0 pounds per gallon while drilling the intermediate portion of the wellbore. The operators completing wells in the nine-township area that reported mud weights used a solution of 8.6 to 10.0 pounds per gallon saturated brine for drilling the intermediate section of the well through the salt formation.

2.1.2 Air Drilling

A method of hydrocarbon drilling not emphasized in Appendix DEL is air drilling. As defined by the oil industry, air drilling is a method of rotary drilling using compressed air as the circulation medium. The conventional method of removing cuttings from the wellbore is to use a flow of water or drilling mud. In some cases, compressed air removes the cuttings with equal or greater efficiency. The rate of penetration is usually increased considerably when air drilling is used; however, a fundamental problem in air drilling is the penetration of formations containing water, since the entry of water into the system reduces the ability of the air to remove cuttings.

Critics noted the air drilling scenario was not included by DOE in the CCA and raised several issues: (1) air drilling technology is currently successfully used in the Delaware Basin, (2) air drilling is thought to be a viable drilling technology under the hydrological and geological conditions at the WIPP Site, and (3) air drilling could result in releases of radionuclides that are substantially greater than those considered by the DOE in the CCA. Much research on the issue of air drilling in the Delaware Basin has been done. It has been shown that although air drilling
is a common method of drilling wells it is not practiced in the vicinity of the WIPP Site because (1) it is against R-111-P regulations to drill with anything but saturated brine through the salt formation in the KPLA, (2) it is not economical to drill with air when a driller has to use saturated brine for the intermediate section, and (3) water is encountered prior to and after drilling the salt formation causing the driller to convert to a conventional system of drilling.

Additional information was provided to EPA Docket No. A-93-02, IV-G-7. In this information, the following was provided:

The well record search has continued and now includes information from the entire New Mexico portion of the Delaware Basin. Within the nine-townships surrounding the WIPP, the records showed no evidence of air drilling. One possible exception to this may be the Lincoln Federal #1. This well is said to have been air drilled due to a loss of circulation at a depth of 1290 feet, but this has not been verified. The records associated with the Lincoln Federal #1 do not contain any evidence of air drilling. Rather, this information is based on verbal communications with the operating and drilling companies involved with the well. Nonetheless, the Lincoln Federal #1 may have been drilled with air, although it was not a systematic use of the technology. Air drilling at this well was used from 2984’ to 4725’ merely as a mitigative attempt to continue drilling to the next casing transition depth. After this casing transition, mud drilling was used for the remainder of the hole.

The area of the expanded search contains 3,756 boreholes. Of these, 407 well files were unavailable for viewing (in process), therefore, 3,349 well files constitute the database. Among these wells, 11 instances of air drilling were found in which any portion of the borehole was drilled with air. Only 7 of these were drilled through the Salado Formation at the depth of the repository. This results in a frequency of 7/3349, or 0.0021. This value is conservative in that it includes the Lincoln Federal #1, and four other wells which were proposed to be drilled with air, but no subsequent verification of actual drilling exists in the records.

During the summer of 1999, another search of these same records was conducted as a follow up to the original research. This search of the records was performed by an independent third party and was used as a quality assurance check of the original search. The database consisted of 3,810 boreholes with only 12 records unavailable for viewing. This search added five more wells with indications of some portion of the hole being drilled with air. None were air drilled through the Salado Formation or were located in the nine-township area. Of the five wells added to the count, one had the first 358 feet air drilled while the other four had the conductor pipe drilled with air which consists of the first 40 feet of the borehole and is not usually reported in the drilling process. The conductor casing is typically drilled, set in place, and cemented prior to setting up the rotary drilling rig that will eventually drill the well.

The records on the new wells spudded during the last year (September 1, 2000 thru August 23, 2001) are being checked as they become available at the New Mexico Oil Conservation Division (NMOCID) for instances of air drilling. The records submitted to the NMOCID offices can be as late as two years after the well has been drilled. The record review is an ongoing process that is conducted on a continuous basis. None of the records reviewed to date have indicated any instances of air drilling. As was presented in the testimony (public hearings conducted by the EPA on WIPP certification) and continues to be validated by ongoing review, air drilling is not a
common practice in the vicinity of the WIPP Site.

2.2 Shallow Drilling Events

One of the requirements of 40 CFR Part 194 is that the CCA must adequately and accurately characterize the frequency of shallow drilling within the Delaware Basin, as well as, support the assumptions and determinations, particularly those that limit consideration of shallow drilling events based on the presence of resources of similar type and quantity found in the controlled area. The DOE concluded in Appendix SCR that shallow drilling could be removed from PA consideration based on low consequence. As a result, the DOE did not include shallow drilling in its PA drilling rate calculations and did not include any reduction in shallow drilling rates during the active and passive institutional control periods. In CARD (Compliance Application Review Document) 32, the EPA accepted the DOE’s finding that shallow drilling would not be of consequence to repository performance and need not be included in the PA.

Although the EPA has agreed shallow drilling can be eliminated from PA and need not be tracked, the DBDSP collects data on all wells drilled within the boundaries of the Delaware Basin. The program makes no distinctions between shallow and deep drilling events except when calculating the intrusion rate for deep drilling. Information on all wells drilled is vital for trending future activities.

2.3 Deep Drilling Events

In the Delaware Basin, deep drilling events are usually associated with oil and gas drilling. Commercial sources and visits to the NMOCD offices are used to identify these events. The DBDSP collects data on all drilled wells within the Delaware Basin, making no distinction between resources. Two separate databases are maintained on hydrocarbon wells, one for Texas and one for New Mexico. As information on wells is acquired, it is entered into the individual databases. The Texas database contains information only on the current status of the well, when it was drilled, its location, who the operator is, and the total depth of the well. The Texas portion of the Delaware Basin is used only for calculating the drilling rate. The database for the New Mexico portion of the Delaware Basin contains the same basic information as Texas along with all the information required for PA related drilling events.

The DBDSP continues to monitor all hydrocarbon drilling activity and any new potash, sulfur, water, or monitoring wells for deep drilling events. Information from the drilling of these wells is added to the databases maintained for these separate resources. During the last year, there were 273 new wells added to the different databases. 271 wells were drilled for hydrocarbon extraction and all but three were deep drilling events. Forty-one of these new wells were in the nine-township area immediately surrounding the WIPP Site. Of the two wells not drilled for hydrocarbon extraction, both were located on the WIPP Site. One well is a Culebra water monitoring well to replace a plugged and abandoned monitoring well. The other is a shallow hole to monitor the water movement in the vicinity of the shafts in the central area of the WIPP Site.
2.4 Past Drilling Rates

The EPA provided a formula for calculating the current drilling rate or intrusion rate when 40 CFR Part 194 was promulgated. The formula is as follows: number of holes times 10,000 years divided by the area of the Delaware Basin (23, 102.1 Sq. Km.) divided by 100 years (1896-1996, the year the CCA was submitted). This formula is used to calculate both shallow and deep drilling rates for each resource. Since shallow drilling events are of no consequence, only deep drilling events are applied to the formula. The DBDSP uses all deep drilling events of any resource (potash, oil, gas, water, etc.) to calculate the drilling or intrusion rate. Including resources other than hydrocarbon will not affect the product of the formula due to the high number of deep drilling events recorded over the last 100 years in the Delaware Basin.

</tbody>
</table>

Figure 2 shows the past drilling rates since the submittal of the CCA in 1996. The large increase between 1996 and 1997 is the result of updating the databases with information from June 1995 through August 1997. Also, the 100-year window is considered a sliding window, i.e., 100 years worth of data will be used in the calculation. As each new year’s data is added, the oldest year’s data will be dropped. For example, the drilling rate was calculated in 1999 by using the data from 1899 through 1999.

2.5 Current Drilling Rate

Figure 3 shows the calculated intrusion or drilling rate for 2001. There were 17,920 resource holes within the Delaware Basin. Of those, 12,056 were deeper than 2,150 feet. Applying the formula results in the following: 12,056 boreholes x 10,000 years / 23,102.1 square kilometers / 100 years. This results in a drilling or intrusion rate of 52.2 boreholes per square kilometer over 10,000 years.

The intrusion rate has risen from 46.8 holes per square kilometer to 52.2 holes per square kilometer since 1996 and will continue to climb because of the method of calculation. Since the first well drilled in the area occurred in 1911, it will be 2011 before one well is dropped and 2014 before a second well is dropped from the count. In the meantime, numerous wells will have been added thus driving up the count. Figure 4 depicts the true state of the drilling rate.
Petroleum exploration activity is directly related to the price of crude oil and gas. Figure 4 shows the number of wells drilled per year for the last 22 years in the Delaware Basin and the average price per barrel of domestic crude oil.

2.5.1 Nine-Township Area Drilling Activities

From Sep 1, 2000 through Aug 23, 2001, there were 41 new wells spudded in the nine-township area immediately surrounding the WIPP Site. Three of these 41 wells were located within the one-mile buffer area of the WIPP Site. All three wells were located in Section One, Township 23 South, Range 30 East, southwest of the WIPP Site. One well, spudded in July 2000, completed this fiscal year, located in T22S-R30E-Sec 36, was directionally drilled under the WIPP Site into Sec 31. The leases on Sec 31 start at 6,000 feet below the surface and are held by several different oil companies. This is the second well to be drilled into this section of land, the other well was drilled in the 1970s and is currently a gas producing well. Figure 5 shows the status of all known hydrocarbon wells drilled within the one-mile buffer area of the WIPP Site.

2.6 Pressurized Brine Encounters

WIPP PA included the assumption that a borehole results in the establishment of a flow path between the repository and a pressurized brine pocket that might be located beneath the
repository in the Castile Formation. Research was performed in an attempt to verify this assumption. Studies recorded a total of 27 encounters with pressurized brine in the Castile Formation. Of these, 25 were hydrocarbon wells scattered over a wide area in the vicinity of the WIPP Site. Two wells, ERDA 6 and WIPP 12, were drilled in support of WIPP Site characterization.

As indicated earlier, the independent search of the records performed in 1999 for instances of air drilling also looked for instances of pressurized brine. Although the search of the records noted a number of instances of encounters with sulfur water and brine water, none but the original 27 were found to have been pressurized brine encounters in the Castile Formation.

The DBDSP researches the well files of all new wells drilled in the New Mexico portion of the Delaware Basin each year looking for instances of encounters with pressurized brine. The program also sends out an annual survey to operators of new wells asking if they encountered pressurized brine during the drilling process. As of this report, none of the records reviewed indicated encounters with pressurized brine during the drilling process on new wells spudded in the New Mexico portion of the Delaware Basin between September 2000 and August 2001.

Figure 4
There were two Castile Brine encounters by area drillers reported to WIPP Site personnel but not reported in records on file at State offices. One was located near ERDA 6 northeast of the WIPP Site and reported encountering several hundred barrels of brine per hour. All was contained within the pits thus requiring no report to the State. The other encounter was to the southwest of the WIPP Site and reported that sulfur water was encountered at approximately 2900 feet. Flow dissipated in a matter of minutes.

2.7 Borehole Permeability Assessment - Plugging Practices

The hydrocarbon well plugging practices used for the borehole permeability assessment remain valid. The regulations in place during the submittal of the CCA have not changed. The assessment will not change unless the regulations change to allow a different method of plugging. Regulations require the well be plugged in a manner that will permanently confine all oil, gas, and water in the separate strata in which they were originally found. These regulations require a notice of intent to plug from the operator. This notice includes a diagram of the well bore and the placement of the plugs. A 24-hour notice to the NMOC or to the Bureau of Land Management (BLM) is required before plugging may commence.

Most of the wells in the vicinity of the WIPP Site are in the KPLA. Under R-111-P regulations, the operator is required to run a solid cement plug through the entire salt section and water bearing zones in addition to installing a bridge plug above the perforations. Installing a solid cement plug through the salt provides additional assurance no fluids or gases escape through the casing into potash mining areas or fresh water formations.

*Figure 5*

*Oil and Gas Wells Within the One-Mile Buffer Area of the WIPP Site*
In the New Mexico portion of the Delaware Basin, the DBDSP retrieves a copy of the plugging report from the appropriate NMOCD office when a well has been plugged and abandoned. This information will be added to the records maintained by the DBDSP on each well drilled within the Delaware Basin. By maintaining records in such a fashion, should the regulations change and the plugging methods differ from what is now occurring, a trend would be noticed and the borehole permeability assessment revisited.

2.8 Borehole Depths and Diameters

The DBDSP tracks borehole depths for all wells drilled in the Delaware Basin. Borehole depths tracked by the DBDSP range from 19 feet to 25,201 feet. The 19 foot hole is an exhaust shaft water monitoring well located on the WIPP Site, and the 25,201 foot hole is a gas well located in Texas. Borehole depths in the immediate vicinity of the WIPP Site typically range from 8,000 to 9,000 feet for oil wells and 13,000 to 16,000 feet for gas wells.

The diameter of each well bore is more difficult to ascertain. The DBDSP tracks the casing size and depth for each section of the hole (Figure 6). Drill bit size is not a reportable element although hole sizes are sometimes reported on sundry notices maintained by the NMOCD. The casing size or hole size is used to determine the size of the bit used to drill that particular section of the well. Currently, the most common bit sizes being used are 17 ½” for the surface section, 11” for the intermediate section, and 7 7/8” for the production section of the hole.

In the early days of well drilling, the 12 1/4” bit was popular with rotary drill operators for the surface section of the hole. In those days, the wells were

This table compiles data from 63 of the 105 new wells drilled in the New Mexico portion of the Delaware Basin between Sep-00 and Aug-01. The other wells were not used as not all of the information has been acquired on those wells.

Figure 6
Casing and Hole Sizes for New Wells Drilled in the Last Year in
much shallower and did not require the larger sections of casing. Most holes drilled at that time were a two-string (string refers to the different size of casing in the wellbore) hole versus the three- and four-strings commonly used now. In the area of the WIPP Site, regulations require a three-string hole making the larger bit sizes more popular. Figure 7 shows the typical hole and casing sizes for a three-string well in the vicinity of the WIPP Site.

2.9 Secondary and Tertiary Recovery

Secondary recovery is defined by the oil industry as the first improved recovery method of any type applied to a reservoir to produce oil not recoverable by primary recovery methods. Water flooding is one such method. This method involves pumping water through the existing perforations in a well in which production has decreased sufficiently to merit stimulation. As the water is pumped into a formation, it stimulates production of oil or gas in other nearby wells. This is a proven method of recovering hydrocarbons that otherwise would be economically unretrievable. Water flooding has been a popular form of secondary recovery for over 40 years. Water flooding can be accomplished by one injection well or several injection wells in the immediate vicinity of other producing wells.

In the New Mexico portion of the Delaware Basin, there are three major water flood projects and several one
and two injection well operations. One of the major waterflood projects in the area is the El Mar, located in T26S-R32E, on the Texas border. At one time, this project (currently operated by Quay Valley Inc.) had 31 permitted injection wells. Currently, there are only three wells actively injecting water. The remaining wells are either shut-in (not being used) or plugged and abandoned. The operation for this facility has not changed since last year. The Paduca water flood project, located in T25S-R32E, has 19 permitted injection wells with eight (up from seven this time last year) injecting water into the formation. The third major water flood project (Indian Draw) in this area, located in T22S-R28E, is currently not injecting into the ten permitted wells.

Tertiary recovery is defined by the oil industry as the use of any improved recovery method to remove additional oil after secondary recovery. One method of tertiary recovery practiced in the industry, where conditions permit, is the injection of Carbon Dioxide ($CO_2$) into the formation. This consists of injecting a prescribed amount of $CO_2$ into the reservoir followed by an injection of water and a subsequent injection of $CO_2$. Although $CO_2$ can be injected continuously, it is not cost effective to implement this process. At the time of this report, there are no known $CO_2$ injection wells or tertiary recovery projects being operated in the vicinity of the WIPP Site, although several are being operated by oil companies in the Texas portion of the Delaware Basin.

2.9.1 Nine-Township Injection Wells

Secondary recovery projects occurring in the nine-township area are on a small scale. There are five injection wells located in the nine-township area surrounding the WIPP Site. Phillips Petroleum operates two injection wells, James “A” #3 and #12, located in section 2-T22S-R30E, northwest of the site. Both are active and injecting near the maximum permitted pressure of 945 psi for #3 and 1,120 psi for #12. Both first injected water in the early 1990s. The other three injection wells are operated by Pogo Producing Co. The Neff Federal #3 is located in section 25-T22S-R31E. This well went online in 1995 and has injected approximately 2,097,154 barrels of water at a maximum permitted pressure of 1,410 pounds per square inch. The other Pogo wells recently went on line and no injection data has been reported at this time. All five wells are injecting into the Brushy Canyon Formation of the Delaware Mountain Group at approximately 7,200 feet.

2.9.2 Nine-Township Salt Water Disposal Wells

The most common type of injection well is for the disposal of brine water coming from the producing formation in oil and gas wells. Most producing oil and gas wells produce water along with oil or gas. Salt Water Disposal (SWD) wells have become necessary as a result of the EPA’s ruling that formation water may no longer be disposed of on the surface. The oil companies now dispose of this water by injecting it into approved salt water disposal wells.

There are currently 33 salt water disposal wells, an increase of two over the last year, operated by 12 companies (14 companies in 2000) located in the nine-township area surrounding the
Two operators, Devon Energy and Pogo Producing, operate the majority of the salt water disposal wells. Injection depths range from 3,800 to 8,200 feet. During the last year, all operated within their maximum permitted injection pressure. The volume of disposed brine water depends on the number of producing wells maintained by the operator in the immediate vicinity of the SWD well.

2.10 Pipeline Activity

Pipeline activity is monitored in the nine-township area, specifically within a five mile radius of the WIPP Site. Only pipelines of permanent construction, such as buried rigid metal pipelines, are of concern to the DBDSP. Many oil, gas, and SWD wells are connected to tank batteries by gathering systems constructed of poly flowlines (flexible plastic pipe) that may or may not be buried. These flowlines are semi-permanent, that is, when they are no longer needed they are removed for use elsewhere. This type of pipeline activity is not monitored by the DBDSP. Permanent pipeline activity is of interest because it will be around for a long time thus requiring knowledge of the location of said pipelines. Only natural gas and water pipelines are located within the immediate vicinity of the WIPP Site. The natural gas pipelines are owned and operated by three companies, El Paso Natural Gas Company, Natural Gas Pipeline Company of America, and Transwestern Pipeline Company.

One type of pipeline activity of major concern to the DBDSP is CO₂ pipelines. A form of tertiary recovery of oil discussed previously involves the use of CO₂. An indicator of this form of recovery would be the construction of a CO₂ pipeline in the area. Currently, there are no CO₂ pipelines within the New Mexico portion of the Delaware Basin. The nearest CO₂ pipeline is located south of the WIPP Site in the Texas portion of the Delaware Basin.

2.11 Mining

Resources found in the Delaware Basin that can be mined are potash, sulfur, caliche, gypsum, and halite. Potash and sulfur are present in quantities large enough to be mined profitably. Of the other resources available, only caliche is economically extracted from the earth in conventional mining methods. Caliche is mainly used in the construction of pads for oil and gas well drilling rigs.

2.11.1 Potash Mining

Potash mining in the immediate vicinity of the WIPP Site continues as reported in Appendix DEL of the CCA. There have been several changes to the companies that operate in the area, most notably, only two potash mining companies remain in operation. No plans have been promulgated by either company to sink new shafts or encroach upon the potash reserves identified in Appendix DEL. Currently, these reserves are not economically recoverable, and it does not appear they will be in the foreseeable future.

Mississippi Potash, a subsidiary of Mississippi Chemical Corporation, purchased in August of
1996 all the assets of New Mexico Potash Corporation and Eddy Potash, Inc. These plants were renamed Mississippi East and Mississippi North, respectively. December 1997 saw the Mississippi North plant, the old Eddy Potash mine, shut down because it could no longer be economically operated. Mississippi Potash continues to produce potash fertilizer from both the east and west plant mines and refineries.

The other potash producer in the area, IMC Kalium Potash, is a wholly owned subsidiary of IMC Global. Western Ag-Minerals was purchased by IMC Global in September 1997. This acquisition doubled the potash reserves for IMC Kalium and increased their other reserves by 30 percent. IMC Global merged with Freeport-McMoRan, a major world potash producer, in December 1997 with IMC Global as the surviving entity in the transaction.

2.11.2 Sulfur Extraction

The only viable sulfur mining activity within the Delaware Basin was being conducted by Freeport-McMoRan Sulphur Inc., a wholly owned subsidiary of McMoRan Exploration Company. The mine is located in Culberson County, Texas. The mine was recovering sulfur utilizing the Frasch process which consists of a hole drilled into the sulfur bearing formation and then cased. Then, three concentric pipes are placed with the protective casing to facilitate pumping superheated water down the hole melting the sulfur and recovering the molten sulfur to the surface. In June 1998, it was announced the mine would cease production in September 1998 because it was no longer economically feasible to operate. Because of problems at other sulfur facilities, the Culberson mine was operated until it permanently ceased production on June 30, 1999. Abandonment and salvage operations continued until the early summer of 2000.

Recently, a number of sulfur exploration coreholes were found in the BLM records. These coreholes were drilled in the late 1960s through the early 1980s in the Yeso Hills near Washington Ranch in the far southwest corner of the New Mexico portion of the Delaware Basin. These coreholes have yet to be added to the databases. All were shallow (less than 2,150 feet) drilling events that were conducted for various small-time operators. There have been no reports on whether any of the holes encountered sufficient quantities of mineable sulfur. Estimating from the amount of activity in the area since the holes were drilled, it can be assumed there were not sufficient quantities of mineable sulfur.

2.12 New Drilling Technology

New drilling methods are being researched by the DBDSP for impacts to the drilling methods currently used in the area. To date, no new methods of drilling have been identified or implemented in the vicinity of the WIPP Site.
3.0 Survey of Well Operators for Drilling Information

Periodically a survey of local well operators is performed to acquire information on drilling practices normally not available on the sundry notices supplied to the local state and federal offices by the operator or through commercial sources maintained by the DBDSP. There are no regulatory requirements to provide the information. This survey requests information on other items of interest to the WIPP such as Hydrogen Sulfide (H₂S) encounters, Castile Brine encounters, or if any section of the well was drilled with air. DBDSP personnel review the records on all new wells drilled to look for the above data. The survey provides an additional source of information on drilling activities in the New Mexico portion of the Delaware Basin.

The first such survey of area operators was performed during July 1999 to acquire information on drilling practices not available from the state and federal offices or commercial sources. Drilling information was requested on the 16 wells drilled in the nine-township area of the New Mexico portion of the Delaware Basin. In July 2000, 45 surveys were sent out to nine different operators on wells their companies drilled in the nine-township area during that year (twelve surveys were returned). This year there were 44 surveys sent out to nine different operators the second week of July. As of this date, no responses have been received.

4.0 Summary - 2001 Delaware Basin Drilling Surveillance Program

Very little has changed since 1996 when the CCA was submitted to the EPA. Drilling practices continue to be the same as do the methods for mineral extraction. The drilling rate is in a decline from previous years although the price of oil is at a relatively high price. The potash mining activity has declined from five companies to two companies in recent years with several mines operated by these two companies ceasing active production.
