Abstract

Electrical conductivity of the lower-mantle ferropericlase-(Mg$_{0.75}$,Fe$_{0.25}$)O has been studied using designer diamond anvils to pressures over one megabar and temperatures up to 500 K. The electrical conductivity of (Mg$_{0.75}$,Fe$_{0.25}$)O gradually rises by an order of magnitude up to 50 GPa but decreases by a factor of approximately three between 50 to 70 GPa. This decrease in the electrical conductivity is attributed to the electronic high-spin to low-spin transition of iron in ferropericlase. That is, the electronic spin transition of iron results in a decrease in the mobility and/or density of the charge transfer carriers in the low-spin ferropericlase. The activation energy of the low-spin ferropericlase is 0.27 eV at 101 GPa, similar to that of the high-spin ferropericlase at relatively low temperatures. Our results indicate that low-spin ferropericlase exhibits lower electrical conductivity than high-spin ferropericlase, which needs to be considered in future geomagnetic models for the lower mantle. The extrapolated electrical conductivity of the low-spin ferropericlase, together with that of silicate perovskite, at the lower mantle...
pressure-temperature conditions is consistent with the model electrical conductivity profile of the lower mantle.

1. Introduction

Knowledge of the electrical conductivity of the mineral assemblage in the Earth’s lower mantle, mainly ferropericlase \([(\text{Mg,Fe})\text{O}]\) and silicate perovskite \([\text{Al-(Mg,Fe)SiO}_3]\), is essential to understanding the propagation of the geomagnetic signals to the Earth’s surface, the nature of the core-mantle coupling (e.g., Olsen, 1999; Buffet, 1992, 1996; Holme, 1998a,b), and the subtle chemistry of the deep Earth (e.g., Dobson and Brodholt, 2000a,b; Xu et al., 2000). Although silicate perovskite is believed to be volumetrically the dominant phase in the lower mantle, it has been demonstrated that the electrical conductivity profile of the lower mantle can be modeled with a network of ferropericlase in an insulating matrix of silicate perovskite (Wood and Nell, 1991).

The electrical conductivity of ferropericlase was previously measured up to 40 GPa and temperatures as high as \(\sim3000\) K (e.g., Mao, 1973; Peyronneau and Poirier, 1989; Li and Jeanloz, 1990; Dobson et al., 1997, 2000a). These studies showed that the electrical conductivity of ferropericlase is very sensitive to the iron content, ferrous to ferric iron ratio, and point defects. However, the electrical conductivity of the low-spin ferropericlase has not been measured and the potential effect of the recently observed pressure-induced electronic spin-pairing transition of iron on the electrical conductivity of ferropericlase is still unknown (e.g., Badro et al., 2003, Lin et al., 2005, 2006a,b, 2007; Speziale et al., 2005; Goncharov et al., 2006; Persson et al., 2006; Tsuchiya et al., 2006; Keppler et al., 2007).
Ferropericlase is a solid solution between periclase (MgO), a wide band gap insulator, and wüstite (FeO), a classical Mott insulator and an important member of the highly correlated transition metal monoxide (TMO) group (Mott, 1990; Cohen et al., 1997). The Mott insulator-metal transition results from the closure of the Mott-Hubbard d-d band gap or of the charge-transfer p-d gap, and has been theoretically or experimentally reported to occur in transition metal oxides such as FeO (Cohen et al., 1997; Knittle and Jeanloz, 1986), MnO (Patterson et al., 2004; Yoo et al., 2005), and Fe₂O₃ (Pasternak et al., 1999).

In this regard, it is thus interesting to understand the effect of the electronic spin transition on the electrical conductivity of ferropericlase with iron concentration that is above the percolation threshold of 12% for the face-centered cubic (fcc) lattice, in which Fe²⁺ atoms form infinitely connected percolation path through the whole structure (Lorenz and Ziff, 1998; Lin et al., 2006a).

Abnormal effects of the electronic spin transition of iron on the volume, incompressibility, sound velocities, and optical absorption spectra of ferropericlase have been observed under high pressures and room temperatures; a decrease in volume and radiative thermal conductivity and an increase in incompressibility and sound velocities are reported to occur at high pressures and room temperature (Lin et al., 2005, 2006b; Speziale et al., 2005; Goncharov et al., 2006; Keppler et al., 2007). These new results are changing our view of the physical and chemical states of the lower mantle. Here we have measured the electrical conductivity of ferropericlase-(Mg₀.₇₅,Fe₀.₂₅)O in the diamond anvil cell (DAC) using designer diamond anvils to pressures across the spin-pairing transition and exceeding one megabar. We have also measured the temperature effect on the electrical conductivity of the low-spin ferropericlase and derived its activation energy.
2. Experiments

Polycrystalline (Mg$_{0.75}$Fe$_{0.25}$)O was synthesized under a controlled oxygen fugacity near the iron-wüstite buffer. The sample was compositionally homogeneous in electron microprobe analyses and its ferric iron (Fe$^{3+}$) content was below the detection limit of Mössbauer spectroscopy. The powder sample was first compressed to ~10 GPa in a separate DAC to squeeze out voids in between grain boundaries in the sample, and then loaded into the sample chamber of 60 μm in diameter in the designer DAC (Weir et al., 2000) with two beveled diamonds with an inner culet of 80 to 120 μm and an outer culet of 350 μm (Fig. 1). Tungsten electrical probes of the designer anvils were designed and fabricated at Lawrence Livermore National Laboratory, and the probes were then encased in epitaxial grown diamond layers at the University of Alabama at Birmingham (Weir et al., 2000). The resistance of each tungsten probe was approximately 100 Ω whereas the probe-to-probe leakage was more than 10 GΩ. Two sets of experiments with either a six-probe or four-probe designer anvil were conducted to over one megabar. In both cases, the electrical resistance was measured using a two-probe configuration by a Keithley 6517A electrometer in the DC current. The use of the designer anvil also provided uniform and well-defined sample chamber geometry as the deformation of the sample and probe geometry can affect the resistance measurement in the DAC and complicate data interpretation (Mao et al., 1973; Nellis et al., 1999). We used the cell constant calculated in the three-dimensional current flow simulations (Nellis et al., 1999) to relate the measured sample resistances to the electrical conductivities (Fig. 2). Conductivities obtained in this manner typically have systematic errors of up to 30% (Nellis et al.,
1999), due mainly to the uncertainties in the sample geometry. Our low-pressure conductivities agreed to within 50% of previously reported electrical conductivities of ferropericlase (Hansen and Cutler, 1966; Dobson et al., 2000a)

A small ruby sphere of 5 μm was also loaded into the sample chamber and used for pressure determination using the ruby fluorescence scale (Mao et al., 1978); pressures were also measured using the Raman frequency shift of the diamond first-order peak (Occelli et al., 2003) at above approximately 90 GPa when ruby fluorescence peaks became too weak to permit reliable pressure determination. High temperature measurements were conducted by heating the DAC with an external heater, and temperatures were measured from a K-type thermocouple attached to the diamond surface.

3. Experimental Results

The electrical conductivity of (Mg$_{0.75}$,Fe$_{0.25}$)O has been studied up to 101 GPa and 500 K (Fig. 2) using a six-probe designer anvil. (Mg$_{0.75}$,Fe$_{0.25}$)O remains as a semiconductor in the pressure and temperature range investigated. The electrical conductivity of (Mg$_{0.75}$,Fe$_{0.25}$)O increases with increasing pressure by an order of magnitude up to 50 GPa, though a separate study on (Mg$_{0.78}$,Fe$_{0.22}$)O by Mao et al. (1973) reported an increase of the conductivity by two orders of magnitude up to 32 GPa which was likely due to the relatively undefined sample and probe geometries. Further increase in pressure results in a decrease in the electrical conductivity of (Mg$_{0.75}$,Fe$_{0.25}$)O by a factor of approximately three between 50 to 70 GPa (Fig. 2). The electrical conductivity then increases slightly with increasing pressure above 70 GPa. Another set of
measurements to 104 GPa using a four-probe designer anvil also showed an increase in the electrical conductivity from 50 to 70 GPa by a factor of approximately two.

The electrical conductivity of the low-spin ferropericlase has also been studied at high temperatures up to 500 K at 81 GPa and 101 GPa, respectively. The measured conductivities at high temperature were fitted to the Arrhenius equation to derive the activation energy, $E_a$ (Fig. 2 insert). The activation energy of the low-spin ferropericlase is 0.26 eV at 81 GPa and 0.27 eV at 101 GPa, consistent with the small polaron conduction (electronic hopping, charge transfer) (e.g., Dobson et al., 1997, 2000a).

4. Discussion and Geophysical Applications

The observed decrease in the electrical conductivity between 50 to 70 GPa is consistent with the pressure range of the recently reported electronic spin-pairing transition in ferropericlase (e.g., Badro et al., 2003; Lin et al., 2005; 2006a,b, 2007; Speziale et al., 2005; Goncharov et al., 2006; Persson et al., 2006; Tsuchiya et al., 2006; Keppler et al., 2007). Recent optical absorption spectra under high pressures further showed that the absorption edge of ferropericlase exhibits a red shift with increasing pressure but is shifted deeper into the ultraviolet across the spin transition above ~60 GPa. Such blue shift in the absorption edge implies a higher activation energy for the charge transfer (Gonchrov et al., 2006; Keppler et al., 2007) and is consistent with the reduced electrical conductivity of the low-spin ferropericlase observed here. That is, the electronic spin transition of iron between 50 to 70 GPa results in a decrease in the mobility and/or density of the charge transfer carriers (small polaron) in the low-spin ferropericlase, which in turn decreases the electrical conductivity across the transition.
Field observations of the electrical conductivity profile of the Earth have shown that the electrical conductivity of the Earth’s lower mantle is around one to tens S/m (Olsen, 1999) whereas a highly conducting layer with the conductance of $>10^8$ S may exist at the base of the lower mantle (the exact value of conductivity depends on the thickness of the layer) (Holme, 1998a,b). Laboratory measurements of the electrical conductivity of the high-spin ferropericlase [(Mg,Fe)O] and silicate perovskite [Al-(Mg,Fe)SiO₃] under high pressures and temperatures have been used to explain the field observations (Xu et al., 2000). Our results indicate that low-spin ferropericlase exhibits lower electrical conductivity than high-spin ferropericlase, which needs to be considered in future geomagnetic models for the lower mantle. High temperatures above $\sim$1000 K may affect the conductivity mechanism in the low-spin state, because a large polaron conducting mechanism with an activation energy of 0.6 to 1 eV has been attributed to the high-temperature conductivity of the high-spin ferropericlase (Roberts et al., 1995; Dobson et al., 1997). It remains to be seen how the theoretically predicted spin crossover of iron in ferropericlase that extends from the middle part to the lower part of the lower mantle (Sturhahn et al., 2005; Tsuchiya et al., 2006; Lin et al., 2007) affect the electrical conductivity of ferropericlase as well as silicate perovskite at the lower mantle pressure-temperature conditions.

An extrapolation of the electrical conductivity of the low-spin ferropericlase to the lower-mantle pressure-temperature conditions yields an electrical conductivity in the order of tens of S/m, consistent with the model values for the lower mantle (e.g., Olsen, 1999). Such value is apparently too low to account for the possible existence of a highly conducting layer with the conductance of $>10^8$ S at the base of the lower mantle (the conductivity depends on the thickness of the layer) (Holme, 1998a,b), though possible
existence of metallic FeO and addition of ferrous iron can significantly alter the conductivity of the region (Knittle and Jeanloz, 1986; Cohen et al., 1997; Dobson and Brodholt, 2005). Alternatively, a highly conducting post-perovskite phase existing at the core-mantle boundary (Ono et al., 2006) has been invoked to explain the exchange of the angular momentum and electromagnetic coupling between the liquid core and the solid mantle that result in the observed changes in the Earth’s length of day (e.g., Buffet, 1992, 1996; Holmes, 1998a,b). However, the electrical conductivity of the post-perovskite phase is unknown and is only suggested to be much larger than the perovskite phase based on the analogous transition in Al₂O₃ (Ono et al., 2006) that results in a two order of magnitude increase in the conductivity above 200 GPa (Weir et al., 1996). Future studies on the electrical conductivities of FeO and post-perovskite phase using our novel designer anvil technique with well fabricated electrical probes will help in understanding their potential roles in the geomagnetism at the core-mantle region.

Acknowledgments. This work at LLNL was performed under the auspices of the U.S. DOE by University of California and LLNL under Contract No. W-7405-Eng-48. We thank J. Roberts, R. Cohen, R. Wentzcovitch, D. Dobson, W. Sturhahn, and G. Shen for helpful discussion and S. D. Jacobsen for his help with the sample synthesis. We also acknowledge H. Keppler for sharing his manuscript with us.
